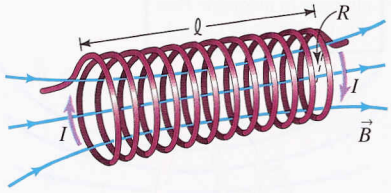
Elements within circuits with a significant self-inductance—we refer to them as **inductors**—provide sources of emf, which must be included when Kirchhoff's loop rule is used for potential changes around a circuit. Inductors, usually in the form of solenoids, are useful devices that are placed in circuits to control time dependence and to store energy. They join capacitors, resistors, and batteries as the basic elements of circuits. They are represented in circuit diagrams by the symbol  . We add the following to our list of rules for application of Kirchhoff's loop rule to circuits:

> **In moving across an inductor of inductance *L along* (or *against*) the presumed direction of the current *I*, the potential change is $\Delta V = -L\,dI/dt$ (or $+L\,dI/dt$, respectively).**

The actual sign of the potential drop depends on the sign of the rate of change of the current and is determined when the circuit equations are solved.

Finding the Inductance

To use the loop rule with inductors present in a circuit, we must know the values of the self-inductance or mutual inductance. As for capacitance, there are only a few simple, but important, geometries for which inductance can easily be calculated. The most important of these is the ideal solenoid. Consider the ideal solenoid of Fig. 32–5, which has length ℓ and radius R. For $\ell \gg R$, the magnetic field within the solenoid is longitudinal and constant and is given by Eq. (29–15):



$$B = \mu_0 nI,$$

where μ_0 is the permeability of free space, n is the number of turns per unit length of solenoid, and I is the current the solenoid carries. The magnetic flux through one turn of the solenoid is the field B times the cross-sectional area A, $\Phi_B = BA = \mu_0 AnI$. The total magnetic flux is this value times the *total* number of turns $N = n\ell$:

$$\Phi_B = \mu_0 An^2 \ell I. \tag{32–7}$$

By comparison with Eq. (32–1), the self-inductance is the coefficient of the current:

$$\text{for an ideal solenoid: } L = \mu_0 A \ell n^2. \tag{32–8}$$

▲ **FIGURE 32–5** A solenoid of length ℓ, radius R, and turn density n carries a current I. Only the magnetic field $\vec{B}$ inside is shown; the field outside the solenoid is zero in the limit that the solenoid is infinitely long.

EXAMPLE 32–1 During a short time period, the current in a cylindrical coil of length 10 cm, radius 0.5 cm, and 1000 turns of wire in a single layer is increased at the steady rate of 10^3 A/s. Find the emf induced during this period.

Strategy We can treat the cylindrical coil as an ideal solenoid, as it is much longer than its coil width. The induced emf is given by Eq. (32–2); the inductance that appears in that equation is in turn given for a coil by Eq. (32–8). Hence this problem is simply a matter of inserting numbers into these equations.

Working It Out We start with the inductance. The turn density is $n = (1000 \text{ turns})/(0.1 \text{ m}) = 10^4$ turns/m. The area of the solenoid is given by $A = \pi r^2$, and

$$\begin{aligned} L &= \mu_0 A \ell n^2 \\ &= (4\pi \times 10^{-7}\ \text{T}\cdot\text{m/A})[\pi(0.005\ \text{m})^2](0.1\ \text{m})(10^4\ \text{m}^{-1})^2 \\ &= 10^{-3}\ \text{H}. \end{aligned}$$

As for the induced emf, the current change rate is $dI/dt = 10^3$ A/s, so if we follow the circuit in the direction of the current, we have

$$\mathcal{E} = -L\frac{dI}{dt} = -(10^{-3}\ \text{H})(10^3\ \text{A/s}) = -1\ \text{V}.$$

The induced emf is negative.

What Do You Think? Which of the following will increase the induced emf the most? In each case the change mentioned is the *only* change. (a) Doubling the length of the solenoid, (b) doubling the rate at which the current changes, (c) doubling the area of the solenoid, (d) doubling the number of turns in the solenoid. *Answers to **What Do You Think?** questions are given in the back of the book.*

CONCEPTUAL EXAMPLE 32–2 A friend claims that he can increase the inductance L of a solenoid with given area and length and that must be constructed with a single layer of wire by using finer wire of the same material. Is he correct? What are the implications of his method of increasing L on the resistance R of the solenoid?

Answer The inductance is proportional to the square of the turn density n^2, and for a single layer $n \propto 1/d$, where d is the diameter of the wire. Thus

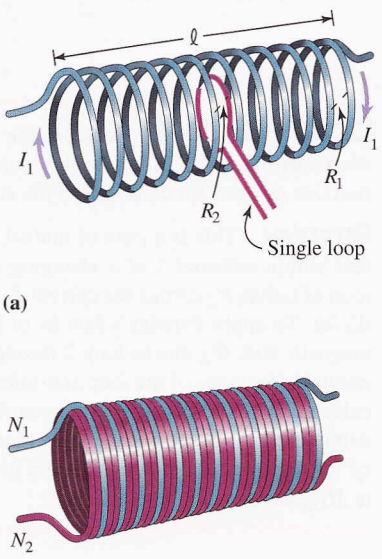
$$L \propto 1/d^2,$$

and decreasing d will certainly increase L. To see the implication of the use of finer wire for the resistance, we can recall from Chapter 26 that the resistance of a wire of length ℓ and area A made of a material of resistivity ρ is $R = (\ell/A)\rho$. In our case, with fixed solenoid length and area, each turn uses the same wire length, and the total number of turns N is proportional to the turn density $n \propto 1/d$. Thus the length of wire needed is proportional to $1/d$. The wire cross-section $A \propto d^2$, so $\ell/A \propto d^{-1}/d^2$, i.e.

$$R \propto 1/d^3.$$

R increases faster than L does as the wire diameter decreases. Whether this has important consequences depends on the circumstances, but the changed value of R would almost certainly have to be taken into account in determining the properties of the circuit.

As an example of a calculable mutual inductance, consider a solenoid (of length ℓ_1, radius R_1, winding density n_1, and current I_1) that contains within it a single loop of radius R_2 whose area $A_2 = \pi R_2^2$ is oriented perpendicular to the axis of the solenoid (Fig. 32–6a). The magnetic field of the solenoid is given by Eq. (30–15), $B = \mu_0 n_1 I_1$. The magnetic flux that passes through the single loop is



$$\Phi_B = BA_2 = \mu_0 A_2 n_1 I_1.$$

By definition, the mutual inductance, M, is the coefficient of I_1:

$$M = \mu_0 A_2 n_1. \tag{32–9}$$

If the single loop is replaced with a second solenoid (Fig. 32–6b) with a total number of turns N_2, then the total flux that links that second solenoid contains a factor N_2, and M must be increased by this same factor:

$$M = \mu_0 A_2 n_1 N_2. \tag{32–10}$$

▶ **FIGURE 32–6** (a) The area of the single, small loop is oriented perpendicular to the axis of the solenoid. (b) Similar qualitative effects are associated with the replacement of the single loop (a solenoid with but a single turn) by a solenoid with multiple turns.

EXAMPLE 32–3 Consider the two solenoids in Fig. 32–6b and take their radii, and hence the areas, to have the same value. Compare the ratio of mutual inductance M to self-inductance L_1 of solenoid 1.

Setting It Up We denote the common area as A. We must assume values for the turn density n_1 and the length ℓ_1 of solenoid 1, as well as the total number of turns N_2 in solenoid 2.

Strategy This is a straightforward use of Eqs. (32–8) and (32–10).

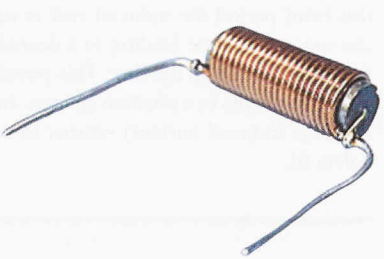
Working It Out We have from Eqs. (32–8) and (32–10)

$$\frac{M}{L_1} = \frac{\mu_0 A n_1 N_2}{\mu_0 A n_1^2 \ell_1} = \frac{\mu_0 A n_1 N_2}{\mu_0 A n_1 N_1}.$$

In the last step, we have used the fact that the factor $n_1\ell_1$ is the total number of turns N_1 in solenoid 1. Both the area A and the turn density n_1 cancel, and we are left with

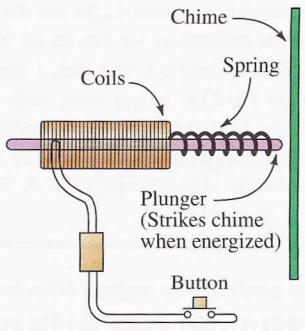
$$\frac{M}{L_1} = \frac{N_2}{N_1}.$$

If solenoid 2 has many fewer windings than solenoid 1, then the effect of the mutual inductance on solenoid 1 is small compared to that of the self-inductance.



What Do You Think? (a) If the radius R_1 is doubled, what happens to L_1 and M? (b) If instead, the radius R_2 is doubled, what happens to L_1 and M?

The Effects of Magnetic Materials on Inductance



In Chapter 31, we considered modifications to a magnetic field due to a current in the presence of materials with magnetic properties. We saw that the presence of materials can modify, and in the case of ferromagnetic materials greatly magnify, the magnetic field present and hence the flux. This is made explicit in expressions that include the free (or real) current by replacing the permeability of free space μ_0 with the permeability of the material μ. The permeability is given by Eq. (31–7),

$$\mu = \mu_0(1 + \chi_m).$$

Here, χ_m is the magnetic susceptibility of the material, which is negative and small for diamagnets, positive and small for paramagnets, and positive and large for ferromagnets. If a solenoid is filled with a magnetic material, its self-inductance would change, with the replacement of μ_0 by μ in Eq. (32–8). For ferromagnetic materials, self-inductances can thereby be increased manyfold (Fig. 32–7). In Fig. 32–8, we illustrate the application of inductors that use the magnetic properties of materials in a doorbell.

▲ **FIGURE 32–7** The inclusion of an iron core in this solenoid (an actual inductor) increases the magnetic field produced by a given coil current.

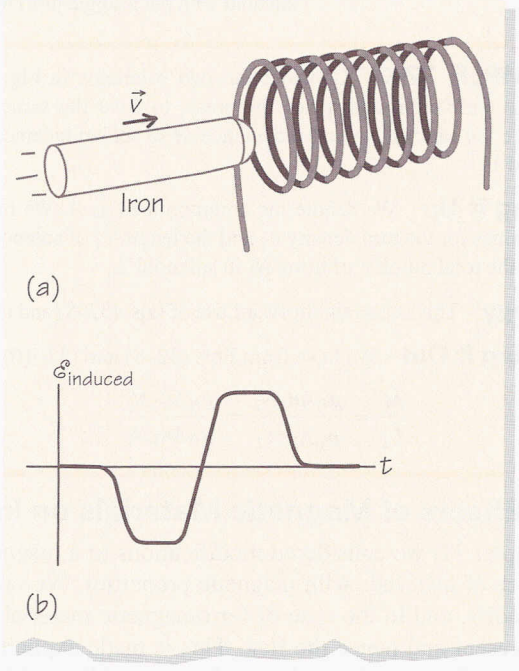
▶ **FIGURE 32–8** The chiming doorbell is a simple application of inductance. The touch of a doorbell button induces a current in the rods within the solenoid, which then are thrust from the solenoid according to Lenz's law and strike a chime.

EXAMPLE 32–4 Consider the single loop and the solenoid shown in Fig. 32–6. Suppose the loop carries a current I_2 that is a function of time. Find the emf in the solenoid induced by current I_2.

Strategy This is a case of mutual inductance—we want the effect within solenoid 1 of a changing current in loop 2. The single loop of radius R_2 carries the current I_2 in this case, which changes as dI_2/dt. To apply Faraday's law as in Eq. (32–5), we must find the magnetic flux Φ_B due to loop 2 through solenoid 1. This flux is the mutual inductance of the loop and solenoid times current I_2. A direct calculation of the flux might be complicated here, but we can fortunately use Eq. (32–9) for the inductance together with the "mutuality" of the inductance—the equation gives M_{21}, while what we want is M_{12}, but the two are equal.

Working It Out Using Eq. (32–9) for M gives

$$\Phi_B = MI_2 = \mu_0 \pi R_2^2 n_1 I_2.$$



The emf in the solenoid is then the negative time derivative of this flux:

$$\mathcal{E} = -\frac{d\Phi_B}{dt} = -\mu_0 \pi R_2^2 n_1 \frac{dI_2}{dt}.$$

What Do You Think? If a ferromagnetic material is placed inside the solenoidal coil (without the single loop), the self-inductance of the coil will (a) increase, (b) decrease, (c) stay the same.

CONCEPTUAL EXAMPLE 32–5 A hollow solenoid is carrying a steady current I when a cylindrical piece of iron is sent through the cylindrical space and out the other side. The cylinder of iron fits the interior of the solenoid and is a little shorter than the solenoid. Describe the emf induced in the circuit containing the solenoid and include a sketch. What is the effect on the current?

Answer As the iron passes into the solenoid (Fig. 32–9a), the magnetic field (and magnetic flux) inside the solenoid will suddenly increase, because the space is increasingly filled with a material with a permeability much larger than the permeability of the air, which is to a very good approximation that of the vacuum. According to Lenz's law, an emf will be generated within the solenoid that opposes this increase in flux. The sign of the emf corresponds to this "opposition," and we will call it negative, as shown in Fig. 32–9b. If the speed of the cylinder entering the space is held constant, then the rate of increase in flux will be constant, and the induced emf will be constant. The emf will induce a current I_{induced} in the coil that will be opposite to the original current. Once the iron cylinder is entirely within the solenoid, there is no change in flux and no further emf; for this brief period the induced emf is zero. Finally, the cylinder exits the space, this time leading to a decreasing flux and an induced emf that tries to hold up the flux. This positive emf is also indicated in the figure; it results in a positive current. Just as quickly, the induced emf (and the induced current) returns to zero once the iron has left the solenoid.

▲ **FIGURE 32–9** (a) A ferromagnetic cylinder moves into and through a coil. (b) The emf induced in the coil as a result of steady movement of the cylinder.

32–2 Energy in Inductors

Just as a capacitor is a device for storing energy in an electric field, an inductor is a device for storing energy in a magnetic field. Because any emf induced in the inductor opposes the change in current, work must be done by an external source, such as a battery,

to cause a current to pass through an inductor. By the work–energy theorem, just how much work is done is a measure of the energy stored in the inductor. To calculate this energy, we proceed as we did for the capacitor in Chapter 25, and calculate the work that must be done by some external emf to pass a current through the inductor.

We derive the general expression for the rate dW/dt (the power) at which an external emf $\mathscr{E}_{\text{ext}}$ does work when a current I flows from Eqs. (26–26) and (26–27):

$$\frac{dW}{dt} = I\mathscr{E}_{\text{ext}}.$$

If we have only the external emf and an inductor, the external emf must be equal but opposite to the induced emf in the inductor, given by Eq. (32–2). Thus

$$\frac{dW}{dt} = +LI\frac{dI}{dt}. \tag{32–11}$$

If the current is increasing, the power is positive, meaning that the external source must do positive work in supplying energy to the inductor; the internal energy U_L in the inductor is increasing. If the current is decreasing, the power is negative, meaning that the external source takes energy from the inductor; the inductor's internal energy is decreasing. The net change ΔU_L in the total magnetic energy of the inductor as the current changes from a value I_1 to a value I_2 between the times t_1 and t_2 can be found by integrating the work done by the external source as the current changes. We integrate Eq. (32–11) for dW/dt from an initial time t_1 to a later time t_2:

$$\begin{aligned}\Delta U_L &= \int_{t_1}^{t_2}\frac{dW}{dt}\,dt = \int_{t_1}^{t_2} LI\frac{dI}{dt}\,dt = L\int_{I_1}^{I_2} I\,dI \\ &= \frac{1}{2}LI_2^2 - \frac{1}{2}LI_1^2.\end{aligned} \tag{32–12}$$

In particular, if the inductor carries a current I, then the increase in energy as the current increases from zero up to I, which we refer to simply as the energy of the inductor, is

$$U_L = \frac{1}{2}LI^2. \tag{32–13}$$

ENERGY IN AN INDUCTOR

In applications to circuits (see Section 32–4 as well as later chapters), we'll see that it is not only the storage of energy that is interesting but the time dependence of that process.

Equation (32–13) should be compared to the expression for the energy U_C contained in a capacitor of capacitance C that carries charge Q from Eq. (25–8):

$$U_C = \frac{1}{2}\frac{Q^2}{C}.$$

EXAMPLE 32–6 A solenoid is designed to store $U_L = 0.10$ J of energy when it carries a current I of 450 mA. The solenoid has a cross-sectional area A of 5.0 cm^2 and a length ℓ of 0.20 m. How many turns of wire must the solenoid have?

Strategy We know the energy, which is a function of the inductance L and the given current; L is in turn a function of N, through Eq. (32–8). The only modification necessary in Eq. (32–8) is to write it in terms of the total number of turns N rather than the turn density n by using $N = n\ell$, where ℓ is the length of the solenoid. We can then solve for N in terms of L and hence in terms of the energy.

Working It Out With the change to Eq. (32–8), we have

$$L = \frac{\mu_0 AN^2}{\ell}.$$

The expression for the energy, Eq. (32–13), then reads

$$U_L = \frac{1}{2}\frac{\mu_0 AN^2}{\ell}I^2.$$

We solve this for N and insert numbers:

$$\begin{aligned}N &= \frac{1}{I}\sqrt{\frac{2U_L\ell}{\mu_0 A}} \\ &= \frac{1}{4.5\times10^{-1}\text{ A}}\sqrt{\frac{2(0.10\text{ J})(0.20\text{ m})}{(4\pi\times10^{-7}\text{ N/A}^2)(5.0\times10^{-4}\text{ m}^2)}} \\ &= 1.8\times10^4\text{ turns}.\end{aligned}$$

What Do You Think? What is the easiest way to increase the energy stored in a solenoid if its size is fixed and the wire (of which you have an abundant supply) can carry no additional current?

An inductor has an energy given by Eq. (32–13) even if the current is steady. We have, however, argued that the origin of the effects of inductance is Faraday's law, which involves changes in current. How can we reconcile these two facts? As we are going to describe in more detail in the next section, the energy of an inductor is in the magnetic field within it, just as the energy of a capacitor lies within the electric field between the plates. The energy of an inductor carrying steady current must arise from the original buildup of current—even if it occurred in the distant past. It is when the current changes that the magnetic field changes and, along with it, the energy in the magnetic field.

32–3 Energy in Magnetic Fields

In Chapter 25, we demonstrated that the electric energy associated with a capacitor is located in the electric field within the capacitor. Similarly, the energy of an inductor is located in its magnetic field. Just as the ideal parallel-plate capacitor was a means to learn about energy in the electric field, the ideal solenoid presents us with a tool to explore the energy density in a magnetic field.

The inductance of an ideal solenoid of area A and length ℓ is given by Eq. (32–8), so from the expression for the total energy of an inductor [Eq. (32–13)], we find

$$U_L = \frac{1}{2}LI^2 = \frac{1}{2}\mu_0 A\ell n^2 I^2. \tag{32–14}$$

We also know that the magnetic field in the solenoid is proportional to the current. Equation (29–15) gives the precise connection, $B = \mu_0 nI$. If we substitute for I in terms of B in Eq. (32–14), we obtain

$$U_L = \frac{1}{2}\frac{B^2}{\mu_0}A\ell. \tag{32–15}$$

The volume enclosed within the solenoid is $A\ell$. Because the magnetic field is uniform within the solenoid, we can identify the **energy density** u_B, the energy per unit volume of the magnetic field, as

$$u_B = \frac{1}{2}\frac{B^2}{\mu_0}. \tag{32–16}$$

ENERGY DENSITY IN A MAGNETIC FIELD

This result generalizes to the case of a nonuniform magnetic field, no matter how it is produced. It should be compared to our expression for the energy density of an electric field, Eq. (25–12):

$$u_E = \frac{1}{2}\varepsilon_0 E^2,$$

a result derived in a similar way. It is important to realize that *energy is located within the electric and magnetic fields themselves.*

When both magnetic and electric fields are present, the energy density is the sum of both magnetic and electric energy densities:

$$u = u_B + u_E = \frac{1}{2}\left(\frac{B^2}{\mu_0} + \varepsilon_0 E^2\right). \tag{32–17}$$

EXAMPLE 32–7 A large electromagnet produces a magnetic field of 1 T. Compare the energy density associated with this field to that of the largest electric field in air, about 10^6 V/m (beyond this value, there is breakdown).

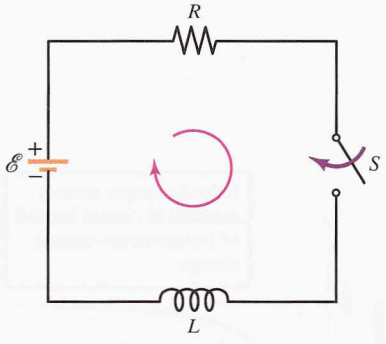
Strategy Equations (32–16) and (25–12) express the energy density in magnetic and electric fields, respectively, and we can directly obtain the ratio of the magnetic and electric energy densities from them.

Working It Out We have

$$\frac{u_B}{u_E} = \frac{\frac{1}{2}\frac{B^2}{\mu_0}}{\frac{1}{2}\varepsilon_0 E^2} = \frac{1}{\mu_0\varepsilon_0}\frac{B^2}{E^2}.$$

In our case, the magnitudes of both the magnetic and electric fields are given, and

$$\frac{u_B}{u_E} = \frac{1}{(4\pi \times 10^{-7}\ \text{N/A})(8.85 \times 10^{-12}\ \text{F/m})} \frac{(1\ \text{T})^2}{(10^6\ \text{V/m})^2} = 9 \times 10^4.$$

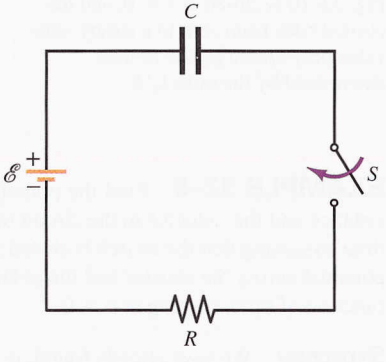


Depending on the medium, electric breakdown properties may limit the size of electric fields that can be easily maintained and make magnetic fields more suitable for storing energy at high density. How rapidly that energy can be delivered back for other uses is another story, however, and capacitors remain the best way to deliver a lot of energy as fast as possible.

What Do You Think? What puts a limitation on the production of large magnetic fields?

32–4 Time Dependence in *RL* Circuits

The fact that the potential drop across an inductor depends on how rapidly the current passing through it changes leads to new time-dependent behavior in circuits with inductors. For example, if we attempt to stop a current already flowing—say, by opening a switch—then an emf is induced that attempts to keep the current flowing, possibly creating an arc across the switch. The simplest illustration of time-dependent behavior involves a circuit with a source of emf $\mathscr{E}$, a resistor of resistance R, and an inductor of inductance L (Fig. 32–10). We call such a circuit an ***RL* circuit**. A switch allows us to control the initial conditions. When we close the switch, the inductor acts to oppose the changing current, and as a result, the current cannot jump suddenly but must build up over time. If we apply the loop rule to the circuit in the direction of the pink arrow in Fig. 32–10, we can see this quantitatively. We have



$$\mathscr{E} - IR - L\frac{dI}{dt} = 0. \tag{32–18}$$

▲ **FIGURE 32–10** An *RL* circuit, including a source of constant emf.

To find the solution to this differential equation for I, compare Eq. (32–18) with Eq. (27–21), which comes from applying the loop rule to the *RC* circuit shown in Fig. 32–11:

$$\mathscr{E} - \frac{Q}{C} - R\frac{dQ}{dt} = 0. \tag{27–21}$$

▲ **FIGURE 32–11** An *RC* circuit is analogous to the *RL* circuit of Fig. 32–10.

Here, Q is the charge on the capacitor. The first differential equation determines the current in *RL* circuits and has exactly the same *form* as the equation for the charge in *RC* circuits. The similarities between the *RC* and *RL* circuits are summarized in Table 32–1, and the solution of Eq. (32–18) for the current in the circuit is the same as the solution of Eq. (27–21) for charge if we make the substitutions indicated in the table. In particular, if we replace RC with L/R, the current in the *RL* circuit will have the time dependence $\exp[-t/(L/R)]$. The *RL* circuit is said to have a *time constant* L/R. Note that, as for the *RC* circuit, the time dependence is transient. Large values of the time constant (large L and/or small R) mean that the transient behavior is slow to disappear, so that long times are required for the current to build up or decay; small values of the time constant (small L and/or large R) mean that the transient behavior quickly disappears, and current builds up or decays rapidly. Of course, the "large" and "small" times are relative terms.

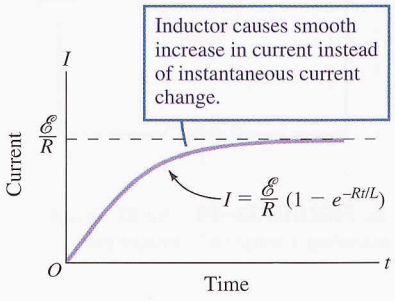
For complete solutions of Eq. (32–18) for the current, including the initial conditions, we can directly apply the results of Section 27–5 for the solution of the differential equation for the *RC* circuit. As in Section 27–5, it is important to understand

TABLE 32–1 • Analogy Between *RC* and *RL* Circuits

	RC Circuit Parameter	*RL* Circuit Parameter
Variable	Q	I
Coefficient of variable	$1/C$	R
Coefficient of $\frac{d}{dt}$ (variable)	R	L
Time constant	RC	L/R

physically how different initial conditions will affect the solution. As a guiding principle, keep in mind the following:

The current in an inductor never changes instantaneously, but after the current settles down to a constant value, the inductor plays no role in the circuit.



Finally, we should mention that real (as opposed to ideal) inductors may contain relatively long lengths of wire and always have some resistance. Depending on the circuit, this resistance can be significant.

Let's look again at time dependence in an *RL* circuit, this time being explicit about some boundary conditions. Suppose that the switch in Fig. 32–10 has been open for a very long time and is suddenly closed at $t = 0$. What happens? Since the inductor acts to prevent any sudden change in current, the current must ramp up smoothly from zero following the switch closing. We also know that after a very long time, the system will have stabilized, with any transient effects having disappeared. The inductor will play no role at these late times, and the circuit effectively consists of only an emf $\mathscr{E}$ and a resistance R (including any resistance in the inductor). The constant current will be $I = \mathscr{E}/R$. In between these times the current has gone from 0 at $t = 0$ to $\mathscr{E}/R$ at large times with a time constant L/R—in other words, the current must reach its asymptotic value exponentially over this time scale.

Without going through the formal steps (see Problem 47 to verify the solution to the differential equation), we can say that the function that fits these criteria is

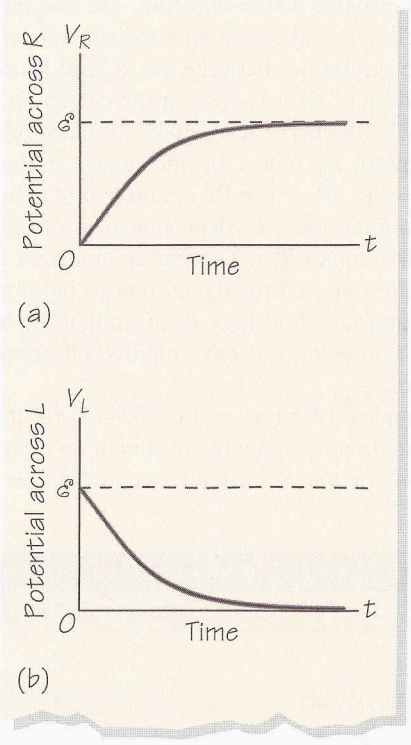
$$I = \frac{\mathscr{E}}{R}[1 - e^{-t/(L/R)}] = \frac{\mathscr{E}}{R}(1 - e^{-Rt/L}). \tag{32–19}$$

Figure 32–12 is a graph of current versus time for this case. At $t = 0$, the exponential term is unity and $I = 0$, consistent with the principle that the current cannot change instantaneously. As $t \to \infty$, the transient exponential term drops out and I approaches $\mathscr{E}/R$—as though the inductor were not present at all.

▲ **FIGURE 32–12** The switch of Fig. 32–10 is closed at $t = 0$, and the current rises from zero to a steady-state value only after a period of time determined by the ratio L/R.

EXAMPLE 32–8 Find the potential magnitude across the resistance and the inductor in the circuit of Fig. 32–10 as a function of time, assuming that the switch is closed at $t = 0$. Draw graphs of the potential across the resistor and the potential across the inductor as a function of time, starting at $t = 0$.

Strategy We have already found, in Eq. (32–19), the current as a function of time in this situation. This is sufficient to find the potentials across these elements, which in the case of the resistor is IR and in the case of the inductor is $L\,dI/dt$.



Working It Out The potential across the resistor is just Eq. (32–19) multiplied by R; we won't write that out again. For the magnitude of the potential across the inductor, we must evaluate

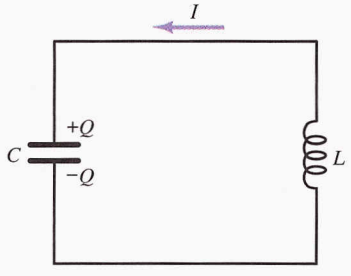
$$V_L = L\frac{dI}{dt} = L\frac{\mathscr{E}}{R}\left[-\frac{-R}{L}e^{-Rt/L}\right] = \mathscr{E}e^{-Rt/L}.$$

This starts at $t = 0$ with a maximum value of $\mathscr{E}$, then drops off exponentially to zero at long times; there is a potential across an ideal inductor only when the current through it is changing. In this case, it is changing fastest at $t = 0$ and not changing at all at large values of time.

We have plotted V_R and V_L in Figs. 32–13a and b.

What Do You Think? If L is arbitrarily large, the argument of the exponential in the expression for V_L is zero and the potential across the inductor never drops to zero. Is that correct?

▲ **FIGURE 32–13** (a) The potential across the resistor in the *RL* circuit. (b) The potential across the inductor.



THINK ABOUT THIS. . .

HOW WOULD YOU MEASURE INDUCTANCE?

We have described the calculation of inductance for simple geometries—for example, a long coil—but in many cases the geometry is complicated, and it is not possible to calculate L. The time dependence we have described in this section and the section to come provides us with very simple tools to measure L directly. Here we have seen that the presence of an inductor in a circuit that additionally contains a resistor of known resistance R exhibits exponential time dependence with a time constant L/R. Measurement of a curve of rise time or of fall time allows us to extract L. In the next section we'll see that circuits with an inductor and a capacitor but no (or negligible) resistance exhibit oscillatory behavior whose frequency depends on L and C. Since it is possible to measure the time for N oscillations of such a circuit and to count N with precision, one can learn the value L of an unknown inductance very accurately this way. Finally, in the next chapter we shall learn and discuss still another way in which an unknown L can be determined, using a resonance phenomenon.

32–5 Oscillations in *LC* Circuits

A single-loop circuit with inductance and capacitance but negligible resistance exhibits a behavior we have not yet encountered in electric circuits but which played a central role in our study of mechanics—oscillatory behavior. Such a circuit is called an ***LC* circuit**, and it is analogous to a mass on the end of a spring—a familiar mechanical system. If we look at Fig. 32–14, we can see what the oscillatory behavior is and why it is plausible. Imagine that the capacitor is fully charged at an initial time. Then current will flow off the positively charged plate of the capacitor through the wire toward the negatively charged plate; without the inductor, the discharge through the wire would be rapid and direct. With the inductor present, the current is held back initially and grows smoothly from zero. Moreover, once the current reaches some maximum value, the inductor will induce an emf that tends to maintain this maximum current. This allows the discharge to "overshoot," with positive charge building up on the initially negatively charged plate. Conditions are then right for the process to repeat in the other direction.

▲ **FIGURE 32–14** An *LC* circuit, consisting simply of an inductor and a capacitor in series.

At this point we need to establish not simply oscillatory behavior but harmonic behavior, and this must be done in a quantitative fashion. We do this by establishing a direct correspondence between the *LC* circuit and the mass on an ideal spring. We start with the loop rule for our *LC* circuit (Fig. 32–14). Following the clockwise direction, we have

$$\frac{Q}{C} + L\frac{dI}{dt} = 0, \tag{32–20}$$

where Q is whatever charge is on the capacitor and I is the current in the circuit with direction indicated. The current I is dQ/dt, so this expression is actually a *second-order* differential equation for the charge:

$$\frac{Q}{C} + L\frac{d^2Q}{dt^2} = 0. \tag{32–21}$$

At this point recall the equation of motion for a mass m on the end of an ideal spring of spring constant k, namely $-kx = ma$. The acceleration is the second derivative of displacement, so that this equation of motion is

$$kx + m\frac{d^2x}{dt^2} = 0. \tag{32–22}$$

This equation for x has the same form as the equation for Q, and so the solutions for these variables have the same form. But we already know that the mechanical motion is harmonic—$x = A\sin\omega t + B\cos\omega t$—and so the same is true for the charge on the capacitor. We must change the variable names using the correspondences summarized in Table 32–2. In particular, the angular frequency of the mechanical system is $\omega = \sqrt{k/m}$, so from the table of equivalences the angular frequency of the *LC* circuit is

$$\omega = \frac{1}{\sqrt{LC}}, \tag{32–23}$$

TABLE 32–2 • Analogy Between *LC* Circuit and Mass on a Spring

	Mass on Spring Parameter	*LC* Circuit Parameter
Variable	x	Q
Coefficient of variable	k	$(1/C)$
Coefficient of $\frac{d^2}{dt^2}$ (variable)	m	L
Natural frequency	$\sqrt{k/m}$	$1/\sqrt{LC}$

and the charge on the capacitor varies as

$$Q = Q_1 \sin(\omega t) + Q_2 \cos(\omega t). \tag{32–24}$$

Equivalently, this can be written as

$$Q = Q_0 \cos(\omega t + \phi). \tag{32–25}$$

The constants, either Q_1 and Q_2 or Q_0 and ϕ, are determined by the initial conditions. For example, if we know that the capacitor has a given total charge at time $t = 0$ and that the current at $t = 0$ is also zero (because a switch has been open until that time), then we can determine the two unknown constants.

Once we know the charge on the capacitor, we also know the current flowing through the inductor; we need only apply the relation $I = dQ/dt$. For example, Eq. (32–25) gives

$$I = \frac{d}{dt}[Q_0 \cos(\omega t + \phi)] = -Q_0\omega \sin(\omega t + \phi). \tag{32–26}$$

Thus the current, like the charge, is oscillatory, and with the same angular frequency $\omega = 1/\sqrt{LC}$. Here we have rather directly used the equivalent of the equations of motion, but we shall see in Section 32–7 that it is also possible to understand the oscillations in terms of energy flow.

EXAMPLE 32–9 The capacitor ($C = 0.80\ \mu\text{F}$) in the circuit of Fig. 32–14 carries a charge in the form $Q = Q_0 \cos(\omega t)$. Find the voltage drop across the inductor ($L = 12\ \mu\text{H}$) and the period of oscillation of that voltage.

Strategy The current through the circuit is the time rate of change of the charge on the capacitor, so the voltage across the inductor is

$$V_L = -L\frac{dI}{dt} = -L\frac{d^2Q}{dt^2}.$$

The time dependence of Q is given, and the derivative can be carried out to find V_L. Since two derivatives of a cosine give the cosine back again, the time dependence of V_L, like that of the charge, will be $\cos \omega t$. The angular frequency ω is given for our circuit by Eq. (32–23), $\omega = 1/\sqrt{LC}$, and from this the period $T = 1/f = 2\pi/\omega = 2\pi\sqrt{LC}$ can also be evaluated.

Working It Out We have

$$\frac{d^2Q}{dt^2} = Q_0\frac{d}{dt}\left(\frac{d}{dt}\cos \omega t\right)$$
$$= Q_0\frac{d}{dt}[-\omega \sin \omega t] = -\omega^2 Q_0 \cos \omega t = -\omega^2 Q.$$

Thus

$$V_L = \omega^2 LQ = \omega^2 LQ_0 \cos \omega t = (Q_0/C) \cos \omega t,$$

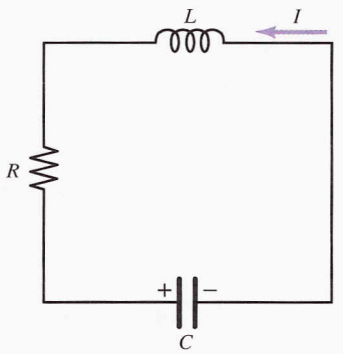
where in the last step we used $\omega^2 = 1/LC$. The oscillation period of this voltage drop is given by

$$T = \frac{2\pi}{\omega} = 2\pi\sqrt{LC} = 2\pi\sqrt{(12 \times 10^{-6}\ \text{H})(0.80 \times 10^{-6}\ \text{F})}$$
$$= 1.9 \times 10^{-5}\ \text{s}.$$

Circuits such as this are useful where internal timing is necessary—here we have a clock with a 20 μs "tick," or equivalently a 0.05 MHz frequency. When you realize that FM radio is in the range of 100 MHz, then you can begin to see why circuits such as this have direct relevance to FM radio broadcasting; for example, decreasing the inductance by a very reasonable factor will lead to oscillations in the FM realm.

What Do You Think? Does the maximum voltage across the inductor depend more strongly on the inductance L or the capacitance C in this example?

THINK ABOUT THIS. . .



ARE THERE TECHNOLOGICAL APPLICATIONS FOR CURRENT OSCILLATIONS?

Every time you use your cell phone you are making use of the phenomenon. In what has become a very important application, wireless communication relies on circuits with natural frequencies of what are effectively *LC* circuits produced on chips with a so-called CMOS (Complementary Metal Oxide Semiconductor) technology. These circuits, which are microscopic and involve very little energy, are used for both the generation and reception of signals—the reception occurs through what we will learn are resonance phenomena analogous to those seen in mechanical systems.

Another class of application is in sound synthesizers. We have seen in Chapter 15 that the sounds we hear are a complex combination of different frequencies, and successful simulation of, say, a trumpet or a violin is possible only when the entire set of frequencies and their relative amplitudes approximates the spectrum of a real instrument. For this purpose *LC* circuits with enough of a variety of inductances and capacitances can generate fairly complex spectra.

32–6 Damped Oscillations in *RLC* Circuits

When resistance, inductance, and capacitance are all present in a single-loop circuit, as in Fig. 32–15, we have an ***RLC* circuit**. The addition of a resistance to the *LC* circuit gives us an element for which there is energy loss—energy dissipated in Joule heating—and as we shall see next, the resistance term in Kirchhoff's loop rule is analogous to a drag force, proportional to the speed of the mass, in a mechanical harmonic oscillator. Thus we would expect behavior characteristic of damped mechanical oscillations in *RLC* circuits. It is worth noting that since any inductor has some resistance, all *LC* circuits are really *RLC* circuits.

▲ **FIGURE 32–15** A basic *RLC* circuit.

To analyze this case, we assume that a current is present in the circuit and apply the loop rule by following the direction of the current:

$$-L\frac{dI}{dt} - IR - \frac{Q}{C} = 0. \tag{32–27}$$

Here Q is the charge on the capacitor. Because $I = dQ/dt$, Eq. (32–27) can also be written as

$$L\frac{d^2Q}{dt^2} + R\frac{dQ}{dt} + \frac{Q}{C} = 0. \tag{32–28}$$

This equation is a differential equation for the charge Q; with the appropriate initial conditions, it determines the charge on the capacitor, including its time dependence. The current in the circuit is then found by differentiation of the charge.

Equation (32–28) has an analogue in mechanics problems that involve masses on springs in the presence of drag: To Newton's second law for a mass on an ideal spring [Eq. (32–22)], add a term for a drag force. The drag force $-bv$ is proportional to the velocity or first derivative of x. With this term Newton's second law for the damped harmonic oscillator becomes

$$m\frac{d^2x}{dt^2} + b\frac{dx}{dt} + kx = 0. \tag{32–29}$$

This equation [which is Eq. (13–45)] describes the motion of a mass at the end of a spring immersed in a fluid that gives rise to a drag force, and it is a physical system about which we have prior knowledge—it was the subject of Section 13–7. Intuition about this system and the mathematical equivalence of Eqs. (32–28) and (32–29), described in detail in Table 32–3, is immensely helpful in understanding the *RLC* circuit. We note in particular that the mechanical drag term $bv = b\,dx/dt$ corresponds to the circuit resistance term $RI = R\,dQ/dt$.

As you can review in Section 13–7, damping modulates the harmonic behavior of a mass on an ideal spring by changing the period slightly and imposing an envelope on the harmonic motion in the form of a falling exponential. The harmonic motion occurs with an exponentially decreasing amplitude. In the same way, the charge on the capacitor of an *RLC* circuit will display harmonic oscillatory time dependence within an envelope that

TABLE 32–3 • Analogy Between *RLC* Circuits and Damped Harmonic Motion

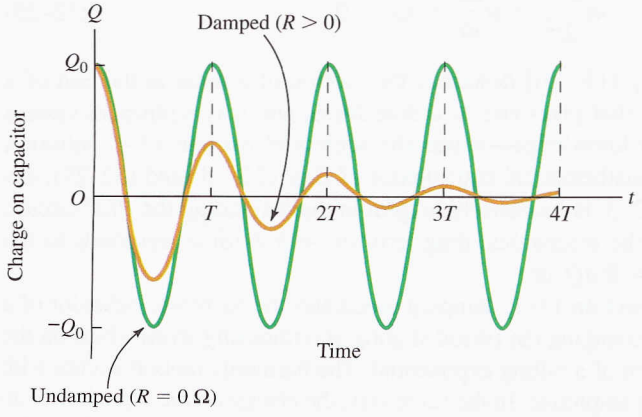
	Damped Harmonic Motion Parameter	*RLC* Circuit Parameter
Variable	x	Q
Coefficient of variable	k	$1/C$
Coefficient of $\frac{d}{dt}$ (variable)	b	R
Coefficient of $\frac{d^2}{dt^2}$ (variable)	m	L

falls exponentially with time. Current is the time derivative of charge, and because the derivatives of sines, cosines, and exponentials are cosines, sines, and exponentials, the current will also be harmonic in time within an exponentially decaying envelope.

We now flesh this out in a quantitative way. We can follow the techniques of Section 13–7 to find a solution to the loop rule equation for the *RLC* circuit, Eqs. (32–27) or (32–28). Using our solution to the damped oscillator, Eq. (13–46), along with the equivalences in Table 32–3, we find

$$Q = Q_0 e^{-\alpha t} \cos(\omega' t + \phi). \tag{32–30}$$

The constants α and ω' are determined either by substitution back into the original loop rule equation, Eq. (32–28), or simply by using the correspondences in Table 32–3 together with the results of Section 13–7. They are



$$\alpha = \frac{R}{2L} \tag{32–31}$$

and

$$\omega'^2 = \frac{1}{LC} - \frac{R^2}{4L^2} = \frac{1}{LC} - \alpha^2 = \omega^2 - \alpha^2. \tag{32–32}$$

The quantity α determines the rate of exponential damping and has dimensions of inverse time. The constants Q_0 and ϕ are determined from the initial conditions.

The exponential damping constant α depends only on L and R, as in *RL* circuits. This factor shows that the resistive element is the crucial element in damping; when there is no resistance, there is no damping. (Recall that pure *LC* circuits oscillate without damping.) The damping factor $e^{-\alpha t}$ forms a decreasing envelope for the harmonic behavior within the envelope. Note how the angular frequency ω' differs from the angular frequency $\omega = 1/\sqrt{LC}$ of the undamped circuit (an *LC* circuit). If the damping constant α is *small* compared to ω, then ω' is only slightly less than ω. In Fig. 32–16, we plot the behavior of the capacitor charge for a circuit in which $L = 1$ H, $C = 1$ F, and $R = 0.3\ \Omega$, and compare it to the previous case of $R = 0$. The period in the damped case is only slightly larger than the period for the undamped case, and this difference is not very apparent in the figure.

▶ **FIGURE 32–16** Comparison of an *RLC* circuit with and without damping: the charge on the capacitor versus time. The damped case has a very slightly larger period, so close to that of the undamped case that it cannot be seen in the figure. T is the period of the undamped oscillator.

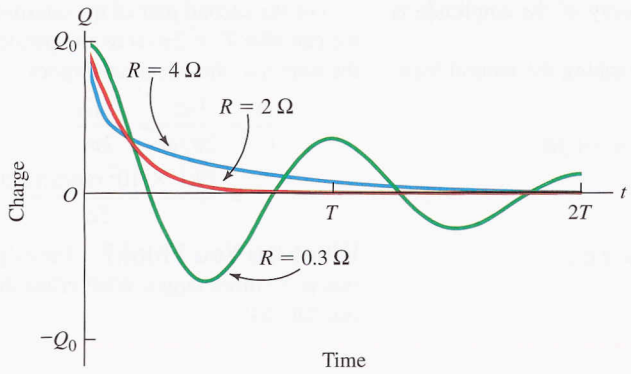


FIGURE 32–17 The *RLC* circuit of Fig. 32–15 for various values of R. The critical value R_c is $R = 2\ \Omega$. There is no oscillatory behavior, only damping, when $R > R_c$.

Figure 32–17 shows what happens to the charge if R is increased to 2 Ω and to 4 Ω. What is the explanation for this behavior? Equation (32–32) shows that when R is increased to a critical value R_c, ω'^2 decreases to zero. For $R = R_c$, we have

$$0 = \frac{1}{LC} - \frac{R_c^2}{4L^2},$$

which has the solution

$$R_c = 2\sqrt{\frac{L}{C}}. \tag{32–33}$$

When ω'^2 is zero, there is no more oscillation; as in Chapter 13, we refer to this case as *critical damping*. Judicious use of a resistance that will lead to critical damping will *eliminate* current oscillations in situations where it is not wanted. The value $R = 2\ \Omega$ in Fig. 32–17 represents this case: When $L = 1$ H and $C = 1$ F, we have $R_c = 2\ \Omega$. For values of R that are larger than the critical value, there is *overdamping*. This kind of motion has its mechanical analogue in the motion of a mass at the end of a spring when the mass is moving in a jar of thick molasses. There is no oscillation, just a slow movement directly to the equilibrium position. An example of this behavior is illustrated in Fig. 32–17, where we have chosen $R = 4\ \Omega$ (a value greater than R_c).

EXAMPLE 32–10 A switch is used to introduce a resistor of 0.052 Ω as a series element into an *LC* circuit that is undergoing oscillatory behavior (Fig. 32–18). The values of the inductance and the capacitance are 75 mH and 16 μF, respectively. How much time passes between $t = 0$, when the switch is thrown, and the moment when the amplitude of the oscillations has decreased to one half of its value prior to $t = 0$? How many oscillations does the circuit undergo during this time?

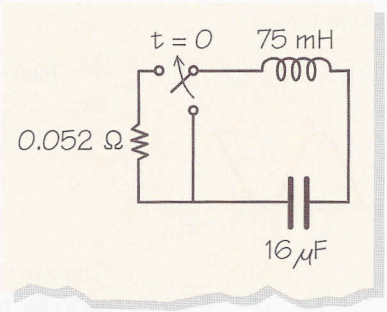

FIGURE 32–18

Strategy This problem is a straightforward application of our expression for the capacitor charge Q, Eq. (32–30). The envelope factor is $\exp(-\alpha t)$, and at the time $t_{1/2}$ when this factor is one half, we say by definition that the amplitude of the oscillations will have been cut in half. We know all the factors that go into α, so the relation $\exp(-\alpha t_{1/2}) = \frac{1}{2}$ is a relation that we can solve for $t_{1/2}$. We then see how many periods $T = 2\pi/\omega'$ will fit into $t_{1/2}$, and this is the answer to the second part of the question.

It is worth noting that if $\omega \gg \alpha$, the envelope that characterizes the decay of the oscillations changes slowly compared to the oscillation time. Many oscillations take place during the time that the envelope decreases only a little, and it is meaningful to speak of the decay of the amplitude itself, according to

$$\text{amplitude} = A_0 \exp(-\alpha t).$$

We can verify numerically whether this situation holds or not.

Working It Out Equation (32–31) is used to determine the damping factor α:

$$\alpha = \frac{R}{2L} = \frac{(0.052\ \Omega)}{2(75 \times 10^{-3}\ \text{H})} = 0.35\ \text{s}^{-1}.$$

By comparison, the angular frequency of the oscillations of the (undamped) *LC* circuit is

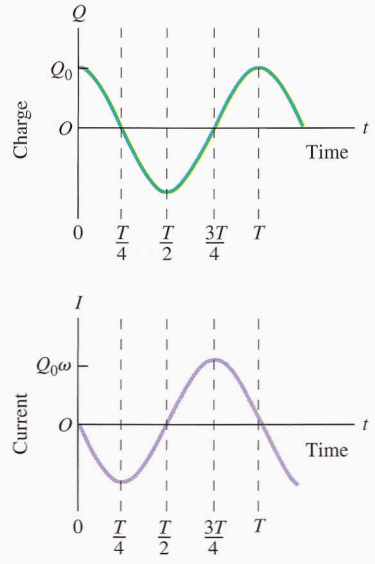
$$\omega = \frac{1}{\sqrt{LC}} = \frac{1}{\sqrt{(75 \times 10^{-3}\ \text{H})(16 \times 10^{-6}\ \text{F})}}$$
$$= 9.1 \times 10^2\ \text{rad/s}.$$

(continues on next page)

Indeed $\omega \gg \alpha$, and the concept of the decay of the amplitude is reasonable.

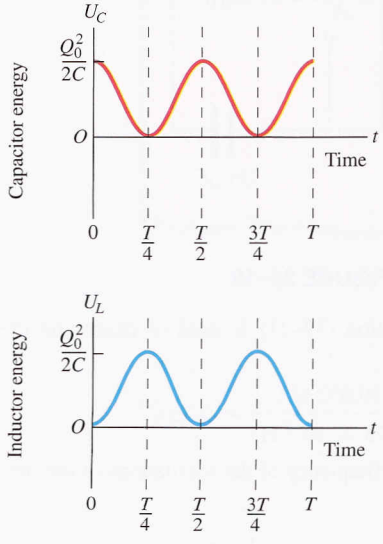
For $t_{1/2}$, we have $\exp(-\alpha t_{1/2}) = \frac{1}{2}$, or taking the natural logarithm of both sides,

$$-\alpha t_{1/2} = \ln(1/2) = -\ln 2 = -0.69.$$



Thus

$$t_{1/2} = \frac{0.69}{\alpha} = \frac{0.69}{0.35\ \text{s}^{-1}} = 2.0\ \text{s}.$$



For the second part of the question, with $\omega \gg \alpha$, $\omega \cong \omega'$, and we can take $T = 2\pi/\omega$ as the period of the oscillator. Then during the time $t_{1/2}$, the circuit undergoes

$$\frac{t_{1/2}}{T} = \frac{t_{1/2}}{2\pi/\omega} = \frac{\omega t_{1/2}}{2\pi}$$
$$= \frac{(9.1 \times 10^2\ \text{rad/s})(2.0\ \text{s})}{2\pi} \cong 290\ \text{oscillations}.$$

What Do You Think? The original resistor is replaced by one that is 10 times larger. What effect does this have on the number of oscillations?

▲ **FIGURE 32–19** The capacitor charge and the current in a circuit that contains only inductance and capacitance are harmonic functions of time. Note the relative positions of the maxima and minima for current and charge.

▲ **FIGURE 32–20** The energies of capacitor and inductor for charge and current of the circuit in Fig. 32–15, but with $R = 0$. These oscillate out of phase.

32–7 Energy in *LC* and *RLC* Circuits

Energy is a useful concept in *RLC* circuits, just as it is for the harmonic oscillator. Let's reconsider instances without and with damping.

No Resistance: We set $R = 0$, i.e. there is no damping. We take initial conditions such that the charge on the capacitor is

$$Q = Q_0 \cos \omega t. \tag{32–34}$$

The current in the circuit is then

$$I = \frac{dQ}{dt} = -\omega Q_0 \sin \omega t. \tag{32–35}$$

One full period of both of these functions is plotted in Fig. 32–19.

The energy contained in a capacitor is given by Eq. (26–8), $U_C = Q^2/2C$, or

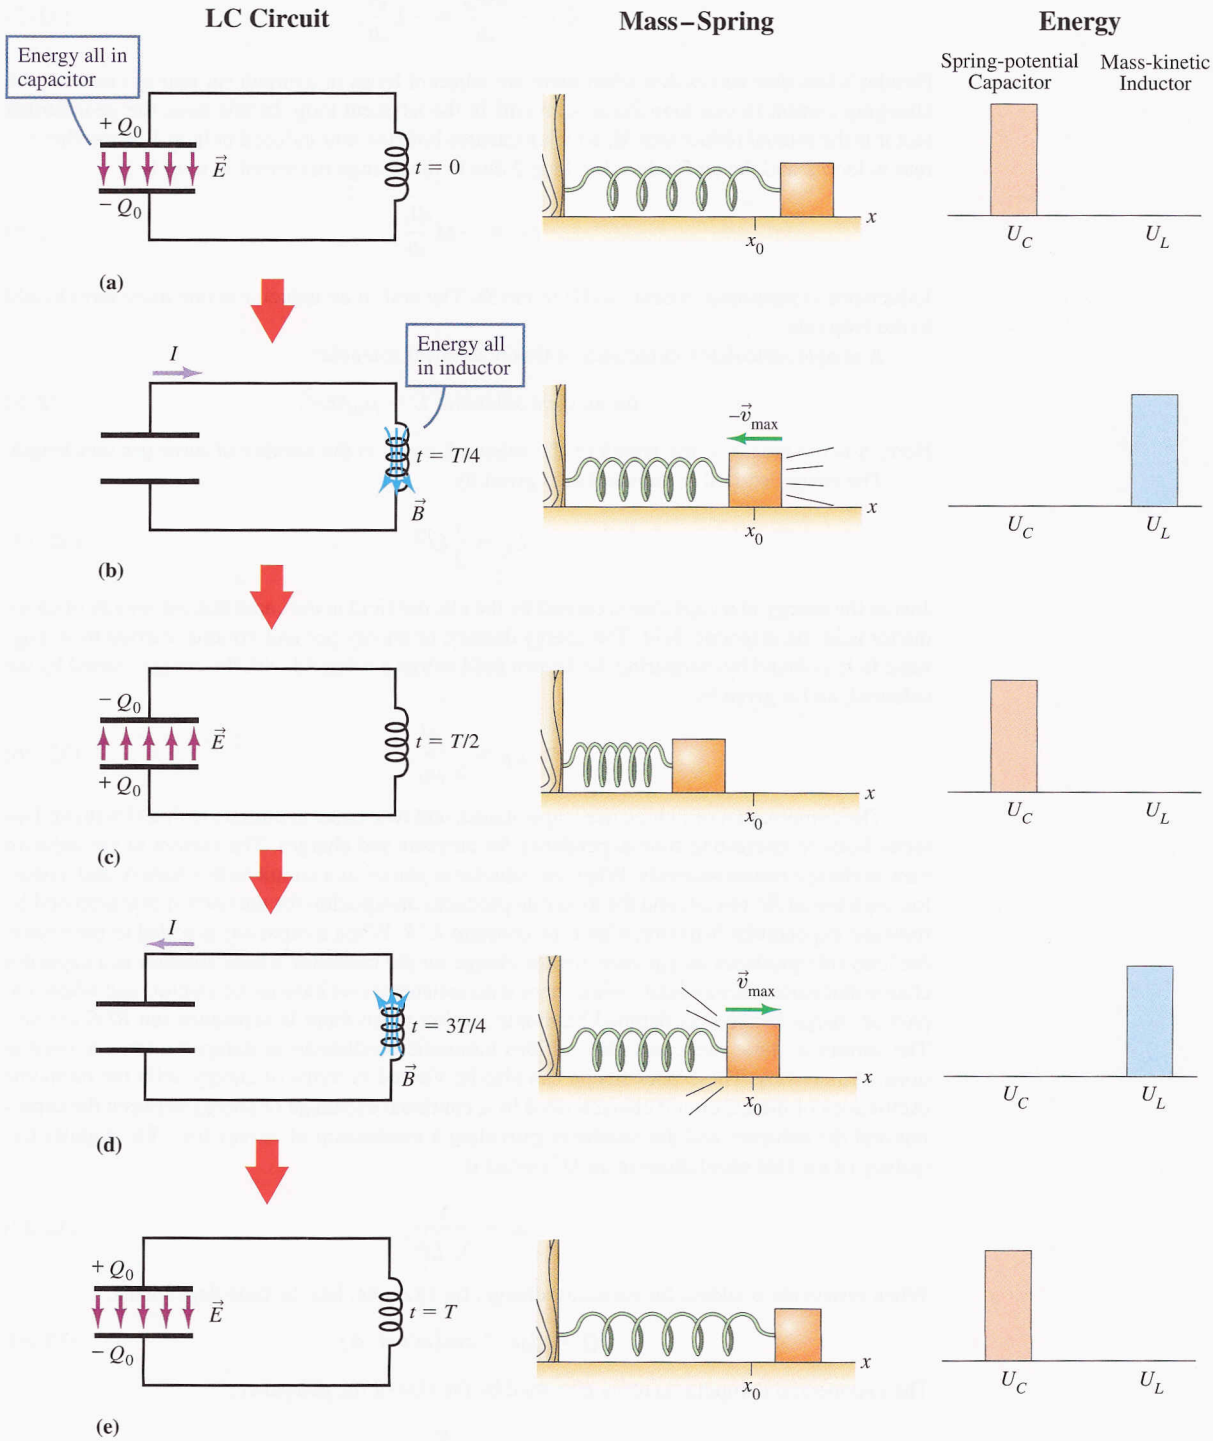
$$U_C = \frac{Q_0^2}{2C} \cos^2(\omega t). \tag{32–36}$$

Equation (32–14) gives the magnetic energy in an inductor, $U_L = \frac{1}{2}LI^2$:

$$U_L = \frac{1}{2} L\omega^2 Q_0^2 \sin^2(\omega t) = \frac{Q_0^2}{2C} \sin^2(\omega t). \tag{32–37}$$

We have used $\omega = 1/\sqrt{LC}$. The (positive) functions U_C and U_L are plotted in Fig. 32–20. The energy of one rises to a maximum as the other falls to zero. But the *total* energy in the inductor and capacitor is *constant*:

$$U = U_C + U_L = \frac{Q_0^2}{2C}[\cos^2(\omega t) + \sin^2(\omega t)] = \frac{Q_0^2}{2C}. \tag{32–38}$$



The two circuit elements swap the constant total energy back and forth harmonically, just as in the mechanical oscillator, for which the constant total energy is made up of a back-and-forth exchange of the potential energy of the spring and the kinetic energy of the attached mass. In both the mechanical and circuit case, this is an expression of the conservation of energy. In Figs. 32–21a to 32–21e, we have drawn the progression in a series of snapshots over a full period T, starting with no current and a fully charged capacitor at $t = 0$. Without a resistor to dissipate energy, the oscillation will continue forever.

Resistance Is Introduced: We can easily understand the role of resistance in terms of energy. The power P_R dissipated in the resistor is voltage times current:

$$P_R = IV_R = I^2R, \tag{32–39}$$

where we have used Ohm's law, $V_R = IR$. This power is proportional to the current squared and is always positive. Energy is *always* lost to Joule heating in a resistor, regardless of the sign of the current. This is the origin of the exponential damping in *RLC*

circuits. The power loss in resistors should be contrasted to the equivalent expressions for inductors ($P_L = IV_L$) or capacitors ($P_C = IV_C$). In each case, the rate of energy expenditure can be positive or negative, according to the situation [see Eq. (32–11)]. Unlike the resistor, these elements sometimes take energy from the other circuit elements and sometimes give it back.

▲ **FIGURE 32–21** (a)–(e) A time sequence showing how the electric and magnetic fields, and therefore the energies, of Fig. 32–20 are realized within the capacitor and inductor. We also show the analogous mechanical system at corresponding times, as well as the balance of energy in the capacitor and inductor for those times.

Summary

An inductor is a circuit element that behaves as a current-carrying loop, or solenoid. It has an inductance L defined by the ratio between the magnetic flux and the current that passes through it:

$$\Phi_B = LI. \tag{32–1}$$

By Faraday's law, the emf induced in this circuit element is

$$\mathcal{E} = -\frac{d\Phi_B}{dt} = -L\frac{dI}{dt}. \tag{32–2}$$

Faraday's law also shows that when there are adjacent loops in a circuit (or pair of circuits), the changing current in one loop induces an emf in the adjacent loop. In this case, the geometrical factor is the mutual inductance M, which measures both the emf induced in loop 1 due to the current in loop 2 and the emf induced in loop 2 due to the change in current in loop 1,

$$\mathcal{E}_{21} = -M\frac{dI_1}{dt}. \tag{32–5}$$

Inductance is measured in henries (H) in the SI. The emf in an inductor is one more term to add to the loop rule.

A simple, calculable inductance is that of an ideal solenoid:

$$\text{for an ideal solenoid: } L = \mu_0 A\ell n^2. \tag{32–8}$$

Here, A is the area, ℓ is the length of the solenoid, and n is the number of turns per unit length.

The energy carried in an inductor is given by

$$U_L = \frac{1}{2}LI^2. \tag{32–13}$$

Just as the energy of a capacitor is carried by the electric field in the capacitor, the energy of an inductor is in the magnetic field. The energy density, or energy per unit volume, carried by a magnetic field is found by comparing the known field within a solenoid with the energy carried by the solenoid, and is given by

$$u_B = \frac{1}{2}\frac{B^2}{\mu_0}. \tag{32–16}$$

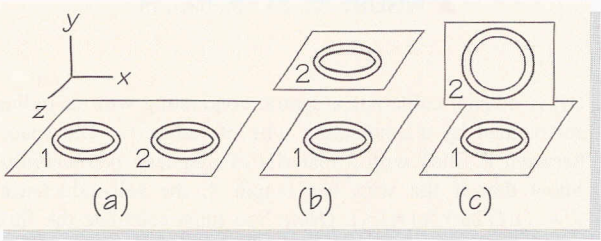
The combination of inductance, capacitance, and resistance in circuits with and without batteries leads to interesting time dependence for currents and charges. The current in the inductor cannot change instantaneously. When an inductor is placed in a circuit with a battery and a resistor, we have an *RL* circuit, and the loop rule produces an equation for the current characterized by transient exponential behavior, with time constant L/R. When a capacitor is added to the circuit, the loop rule produces an equation for the charge on the capacitor whose solution is a capacitor charge that varies harmonically when there is no resistance (we have an *LC* circuit) and whose capacitor charge behaves as damped harmonic motion when there is resistance (an *RLC* circuit). The current in these two cases also exhibits harmonic oscillations or damped harmonic oscillations, respectively. These phenomena can also be viewed in terms of energy, with the harmonic oscillations of the *LC* circuit characterized by a continual exchange of energy between the capacitor and the inductor, and the resistance providing a mechanism of energy loss. The angular frequency of the free oscillations in an *LC* circuit is

$$\omega = \frac{1}{\sqrt{LC}}. \tag{32–23}$$

When resistance is added, the capacitor charge, for example, has the time dependence

$$Q = Q_0 e^{-\alpha t}\cos(\omega' t + \phi). \tag{32–30}$$

The exponential damping factor is governed by the size of the resistance,



$$\alpha = \frac{R}{2L}, \tag{32–31}$$

while the frequency is shifted to the value

$$\omega'^2 = \omega^2 - \alpha^2. \tag{32–32}$$

Understanding the Concepts

1. Two electric circuits are placed near one another. Each circuit has self-inductance. Must there be a mutual inductance?
2. Does it take more work to cause current to flow through a coil of wire than through the same wire when it is straight?
3. Consider two circular coils that are in a variety of configurations (Fig. 32–22). Assuming that the separation between the coils is roughly the same for the various configurations, can you order the mutual inductances from largest to smallest?

▲ **FIGURE 32–22** Question 3.

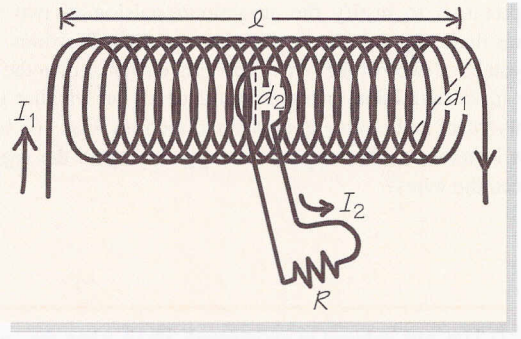
4. Why might Faraday's law cause the lights in a house to dim when an electrical appliance that uses a lot of energy, such as an electric clothes dryer, is turned on?
5. Is it possible to calculate the mutual inductance between a straight wire and a wire loop?
6. If the energy in a given region is equally split between energy in the electric and the magnetic fields, what does this tell you about the relative magnitude of the magnetic and electric fields?
7. The time for the current amplitude to drop to $\frac{1}{2}$ its initial value in Example 32–10 is (a) larger than, (b) the same as, or (c) smaller than the time for the charge amplitude to be one half its initial value.
8. Why do you sometimes see a spark at a light switch when the switch is turned off? Is there a spark when the switch is turned on? Why or why not?
9. Describe how you could measure inductance with a battery of known emf, a known resistor, a voltmeter, and a timer.
10. A lightbulb is placed in series with a resistor and in parallel with a coil of large inductance and negligible resistance. When a switch that connects a battery to this circuit is closed, the lightbulb flashes before glowing dimly. When the switch is opened, the bulb flashes again before going out. Explain.
11. In the oscillations of an *LC* circuit, the energy is transferred from the electric field in the capacitor to the magnetic field in the inductor. How does the energy get from one place to the other?
12. Given your knowledge of the largest and smallest practical sizes of capacitors and inductors, what would you estimate is the electronic oscillator with the smallest frequency possible? The largest?
13. Consider Example 32–9. What determines the value of the maximum charge on the capacitor in that example?
14. Given a certain length of wire, you are asked to wind it in the form of a solenoid in a way that maximizes the self-inductance. You may change the radius of the core and the number of turns per unit length, but must take into account that the wire has a certain fixed thickness. What should you do?
15. A solenoid has magnetic flux outside as well as inside, because magnetic field lines must close on themselves. Does this mean that there is magnetic energy outside the solenoid as well as inside it?
16. In Section 32–3, the magnetic energy calculation for a solenoid used the inductance of a portion of the solenoid, and that was translated into the energy density expression $B^2/2\,\mu_0$. The magnetic field must come around the outside of the solenoid because all magnetic field lines are closed. Why then does the above calculation give the correct answer for the energy density?
17. When $R = 0$, the time constant for the *RL* circuit is infinite. Physically, why?
18. If a diamagnetic material is placed inside the solenoidal coil, the self-inductance of the coil will (a) increase, (b) decrease, (c) stay the same.
19. We have made an analogy between a damped harmonic oscillator and an *RLC* circuit. What mechanical quantities are analogous to the energies $LI^2/2$ and $Q^2/2C$ of the *RLC* circuit?
20. How would you go about finding a generalization of Eq. (32–13) when two circuits with different currents are placed in such close proximity that their mutual inductance plays a role?
21. The magnetic energy density $B^2/2\,\mu_0$ has the dimensions of pressure and may be viewed as a magnetic pressure. Use this interpretation to justify the attraction/repulsion of two parallel wires that carry currents in the same/opposite directions.
22. If you have two parallel wires carrying currents, then the sign of the force (attraction or repulsion) depends on whether the currents travel in the same or opposite directions. Can you interpret this in terms of the magnetic energy density in the region between the wires?

Problems

32–1 Inductance and Inductors

1. (I) A wire loop has an inductance of 2 mH when a current of 30 mA passes through the circuit. What is the value of the magnetic flux that passes through the loop?
2. (I) What is the self-inductance per unit volume of a solenoid?
3. (I) Calculate the mutual inductance of a solenoid 25 cm long of radius 1.8 cm with 600 turns, and a single loop of radius 3.0 cm centered on the solenoid, with its area perpendicular to the axis of the solenoid.
4. (I) A current that changes at the rate of 1.25 A/s passes through a solenoid; an induced emf of 520 mV is the result. The length and diameter of the solenoid are 12 cm and 0.50 cm, respectively. What is the number of turns?
5. (I) The emf induced in an isolated circuit when the current in the circuit is changing by 10 A/s is 0.3 V. What is the self-inductance?
6. (II) An electrical engineer needs an inductor capable of producing an emf of 150 mV. The current source available produces current of the form $I = I_0 \cos(\omega t)$, with $I_0 = 0.60$ A and $\omega = 2.7 \times 10^2$ rad/s. What size inductor should be used?
7. (II) A current of 1 A flows through a circuit placed in isolation. A magnetic flux of 0.010 T · m^2 passes through the circuit area. When this circuit is placed near another circuit with a current flow of 2 A, the magnetic flux through the first circuit increases to 0.012 T · m^2. (a) What is the mutual inductance of the two circuits? (b) How much magnetic flux passes through the second circuit, whose self-inductance is 1 mH?

8. (II) What is the self-inductance of the single inductor that is equivalent to two inductors of values L_1 and L_2, respectively, placed in series? Neglect the mutual inductance.

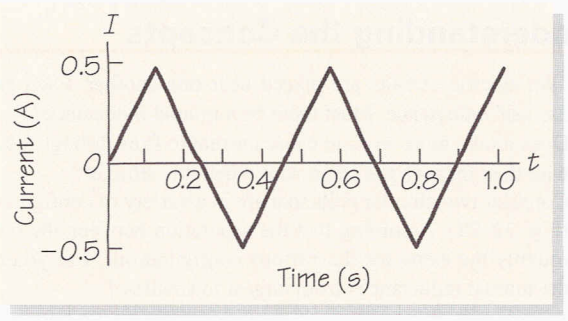


9. (II) A solenoid of length L consists of two coils tightly placed on top of each other. One coil has N_1 turns, the other N_2, and the area of the coils is A. Calculate the self-inductances of the coils (a) if only one of the two coils is used; (b) if the two coils are connected in series with their windings going in the same direction; (c) if the two coils are connected in series with their windings going in the opposite direction. (d) Calculate the mutual inductance of the two coils.

10. (II) Consider two inductors with inductances L_1 and L_2, respectively, connected in parallel. What is the value of the single equivalent inductance that could replace the two inductances, assuming that the mutual inductance can be neglected?

11. (II) A solenoid of length L and area A contains two windings—one tightly placed on top of the other—with N_1 and N_2 turns, respectively. What happens if the two windings are connected in parallel and the composite coil is included in a circuit with a variable current?

12. (II) Equation (32–8) was derived for an ideal cylindrical solenoid. Show that this result holds also for a solenoid of any shape cross section, provided that the length is large compared to any cross-sectional measure.

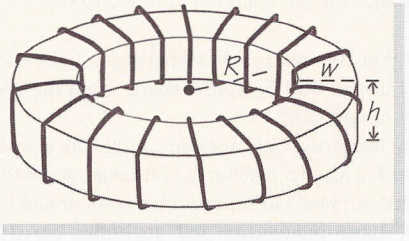


13. (II) Consider the cylindrical solenoid and ring illustrated in Fig. 32–23. The solenoid, of diameter $d_1 = 2.0$ cm, has length $\ell = 20$ cm and 120 turns of wire. The ring of wire inside, with diameter $d_2 = 1.5$ cm and area perpendicular to the solenoid's axis, is connected by two wires to a single resistor of resistance $R = 33\ \Omega$. The current I_1 is in the form of a pulse that starts to rise linearly at $t = 0$ s. The current reaches a maximum of 30 A at $t = 0.30$ s, then starts to descend linearly; when the current reaches 0 A at $t = 0.60$ s, it ceases to flow. Find the current I_2 induced in the ring as a function of time.

▲ **FIGURE 32–23** Problem 13.

14. (II) The ring contained within the cylindrical solenoid in Fig. 32–6a is replaced by a second cylindrical solenoid, of length ℓ_2, radius R_2, and turn density n_2. Calculate the mutual inductance of this system.

15. (II) The current in an inductor has the periodic triangular form plotted in Fig. 32–24, with an amplitude of 0.50 A and a period of $T = 0.45$ s. What is the voltage across the inductor as a function of time if $L = 2.3 \times 10^{-3}$ H? Express your answer algebraically or plot it.

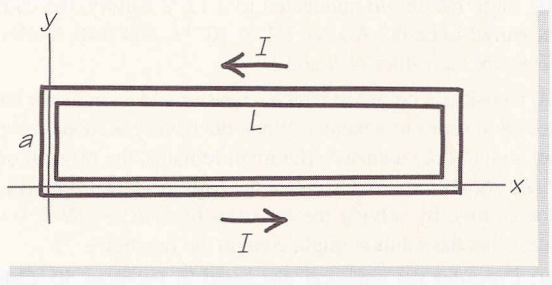


▲ **FIGURE 32–24** Problem 15.

16. (II) A coaxial cable has a central conducting wire of radius r_0 surrounded by a conducting tube of radius r_1. The space in between is filled with a material of magnetic permeability μ. Show that if the wire has length ℓ, the self-inductance is $L = (\mu\ell/2\pi)\ln(r_1/r_0)$. [*Hint*: You must calculate the flux in the region between the cylinders.]

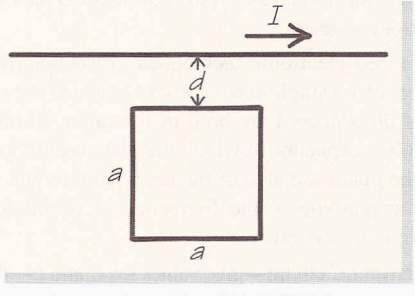
17. (II) Consider two identical solenoids placed end to end, with the windings going in the same direction. Prove that the total self-inductance of the combined system is $2(L + M)$, where L is the self-inductance of either solenoid and M is the mutual inductance.

18. (II) A torus of rectangular cross section with width w, height h, and inner radius R is wound with N turns of wire (Fig. 32–25). What is the self-inductance of the torus? Use the approximation $\ln(1 + x) = x$, valid for $x \ll 1$, to discuss the case where $R \gg w$ and its relation to the self-inductance of a solenoid.



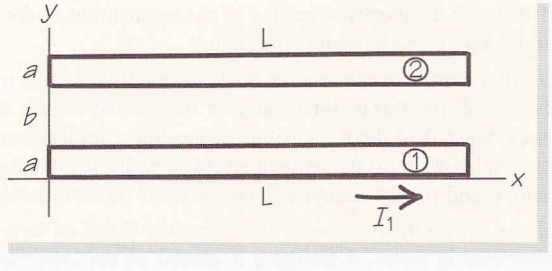
▲ **FIGURE 32–25** Problem 18.

19. (II) Consider a torus of square cross section. The radius of the torus (distance from the symmetry axis to the center of the square) is 35.0 cm; the sides of the square are 5.00 cm. The torus is wound with 1650 turns of wire. (a) What is the self-inductance of the torus? (b) What is the self-inductance if the core of the torus is made of soft iron, with $\mu = 4200\mu_0$?



20. (II) Consider a toroidal coil wound around an empty core whose self-inductance is 15 mH. The current in the coil changes uniformly by 120 mA in 0.50 s. (a) What is the induced emf? (b) If the hollow center of the torus is filled with an iron core, with $\mu = 3400\mu_0$, what is the induced emf?

21. (II) Calculate the inductance of an elongated rectangular circuit, such as a length of a two-wire ribbon cable (Fig. 32–26). The length of the circuit is L and its width is $a \ll L$. If the radius of the wire is much less than a, can it (the radius) be neglected?



▲ FIGURE 32–26 Problem 21.

22. (II) Figure 32–27 shows a straight wire that carries a current I and a square loop of wire with one side oriented parallel to the straight wire a distance d away. The square has sides of length a. Calculate the mutual inductance of this system. [*Hint*: The magnetic field due to the straight wire through a slice of the square of width dx parallel to the wire is constant, so the flux through this slice is easily calculable. Integrate to find the total flux through the square.]

▲ FIGURE 32–27 Problem 22.

23. (III) Calculate the mutual inductance of the two elongated rectangular circuits shown in Fig. 32–28. Assume that $L \gg a, b$.

▲ FIGURE 32–28 Problem 23.

32–2 Energy in Inductors

24. (I) A cylindrical solenoid of radius 0.75 cm is wound with a turn density of 140 turns/m. It carries a current of 0.45 A. How much energy is stored per meter length of the solenoid?

25. (I) Consider an inductor with $L = 16$ H and an internal resistance of 0.10 Ω. We wish to use this inductor to store 0.10 MJ of energy. What is the rate at which energy is lost to Joule heating in this system? It is not practical to store large amounts of energy in large inductors unless the wire is superconducting.

26. (I) An inductor with $L = 1.6$ mH has an internal resistance small enough to be ignored. How much work would a battery have to do to increase the current through the inductor from 88 mA to 98 mA?

27. (I) A capacitor with $C = 0.020$ μF has a charge of 15 μC. What is the equivalent steady current that should be carried by an inductor of $L = 20$ μH if the inductor is to store the same amount of energy?

28. (I) A doorbell circuit contains a solenoid with 600 turns of wire, a cross section of 6.0 cm^2, and a length of 12 cm. When the doorbell button is pushed, 100 mA passes through the circuit. How much energy is contained within the solenoid at this time?

29. (II) A current with time dependence $I = I_0 e^{-\alpha t}$ passes through an inductor with $L = 2$ mH; $I_0 = 4.0$ A and $\alpha = 0.02\ s^{-1}$. Compute the power expended in the inductor as a function of time.

30. (II) The voltage across an inductor with $L = 3.0$ mH is fixed at 6.0 V. The current is increased (a) from 0.00 A to 0.25 A, (b) from 0.25 A to 0.35 A, and (c) from 0.35 A to 0.40 A. What average power must be supplied from an external source in each step?

31. (II) Consider an inductor with $L = 1$ H and a capacitor with $C = 1$ F. (a) Compare the energy contained in the inductor when a current of 10 A flows through it with the energy in the capacitor if the charge is the amount of charge contained in the 10-A current, flowing for 1 s. (b) Repeat part (a) for a current of 1 mA.

32. (II) An electrical engineer constructs a cylindrical solenoid of area 8 cm^2 and length 25 cm from 150 m of thin wire. The wire will handle a maximum current of 50 mA. (a) What is the inductance of the solenoid? (b) How much energy can the inductor store?

33. (II) The inductance of a small superconducting solenoid is 8 H. The current is gradually increased from 0 A to 40 A. (a) How much energy is stored in the solenoid? (b) When the current reaches 40 A, the solenoid "quenches"; i.e. the wire of the solenoid loses its superconductive property because of the large magnetic field. The current decreases to zero rapidly, and the magnetic energy is dissipated in the liquid helium coolant. Given that the latent heat of vaporization of helium is 2.7×10^3 J/L, how much of the liquid helium coolant is evaporated during the quench?

32–3 Energy in Magnetic Fields

34. (I) The magnetic field in interstellar space has an approximate magnitude of 10^{-10} T. How much magnetic field energy does this contribute to the spherical region around the Sun of radius matching the mean radius of Neptune's orbit?

35. (I) The two circular pole pieces of a magnet are 63 cm in diameter and 21 cm apart. The magnetic field between them is 0.10 T. What is the magnetic energy stored in the field?

36. (I) An ideal cylindrical solenoid carrying a current of 115 mA has a winding density of 15 turns/cm. If the core is filled with iron, $\chi_m = 5500$, what is the energy density contained in the magnetic field within?

37. (II) A straight wire carries a current $I = 20$ A. Find the energy density in the surrounding magnetic field as a function of the distance r from the wire. At what distance from the wire does the energy density equal that of a parallel-plate capacitor with a charge of 10^{-7} C and a capacitance of 6.3×10^{-9} F, if the separation between the plates is 1.5 mm?

38. (II) (a) What is the energy density of the magnetic field outside a straight wire of radius a that carries a current I? (b) What is the total energy per unit length, due to that magnetic field, that is contained in a cylinder of radius R ($R > a$) centered about the wire?

39. (II) Consider a torus of radius R, wound with n turns per unit length of a wire that carries a current I. The cross section of the torus forms a square with sides of length b; $b \ll R$. We know that the magnetic field inside the torus has the nearly constant value $B = \mu_0 nI$. Use this result and the two expressions related to the magnetic energy [Eqs. (32–13) and (32–15)] to show that, for this torus, $L = 2\pi\mu_0 n^2 R b^2$.

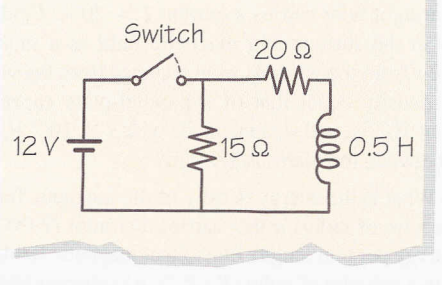
40. (II) Consider an iron ring of cross-sectional area A. The upper half of it has a certain number of turns of wire wrapped around it. The wire is connected to a battery so that a current I flows through the wire. The ring is cut so that there is a small gap of width y. Within the gap, the magnetic field has magnitude B. (a) What is the force exerted by the upper half of the ring on the lower half? (b) Suppose the gap is filled with some material of large (positive) susceptibility. Will the force increase or decrease?

41. (II) Consider a hollow solenoid inside of which there is a magnetic field B. The solenoid is vertical, and a small cylinder of iron that just fits into the solenoid without touching the sides is dropped into the empty space. Will there be a force on the small cylinder? If so, in what direction will it point? How large will it be?

42. (II) (a) What is the magnetic field energy density inside a straight wire of radius a that carries current I uniformly over its area? (b) What is the total magnetic field energy per unit length inside the wire?

43. (II) A coaxial cable consists of a wire 0.15 cm in diameter with a return path for the current in the shape of a very thin cylindrical conductor of diameter 0.80 cm. A current of 0.25 A flows through the cable. Calculate the magnetic energy per unit length of cable within the inner wire. [*Hint*: It will help to do Problem 42 first.]

32–4 Time Dependence in *RL* Circuits



44. (I) You wish to make a circuit in which a resistor and an inductor are connected in series to a battery such that when the switch is closed, the current builds up to within 18% of its steady-state value in 5×10^{-4} s. You have a series of inductors with inductances ranging from 0.010 H to 0.10 H. You must acquire a set of resistors with what range of resistance?

45. (I) Show that the time constant L/R that characterizes RL circuits has dimensions of time.

46. (II) Consider the RL circuit of Fig. 32–10; the switch is closed at time $t = 0$. For the circuit elements, $\mathcal{E} = 6$ V, $R = 3.3\ \text{k}\Omega$, and $L = 2.5$ mH. Using Eq. (32–19), find how much charge flows in the circuit during the first (a) 1 μs, (b) 1 ms, (c) 1 s.

47. (II) Show by direct substitution that Eq. (32–19) is a solution of Eq. (32–18).

48. (II) Consider the RL circuit shown in Fig. 32–29. The switch is opened at time $t = 0$ after it had been closed for a long time. How long will it take for the current in the inductance to drop to 25% of its initial value? How long will it take for the energy in the inductance to drop to 25% of its initial value?

▲ **FIGURE 32–29** Problem 48.

49. (II) In an RL circuit connected to a 12-V battery, the current is measured to be 0.2 A after 1.2×10^{-4} s, and 0.48 A after 10 s. What are the values of R and L?

50. (II) Consider a circuit in which a resistor and an inductor are connected in series to a battery. When the battery is suddenly shorted out so that only a closed RL circuit remains, the original current, V/R, decays to zero. Calculate the form of the current as a function of time by solving the equation $L(dI/dt) + RI = 0$ with a guess that the solution might contain the function $e^{-\alpha t}$.

51. (II) Consider the situation discussed in Problem 50. Calculate the total energy dissipated in the resistor from the time when the switch that shorts out the battery is thrown to the time $t = \infty$. Show that this is the energy stored in the inductor just before the switch is closed.

32–5 Oscillations in *LC* Circuits

52. (I) An electric oscillator consists of a parallel-plate capacitor and a long, cylindrical solenoid. If the resonant frequency of the oscillator is ω_0, what is the frequency of a similar oscillator in which both the capacitance and inductance are reduced by a factor of 12?

53. (I) You have an inductor with an inductance of 40 mH. Using it, you want to make a circuit with oscillations of frequency 20 Hz. What capacitor do you ask your roommate to pick up at the corner electronics store?

54. (II) Advanced electronic techniques utilize microscopic structures. Consider a single-turn solenoid in which the radius and the length of the solenoid are both of the order 10 microns, and a parallel plate capacitor in which the plate separation and the radius of the plates are also of the order 10 microns. *Estimate* the order of magnitude of the frequency of oscillation of such a microscopic LC circuit.

55. (II) Design an LC circuit—give values for C and L—that has an angular frequency of 4.32×10^4 rad/s and a stored energy of 0.30 mJ. The maximum voltage drop across the capacitor must be 20.0 V.

56. (II) Suppose that at time $t = 0$ the current in an ideal LC circuit is zero but the charge on the capacitor is $Q(0)$. (a) What is the energy in terms of $Q(0)$, L and C? (b) If the charge on the capacitor is zero at $t = 0$, and the current has the value $I(0)$, what is the energy? (c) Starting at $t = 0$, when is the first time that the energy is equally stored in the capacitor and in the inductor? (d) What is the electrical analog of the momentum of the oscillating mass in the harmonic oscillator?

57. (II) Two electric oscillators are made of exactly the same materials, but all the linear dimensions of the second circuit are ten times larger than the dimensions of the first circuit. Obtain the relation between (a) the undamped frequencies, (b) the damping factors, and (c) the damped frequencies of the two oscillators.

58. (II) An open circuit consists of a capacitor C and an inductor L connected in series. A charge q is placed on the capacitor, and the circuit is closed at time $t = 0$ by means of a switch. Find the maximum value of the current, as well as the times for which this maximum value occurs.

32–6 Damped Oscillations in *RLC* Circuits

59. (I) An RLC circuit is composed of a resistor $R = 0.883\ \Omega$, an inductor $L = 1.75$ H, and a capacitor $C = 133$ pF, all arranged in series. What is the angular frequency of current oscillations in this circuit?

60. (I) An RLC circuit has $R = 85\ \text{m}\Omega$, $L = 0.60$ mH, and $C = 55\ \mu$F. (a) Find the damping factor and angular frequency. (b) If the resistance is variable, what value of R will give critical damping?

61. (I) Consider a series *RLC* circuit for which the initial capacitor charge is Q_0. If R is chosen such that there is critical damping, what is the instantaneous power consumption in the resistor? [*Hint*: Try the formula in Eq. (32–30).]

62. (II) Consider an *RLC* circuit at critical damping, with $L = 68$ mH. What is the value of R if the current decays by 15 percent in 8.0 ms?

63. (II) Show that Eqs. (32–30) through (32–32) solve Eq. (32–27).

64. (II) Suppose that the values of R, L, and C in a series *RLC* circuit are such that $\omega'^2 < 0$. Assuming that the solution for the charge on the capacitor takes the form $Q = Q_1 \exp(-\alpha_1 t) + Q_2 \exp(-\alpha_2 t)$, find the values of α_1 and α_2.

65. (II) Consider the basic *RLC* circuit. By making an appropriate approximation of Eq. (32–32), show that when α is small compared to $\omega = 1/\sqrt{LC}$ the modified angular frequency ω' of the damped *RLC* circuit is $\omega' \simeq \omega - R^2\sqrt{C/L}/8L$. Find a similar relation for the periods of the undamped and slightly damped cases.

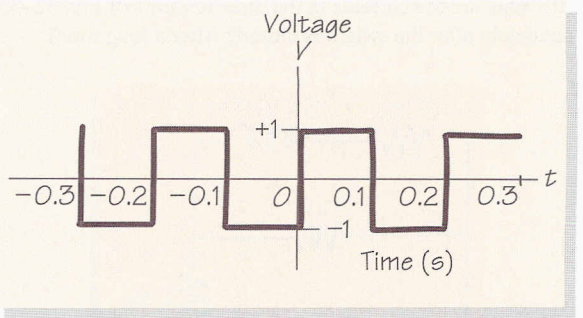
32–7 Energy in *LC* and *RLC* Circuits

66. (II) Calculate the energy in an *LC* circuit, assuming that the initial conditions are such that the charge on the capacitor is $Q = Q_0 \cos(\omega t + \delta)$. Show that the energy is constant.

67. (II) A circuit consists of a capacitor of capacitance $C = 20$ nF connected in series with an inductor of inductance $L = 2 \times 10^{-5}$ H. If a charge of 30 nC is put on the capacitor, there is an oscillation in the circuit. (a) What is the maximum current that moves through this circuit? (b) Find the maximum energy within the inductor. (c) What is the ratio of the maximum energy in the inductor to the maximum energy in the capacitor?

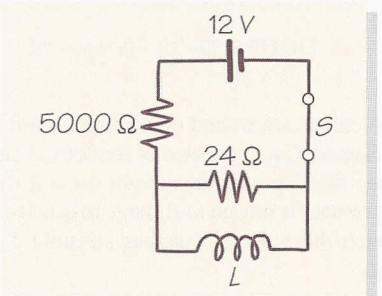
68. (II) An *LC* circuit consists of a 15-mH inductor and a 120-μF capacitor. If the maximum energy stored in the circuit is 3.0×10^{-4} J, what are the maximum charge on the capacitor and the maximum current in the circuit? What are the minimum values?

69. (III) The 3-mF capacitor of an *RLC* circuit is initially charged to 30 μC. The 1.5-mH inductor has a very small resistance. At a particular instant, after 100 oscillations, the current through the inductor is zero while the capacitor is still charged to 5 μC. (a) What is the resistance of the circuit? (b) What are the energies of the circuit before and after the 100 oscillations? (c) Why are the two values of the energy in part (b) different? Where has the energy gone?



70. (III) Consider an *RLC* circuit. The energy is given by $E = LI^2/2 + Q^2/(2C)$. Show that the rate of change of this energy is equal to the power loss in the resistor (the ohmic heating power).

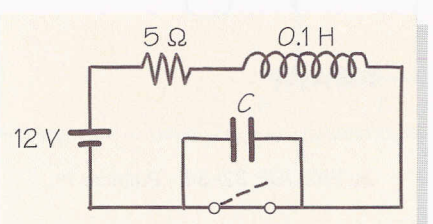
General Problems



71. (II) By considering the definition of inductance, show that if the voltage V across an inductor changes with time, the total current passing through the inductor in that time is given by $I = \frac{1}{L}\int V\,dt$.

72. (II) Suppose that a square wave of voltage, as plotted in Fig. 32–30, is applied across an inductor with $L = 0.005$ H. Use the result of Problem 71 to plot the current as a function of time.

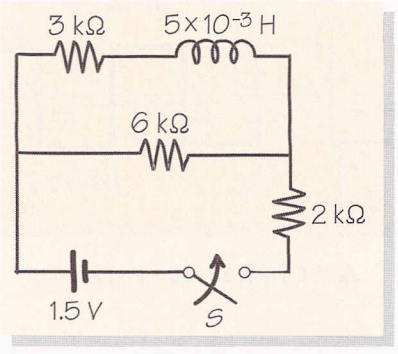
73. (II) The switch in the circuit shown in Fig. 32–31 has been closed for a long time. (a) What is the current in each leg of the circuit? (b) When the switch is opened, the current in the inductor drops by a factor of 2 in 8 μs. What is the value of the inductance? (c) What is the current passing in each leg at 12 μs?



▲ **FIGURE 32–30** Problem 72.

▲ **FIGURE 32–31** Problem 73.

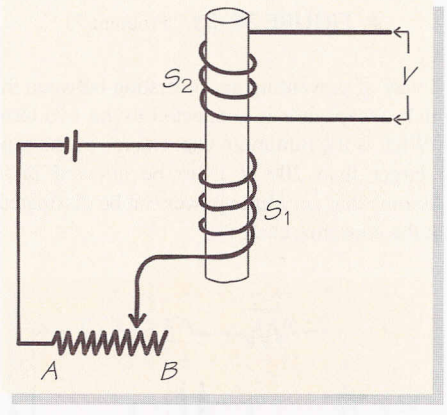
74. (II) As a way of preventing arc formation between the terminals of a switch, a capacitor is connected to the two terminals (Fig. 32–32). What is the minimum capacitance of the capacitor if no voltage larger than 200 V is to be allowed in the circuit? [*Hint*: Assume that very little power can be dissipated during the time that the capacitor charges.]



▲ **FIGURE 32–32** Problem 74.

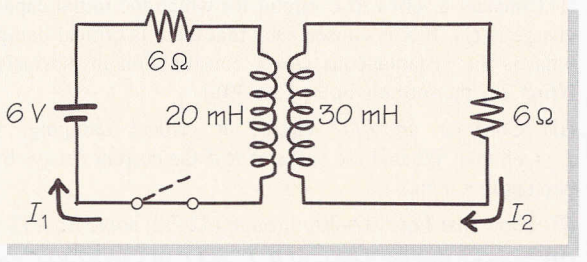
75. (II) A coaxial cable has an inner, solid wire of radius r_1 and an outer, hollow wire of radius r_2. A current I flows through the inner wire and returns through the outer wire. Assuming that the cable is infinitely long, find the magnetic field energy per unit length. Include any field energy inside the inner wire and outside the outer wire.

76. (II) Molybdenum is paramagnetic, with a magnetic susceptibility of 1.2×10^{-4} at 300K, which is about one half its value at 20K. Suppose that the self-inductance of a solenoid filled with molybdenum is $L = 0.35$ mH at 300K. What is the fractional change in self-inductance between 300K and 20K?



77. (II) Consider a cavity uniformly filled with oscillating electric and magnetic fields. (a) Show that the ratio of the amplitude of these fields, E_0 and B_0, respectively, has the dimensions of [velocity]$^{-1}$. (b) For what value of this ratio is the magnetic energy density equal to the electric energy density?

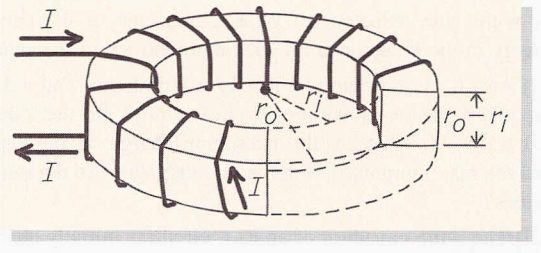
78. (II) What are the currents in the three resistors of Fig. 32–33 immediately after the switch is closed? After a long time?



▲ FIGURE 32–33 Problem 78.

79. (II) Two solenoids are wound on a common soft iron core (Fig. 32–34). Solenoid S_1 is connected in series to a battery and a variable resistor. Starting with the resistor set at A (low resistance), the sliding contact is moved to B (large resistance) and back to A again. Sketch the voltage V across solenoid S_2 while this is happening.

▲ FIGURE 32–34 Problem 79.

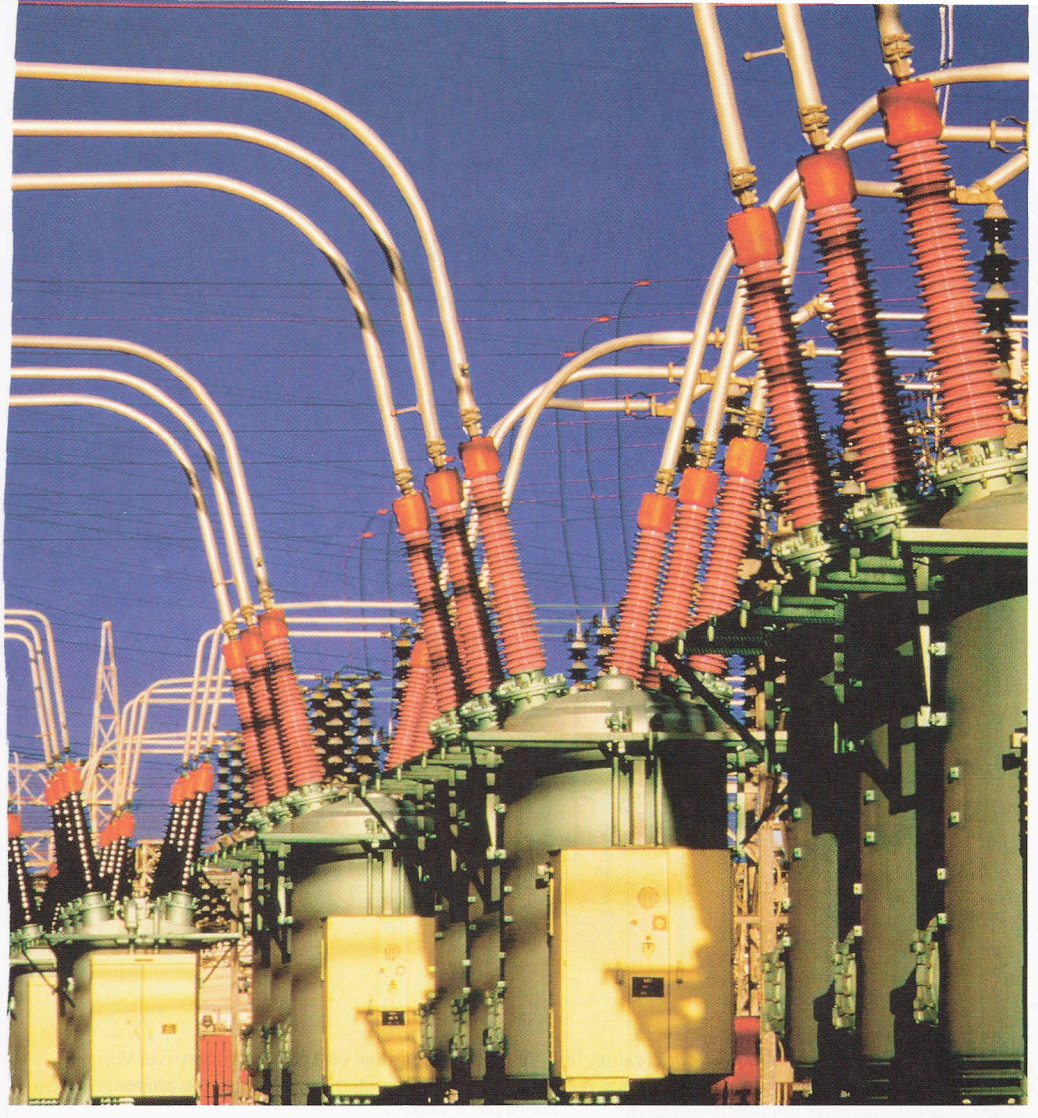


80. (II) The two identical coils in the circuit of Fig. 32–35 are placed close to each other, and their mutual inductance is 0.7 mH. Suppose that the switch has been closed for a long time and is then opened at $t = 0$. Calculate the current in the circuit at $t = 18$ ms.

▲ FIGURE 32–35 Problem 80.

81. (II) A ferromagnetic torus is part of a device to be used in a region where the magnetic permeability has the constant value $\mu = 2500\mu_0$. The torus has a circular cross section of 4 cm^2. Over its total length of approximately 35 cm, the torus is wrapped with 220 turns of wire. Immediately surrounding this winding is a secondary winding of 40 turns of (insulated) wire. What is the mutual inductance of the two windings? What is the role of the iron core, if any, in determining this mutual inductance?

82. (II) A torus of inner radius r_i and outer radius r_0 has a square cross section (Fig. 32–36). It is wound with N turns of wire that carries a current I. (a) Use Ampère's law to find the magnetic field inside the torus. (b) Calculate the magnetic energy density within the torus. (c) Integrate the magnetic energy density to find the total magnetic energy within the torus. (d) Use the formula $U_L = \frac{1}{2}LI^2$ to compute the self-inductance of this torus.



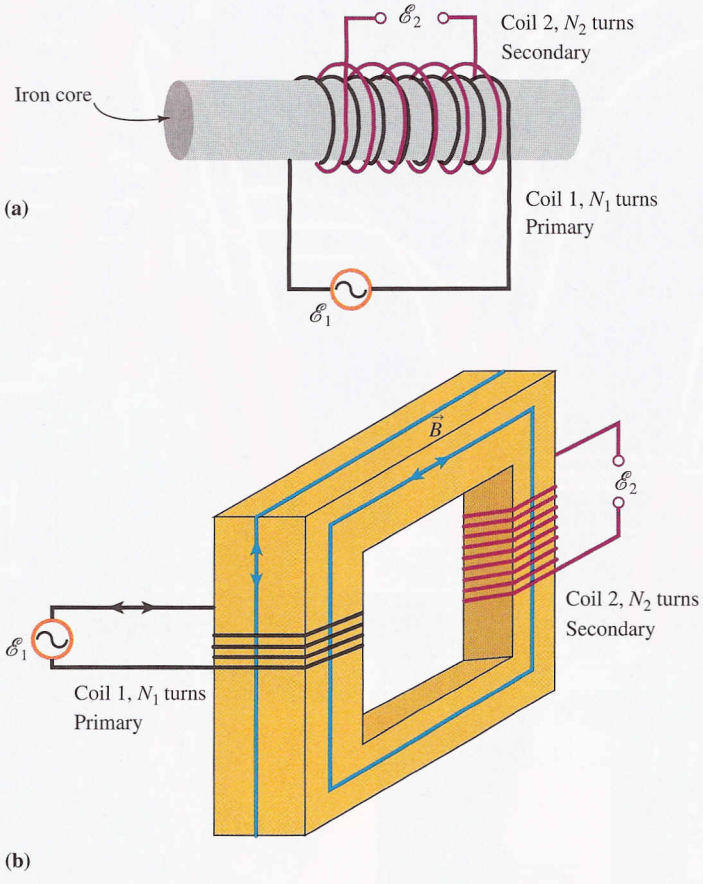
▲ FIGURE 32–36 Problem 82.

83. (II) An LC circuit oscillates with an angular frequency of 1.2×10^6 rad/s. When a second capacitor is inserted in series with the original one, the angular frequency becomes 1.6×10^6 rad/s. If the capacitors are replaced by a resistor of 0.02 Ω, the current drops to 1/2 of its initial value in 3.5 ms. What are the values of the two capacitors and of the inductance L?

84. (III) Consider two adjacent circuits as shown in Fig. 32–2. Show that the total energy is given by $U = \frac{1}{2}L_1I_1^2 + \frac{1}{2}L_2I_2^2 + MI_1I_2$ and that $M \leq (L_1L_2)^{1/2}$.

Chapter 33

This bank of transformers at an electricity substation forms a crucial part of the electricity distribution system. Transformers use Faraday's law to raise or lower the amplitude of time-varying voltages, allowing electrical energy to be transported efficiently at high voltages and consumed at safer low voltages.



Alternating Currents

In Chapter 30 we learned how a changing magnetic flux induces an emf—Faraday's law. In particular, when a coil rotates in the presence of a magnet, an emf is induced in the coil that varies sinusoidally with time. The induced emf produces an alternating current (AC), which is a source of AC power. AC generators use induction to convert the mechanical energy of falling water or the pressure of hot steam into electric currents that vary with time. Such generators are the starting point for the delivery of electric power to home and industry. Alternating current circuits are at the heart of most household equipment, and alternating current flows every time you switch on a light. The ability to vary the maximum voltage of the harmonically oscillating emf that AC power provides is an important element in the delivery of electric power, and learning how to do this is one of our aims here. AC sources of emf in circuits that include resistors, inductors, and capacitors provide currents and voltages with new types of time-dependent behavior. In particular, such circuits exhibit the same kinds of resonance phenomena that we saw in mechanics and are the basis for devices like radio tuners.

33–1 Transformers

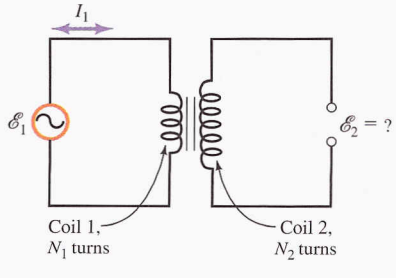
An alternating current is characterized by harmonic (sine and cosine) time dependence, as are the other variables of the circuit, such as voltages[†]. The possibility of being able to vary the maximum AC voltage (the *voltage amplitude*) is of interest because high or

[†]"AC" stands for any kind of current or voltage that varies harmonically in time.

▲ **FIGURE 33–1** Two methods for creating fully linked coils: (a) one coil tightly wound over the other; (b) two coils wrapped around a common core of ferromagnetic material, which has the property of keeping the magnetic field lines within it.

low voltages are useful in differing circumstances. For example, it is more economical to transport electric energy at high voltage (see the "Think About This" box on p. 920). High voltages, however, are dangerous, as well as inefficient in small appliances.

Let's suppose that an AC generator produces an emf of the general form



$$\mathscr{E} = V_0 \sin \omega t \tag{33–1}$$

[see Eq. (30–14)]. The factor V_0 is the voltage amplitude of the source of emf, and this is the quantity we want to vary. In this section we describe a device that can take an AC emf as input and produce another AC emf with a *different* voltage amplitude. This device is called a **transformer**, and it is constructed using the principle of mutual inductance.

Consider two fully linked ideal solenoids. We can arrange this in either of the two ways shown in Fig. 33–1. What we mean by "fully linked" is that the magnetic flux through one turn is equal to the magnetic flux through one turn in the other. The solenoids have a different total number of turns: N_1 and N_2, respectively. Across the first coil—the *primary coil*—there is an AC emf $\mathscr{E}$ with an amplitude V_0, as in Eq. (33–1):

$$\mathscr{E} = V_0 \sin \omega t. \tag{33–2}$$

This emf is changing with time, and you can see from Fig. 33–2 that the voltage drop $V_1(t) = V_{10} \sin \omega_1 t$ across the full primary coil has exactly the same form as Eq. (33–2). The source of this potential is Faraday's law, and this law tells us that the voltage drop across *each turn* is proportional to the rate of change of the flux through the primary coil. It is irrelevant for our purposes that this proportionality has something to do with the self-inductance of the coil; the only thing that matters is that the voltage per turn, V_1/N_1, across the primary coil is proportional to this change in flux. Now, since the coils are fully linked, we see that the voltage across *each turn* of the secondary coil is proportional in exactly the same way to the rate of change of the magnetic flux.

▲ **FIGURE 33–2** Schematic circuit-diagram symbol for two fully linked coils. When one coil is in the same circuit with an AC source of emf, this combination acts as a transformer.

The voltage drop across *each turn* of the secondary coil is thus identical to the voltage drop across each turn of the primary. We learn two things. First, the time dependence of the voltage across the secondary coil is exactly the same as the time dependence of the voltage across the primary coil. Thus the voltage across the secondary coil is $V_2(t) = V_{20} \sin \omega_2 t$, and the time dependence of the voltage across both coils is identical:

$$\omega_1 = \omega_2 = \omega. \tag{33–3}$$

The second thing we learn is a relation between the voltage *amplitudes* in the two coils. We have argued that

$$V_1(t)/N_1 = V_2(t)/N_2, \tag{33–4}$$

RATIO OF VOLTAGES IN A TRANSFORMER

and when we cancel the identical time-dependent factors sin ωt, we are left with $V_{10}/N_1 = V_{20}/N_2$ or, rearranging,

$$\frac{V_{20}}{V_{10}} = \frac{N_2}{N_1}. \tag{33–5}$$

The two-solenoid device we have described is a transformer, a tool for manipulating voltage amplitudes. Transformers find use throughout the power distribution network, and you have no doubt frequently used them for your electronic tools, which may require voltage amplitudes a good deal less than the 120-V or 220-V voltages supplied by a wall plug.

We see from Eq. (33–5) that when the number of turns on the secondary coil is greater than the number of turns on the primary coil ($N_2 > N_1$), the transformer is a *step-up transformer*, and the voltage amplitude in the secondary coil is greater than that in the primary coil. When $N_2 < N_1$, the transformer is a *step-down transformer*; the voltage amplitude in the secondary coil is smaller than that in the primary coil. Note that the terms primary and secondary do not imply any fundamental distinction between the two coils, and either coil could be primary or secondary according to the application.

CONCEPTUAL EXAMPLE 33–1 Assuming that resistance has been reduced to a minimum, how could you use the power associated with an inductor to find an expression for the ratio of currents in the primary and secondary coils of a transformer?

Answer The meaning of the resistance being reduced to a minimum is that there is minimal energy loss to Joule heating—we can ideally assume this to be zero—and any energy flow into or out of the primary coil will be matched by an energy flow out of the secondary coil. The power, or rate of energy flow, in an inductor is given by the product IV. Thus the equality $I_1V_1 = I_2V_2$ can be used to find the ratio of currents in terms of the ratio of emfs, and Eq. (33–4) gives us the latter quantity in terms of the number of turns in each solenoid when the solenoids are fully linked.

Conceptual Example 33–1 shows us how we can find the ratio of currents in the two coils in terms of their numbers of turns: Assuming insignificant losses to Joule heating, conservation of energy gives us $I_1V_1 = I_2V_2$. Rearrangement gives $I_1/I_2 = V_2/V_1$, and then use of Eq. (33–4) implies

$$\frac{I_1}{I_2} = \frac{N_2}{N_1}. \tag{33–6}$$

RATIO OF CURRENTS IN A TRANSFORMER

In other words, the current amplitude in the secondary coil of a step-up transformer ($N_2 > N_1$) is decreased, while it is increased in the secondary coil of a step-down transformer ($N_2 < N_1$). We should add here that when there is resistance in the secondary coil or in the circuit of which the secondary coil is a part—we say that there is a *load* on the secondary coil—then things are more complicated, with the inductances playing an explicit role.

EXAMPLE 33–2 A step-down transformer has 5,000 turns in the primary coil, which handles an AC current with voltage amplitude $V_{10} = 20{,}000$V, and 220 turns in the secondary coil. If the current amplitude desired in the secondary coil is 100 A, what is the maximum power that must be delivered by the primary coil to the secondary coil? Assume negligible resistance.

Setting It Up Imagine a transformer similar to those shown in Fig. 33–1. We know the number of turns of wire, N_1 and N_2 respectively, in both the primary and secondary coils.

Strategy We must find the power P_2 delivered to the secondary coil. Maximum power is related to the unknown voltage amplitude V_{20} and to the known current amplitude I_{20} by the relation $P_{2,\,\max} = I_{20}V_{20}$. (This is actually true only when the load is zero, i.e. when there is no resistance. We'll assume this to be the case here.) We can find V_{20} from the known V_{10} and the known numbers of turns using Eq. (33–5).

Working It Out From Eq. (33–5),

$$V_{20} = \frac{N_2}{N_1}V_{10} = \frac{220}{5{,}000}(20{,}000\text{ V}) = 880\text{ V}.$$

With the maximum current I_{20} carried by the secondary coil at 100 A, the maximum power that it carries is $P_{2,\,\max} = (100\text{ A})(880\text{ V}) = 88$ kW. With negligible resistance, this is equal to the maximum power carried in the primary coil.

What Do You Think? Must the currents in the primary and secondary coils be wound in the same direction for a transformer to work? *Answers to* ***What Do You Think?*** *questions are given in the back of the book.*

THINK ABOUT THIS. . .

WHY IS ELECTRIC POWER TRANSMITTED ALONG HIGH-VOLTAGE LINES?

The long-distance transmission lines that bring power from generating plants to users carry AC with a voltage amplitude as high as $V = 1.0$ MV. (Compare this to the 160-V amplitude—rms 110 V—for typical appliance use.) Why such high voltages? If we label the rate of energy delivery as P, then the current that runs through these lines can be characterized according to $P = IV$. (We are ignoring the "alternating" aspect here—this doesn't have much effect on our argument.) On the way, some of this power will be dissipated as Joule heating. This depends on the resistance, R, of the transmission line—the power dissipated, or lost, in the line will be $P_{\text{lost}} = I^2R = P^2R/V^2$. Now a measure of the efficiency of transmission is the ratio of the power delivered to the power lost in Joule heating—one would want this ratio to be as large as possible. Using our expressions for P and P_{lost},

$$\frac{P}{P_{\text{lost}}} = \frac{V^2}{PR}. \qquad (33\text{–}7)$$

This ratio increases rapidly as V increases, and that is why it is best to deliver the power at as high a voltage as possible. For example, a transmission line delivering power $P = 1.0$ MW may have a total resistance of 10 Ω. If the power is delivered at 110 V, the ratio in Eq. (33–7) would be intolerably low: $(110\text{ V})^2/(1.0\text{ MW})(10\ \Omega) = 1.2 \times 10^{-3}$; 99.9 percent of the electrical power that set off from the generating plant would be lost through Joule heating in the wires! If the power is delivered at 500,000 V, the ratio is $(500{,}000\text{ V})^2/(1.0\text{ MW})(10\ \Omega) = 2.5 \times 10^4$, and nearly all of the electric energy produced is delivered to the end of the line. Then transformers can reduce the voltage amplitude and make the energy safe to use.

In addition to their ubiquitous use in power transmission and distribution, and their role in allowing electronic instruments to take their power from a wall socket, transformers are crucial to the operation of every automobile. The spark that is fired by a spark plug and ignites gasoline in an automobile cylinder requires a very high potential difference between the elements of a spark plug. However, the voltage differences supplied by the automobile battery or alternator are much more modest—the battery maintains 12 V DC, for example. The spark coil is the device that makes the large potential. The coil contains a secondary coil with a large number of windings. When the current in a primary coil is interrupted suddenly, by either mechanical or electronic means, the large change in flux induces a potential difference across the secondary coil that is large enough to cause a spark to form. Timing devices ensure that the potential is set up at the right time for the engine operation.

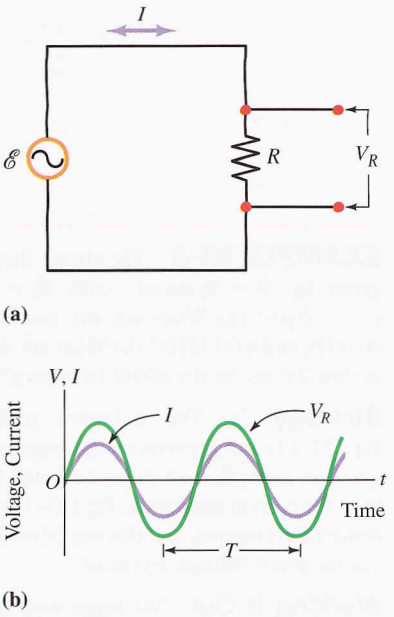
33–2 Single Elements in AC Circuits

We now turn to the question of how AC is used in circuits. We start with an examination of the effects of placing an AC source of emf, for which

$$\mathcal{E} = V_0 \sin \omega t,$$

in a circuit containing only a single resistor, capacitor, or inductor.

Resistive Circuit



We begin with the resistive circuit shown in Fig. 33–3a. The loop rule for the potential change around the circuit is

$$V_0 \sin \omega t - IR = 0. \tag{33–8}$$

The voltage across the resistor is then $V_R = IR = V_0 \sin(\omega t)$, and the current I through the resistor is

$$I = \frac{V_R}{R} = \frac{V_0 \sin(\omega t)}{R}. \tag{33–9}$$

The current through the resistor and the voltage across the resistor have the same sinusoidal time dependence (Fig. 33–3b). With peaks and valleys that occur at the same time, we say that the current and the voltage are *in phase*. The current amplitude is $I_{\max} = V_0/R$.

▲ **FIGURE 33–3** (a) A resistor connected in series with an AC source of emf. (b) The voltage across the resistor and the current through it are in phase. T is the period of the oscillation.

Capacitive Circuit

We now place the AC emf across a pure capacitance in the circuit, so that the voltage across the capacitor is $V_C = V_0 \sin(\omega t)$ (Fig. 33–4a). To find the current in the circuit, we apply the loop rule:

$$V_0 \sin(\omega t) - \frac{Q}{C} = 0. \tag{33–10}$$

This expression gives us the charge Q on the capacitor,

$$Q = CV_0 \sin \omega t. \tag{33–11}$$

The current is then the time derivative of the charge:

$$I = \frac{dQ}{dt} = \omega CV_0 \cos(\omega t). \tag{33–12}$$

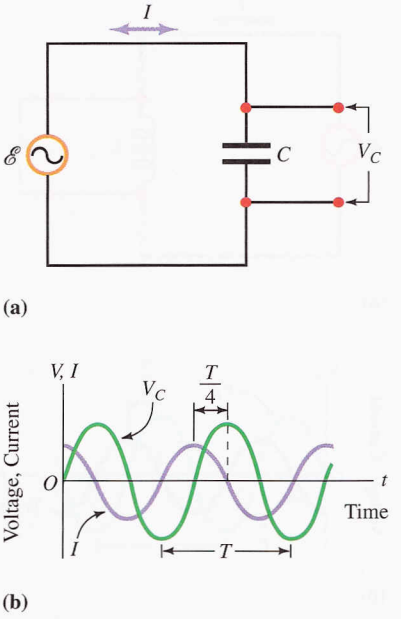
With the aid of the identity $\sin[\theta + (\pi/2)] = \cos\theta$, Eq. (33–12) becomes

$$I = \omega CV_0 \sin\left(\omega t + \frac{\pi}{2}\right). \tag{33–13}$$

The current amplitude in this circuit is

$$I_{\max} = \omega CV_0. \tag{33–14}$$

We can compare this equation to a similar equation for the resistive circuit, for which the corresponding relation was $I_{\max} = V_0/R$. The *effective resistance* for a capacitive circuit is called the **capacitive reactance**, X_C, defined by



$$X_C \equiv \frac{1}{\omega C}. \tag{33–15}$$

Equation (33–14) now takes the form

$$I_{\max} = \frac{V_0}{X_C}. \tag{33–16}$$

The capacitive reactance has units of ohms.

For this circuit, the effective resistance to current flow *decreases* at higher frequencies. This is physically reasonable because a high frequency means that the voltage and current are changing rapidly, and for very rapid oscillations the current must be large enough to allow the charge on the capacitor to build rapidly and thereby oppose the driving emf. In other words, the current grows with frequency. On the other hand, a low frequency means an almost constant current, and no constant current can pass through the wires leading to a capacitor. Once enough charge has been deposited on the plates, there is a large enough potential difference to stop a *steady* current. To repeat this in another way, keep in mind that while current never actually flows across the capacitor, current can flow in the wires leading to and from the capacitor plates as the charge builds up or

▲ **FIGURE 33–4** (a) A capacitor connected in series with an AC source of emf. (b) The current in the circuit leads the voltage across the capacitor by 90°.

flows off the plates. A steady current in the wires would mean an unlimited buildup of charge on the plates—an impossibility.

In Fig. 33–4b, we plot the current I and the voltage V_C versus time. The voltage across the capacitor is zero at time $t = 0$, but the current in the circuit is at a maximum. The phase of the current differs by a quarter cycle, $\pi/2$ rad (90°), from that of the voltage, and we say that the current in the circuit *leads* the voltage across the capacitor by a phase $\pi/2$.

EXAMPLE 33–3 The circuit shown in Fig. 33–4a has an emf given by $\mathcal{E} = V_0 \sin \omega t$, with $V_0 = 6.0$ V, and a capacitance $C = 1.0\ \mu$F. (a) What are the peak currents for frequencies of 60.0 Hz and 6.00 MHz? (b) What are the currents I and voltages V_C at time 2.0 ms for the 60-Hz frequency?

Strategy (a) The unknown peak current is found from Eq. (33–14) and depends on the angular frequency. The angular frequencies ω for the two cases are found from $\omega = 2\pi f$. (b) Once we have the current amplitude, Eq. (33–13) gives us the full time dependence of the current, and this can be evaluated at any specific time, as can the given voltage, $V_0 \sin \omega t$.

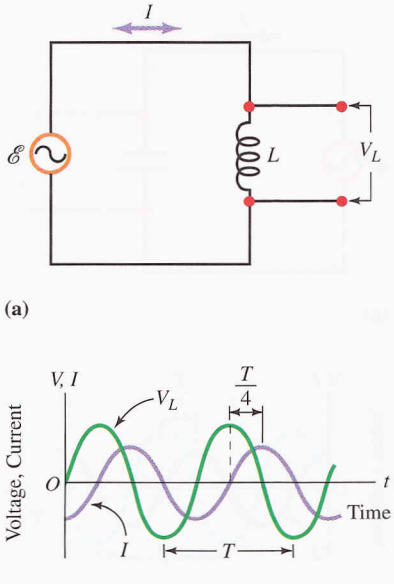
Working It Out We begin with the evaluation of the angular frequencies, $\omega = 2\pi(60.0\text{ Hz}) = 2\pi(60.0\text{ s}^{-1}) = 377$ rad/s and $2\pi(6.00 \times 10^6\text{ s}^{-1}) = 3.77 \times 10^7$ rad/s, respectively.

(a) From Eq. (33–14),

$$\text{for 60 Hz: } I_{\max} = (377\text{ rad/s})(1.0 \times 10^{-6}\text{ F})(6\text{ V}) = 2.3\text{ mA};$$
$$\text{for 6 MHz: } I_{\max} = (3.77 \times 10^7\text{ rad/s})(1.0 \times 10^{-6}\text{ F})(6\text{ V}) = 230\text{ A}.$$

The maximum current is proportional to the frequency.

(b) We evaluate Eqs. (33–13) and the input voltage $V_0 \sin \omega t$ at 2.0 ms. For $f = 60$ Hz, we have $I_0 = 2.3$ mA, $\phi = \pi/2$ rad, $V_0 = 6.0$ V, and $\omega = 377$ rad/s. Thus



$$I(t = 2.0\text{ s}) = (2.3\text{ mA}) \sin\left[(377\text{ rad/s})(0.0020\text{ s}) + \frac{\pi}{2}\right] = 1.7\text{ mA},$$

and

$$V_C(t = 2.0\text{ s}) = (6.0\text{ V}) \sin[(377\text{ rad/s})(0.0020\text{ s})] = 4.1\text{ V}.$$

By $t = 2.0$ ms, the current is coming down from its peak toward zero, while the voltage is rising toward its peak. At $t = 2.0$ ms, they are both about 70 percent of their peak values.

What Do You Think? Why does the higher frequency make such a big difference in the maximum current?

▲ **FIGURE 33–5** (a) An inductor connected in series with an AC source of emf. (b) The current in the circuit lags the voltage across the inductor by 90°.

Inductive Circuit

Repeating the previous procedure for the circuit in Fig. 33–5a, which contains a single inductor, we first note that the voltage drop across the inductor is the emf $V_L = V_0 \sin \omega t$. For the current, we apply the loop rule to the potentials around the circuit:

$$V_0 \sin \omega t - L\frac{dI}{dt} = 0. \tag{33–17}$$

This gives us dI/dt in terms of known quantities; to find I itself, we integrate over time:

$$I(t) = \int^t \frac{dI}{dt'}\,dt' = \frac{V_0}{L}\int^t \sin(\omega t')\,dt' = -\frac{V_0}{\omega L}\cos \omega t + \text{a constant}.$$

The constant must equal zero, because there is no constant emf to drive a constant current term. We now use the trigonometric identity $\cos\theta = -\sin[\theta - (\pi/2)]$ (Appendix IV–4) to rewrite our equation as

$$I = \frac{V_0}{\omega L}\sin\left(\omega t - \frac{\pi}{2}\right). \tag{33–18}$$

The maximum current through the inductor, or current amplitude, is

$$I_{\max} = \frac{V_0}{\omega L}. \tag{33–19}$$

If we compare our expressions for $I_{\max}$ with the similar one from the purely resistive circuit, $I_{\max} = V_0/R$, we see that the effective resistance for an inductive circuit is ωL. We call this the **inductive reactance**, defined by

$$X_L \equiv \omega L. \tag{33–20}$$

The inductive reactance has units of ohms.

For this circuit the effective resistance to current flow *increases* at higher frequencies. This is physically reasonable because inductors react to oppose any *change* in the current flow through them. The more rapidly the current is changing, the larger the opposing induced emf. On the other hand, the inductor is transparent to the unchanging current that corresponds to the limit $\omega = 0$.

We plot the current and voltage of the inductor versus time in Fig. 33–5b. As for the capacitive circuit, one sinusoidal curve is displaced from the other by a quarter cycle, although the role of the current and voltage curves is reversed in the two cases. This time the current in the circuit *lags* the voltage across the inductor.

EXAMPLE 33–4 Use the parameters of Example 33–3, but replace the capacitor with an inductor of inductance $L = 1.00$ mH. Calculate the inductive reactances.

Strategy We simply evaluate Eq. (33–20) to determine the inductive reactances. We have evaluated the angular frequencies in Example 33–3.

Working It Out The inductive reactances are

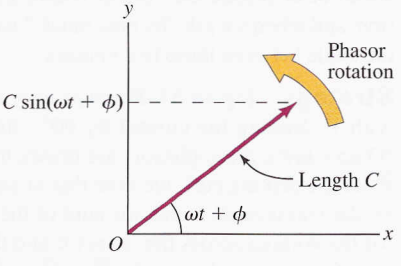
for 60.0 Hz:

$$X_L = \omega L = (377 \text{ rad/s})(1.00 \times 10^{-3} \text{ H}) = 0.377\ \Omega;$$

for 6.00 MHz:

$$X_L = \omega L = (3.77 \times 10^7 \text{ rad/s})(1.00 \times 10^{-3} \text{ H}) = 3.77 \times 10^4\ \Omega.$$

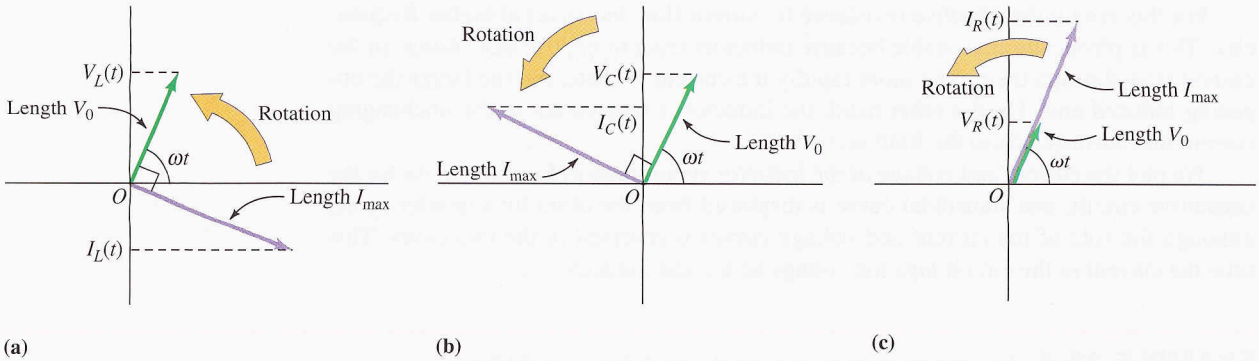
What Do You Think? A capacitor acts as an open switch when there is no time dependence in the current. Under what conditions does the inductor act as an open switch?



*Some Mathematical Devices

Two techniques simplify the treatment of circuits with time dependence. We treat them each here in abbreviated and optional form—in particular, we refer to time dependence with a single frequency. Further study in electrical engineering will involve one or the other of these techniques in more detail than we can supply here. The first involves **phasors**, which make it easier to follow phases by graphically summarizing phase and amplitude relations in AC circuits. The second, **complex analysis**, is a powerful tool that working engineers use a great deal. It simplifies all aspects of circuit analysis problems with time dependence.

Phasors: Any quantity in an AC circuit (or in any other problem) that has harmonic time dependence can be associated with a rotating vector known as a phasor. Thus for the function



$$f(t) = f_0 \sin(\omega t + \phi), \tag{33–21}$$

we define the phasor as follows: The phasor lies in the xy-plane with its tail fixed at the origin, and its length is the function amplitude, f_0. The time dependence is described by a counterclockwise rotation of the phasor with angular speed ω such that the function $f(t)$ itself is the instantaneous projection of the phasor on the y-axis (Fig. 33–6). For an alternating current, the length of the phasor represents the amplitude of the voltage or current, with its angular speed given by the angular frequency of the alternating current. For example, the function $V(t) = V_0 \sin \omega t$ has a phasor that starts at $t = 0$ aligned with the positive x-axis. As time increases and the phasor rotates counterclockwise, the y-component of the phasor increases until it reaches a maximum when $\omega t = \pi/2$. The y-component then decreases as the phasor moves into the second quadrant.

▲ **FIGURE 33–6** The projection of the phasor on the y-axis gives the value of the associated harmonic function.

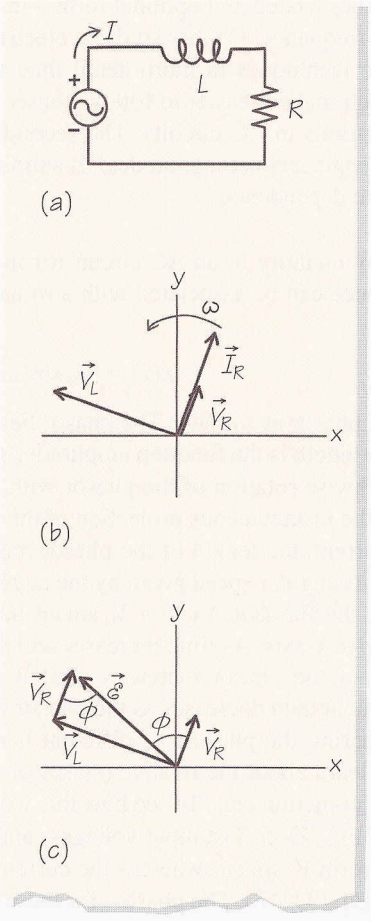
By comparing the phasors of different harmonic functions that appear in an AC problem, we learn about the relative phases of these functions; that is, which function leads or which function lags. To see how this works, let's apply it to the purely inductive AC circuit of Fig. 33–5. The input voltage—and hence the voltage V_L across the inductor—has the form $V_0 \sin \omega t$, whereas the current I_L takes the form $I_{\max} \sin(\omega t - \pi/2)$ according to Eq. (33–18). The phasors for these two quantities (Fig. 33–7a) rotate in the counterclockwise sense as time advances; the phasor for the voltage is always ahead of the phasor for the current. In this diagram, the idea that the voltage *leads* the current for the inductive circuit is easy to visualize and understand. We can easily perform the same exercise for the purely capacitive and purely resistive circuits, whose phasor diagrams are shown in Fig. 33–7b and 33–7c, respectively. Again, we see the phase relationship

▲ **FIGURE 33–7** Phasors associated with the voltage across and current through (a) the inductor; (b) the capacitor; and (c) the resistor of an *RLC* circuit.

clearly in these phasor diagrams: The voltage across the capacitor in the purely capacitive AC circuit lags the current, and the corresponding current and voltage are in phase in the purely resistive circuit.

When elements are combined in certain AC circuits, the phasors combine as vectors, and this can simplify the analysis of these circuits. This is one way of treating the series *RLC* circuit to be discussed in Section 33–3. Here we content ourselves with a brief example.

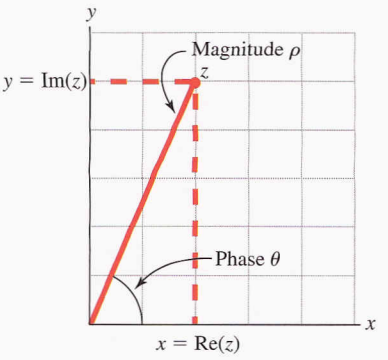
EXAMPLE 33–5 Consider an AC circuit with a driving emf $V_0 \sin \omega t$, an inductor of inductance L, and a resistor of resistance R in series. Does the driving voltage lead or lag the current, and by what amount?



Setting It Up Our circuit diagram (Fig. 33–8a) is accompanied by a phasor diagram (Fig. 33–8b) that specifies the voltages across the elements. In accordance with the discussion above, the projection on the y-axis of the respective phasors $\vec{V}_L$, $\vec{V}_R$, and $\vec{I}$ represents the real values of the corresponding physical quantities. (Note that here the overarrow refers to the fact that the phasor is a rotating vector, not to any new "vector" properties of potential or current.) We also note here what is being asked: When we say that the driving voltage leads or lags the current, we want to know whether its phasor is ahead of or behind the current phasor in its counterclockwise rotation, and when we ask "by how much," we are asking for the value of the angle between these two phasors.

Strategy Figure 33–8b gives only the phasors $\vec{V}_L$, $\vec{V}_R$, and $\vec{I}$, with $\vec{V}_L$ leading the current by 90°. Since $\vec{V}_R$ and $\vec{I}$ are in phase (Ohm's law), these phasors are drawn together. To find the phasor $\vec{\mathcal{E}}$ for the driving emf, we note that at any given time its projection on the y-axis must match the sum of the projections of the phasors for the voltage across the inductor and the resistor. This is guaranteed for vectors if we take $\vec{\mathcal{E}} = \vec{V}_L + \vec{V}_R$. Thus graphical vector addition will give us the phasor for the driving emf; simple geometry will give us its angular location relative to the current.

Working It Out Figure 33–8c shows the required addition of the phasors. We see from the figure that the driving emf leads the current and that the angle between them is determined by



$$\tan \phi = \frac{V_L}{V_R} = \frac{IX_L}{IR} = \frac{X_L}{R}.$$

The angle ϕ is less than 90°, as we can see most easily from Fig. 33–8c.

▲ **FIGURE 33–8** (a) A series *RL* circuit. (b) Phasor diagram of the current, voltage across the resistor, and voltage across the inductor. (c) The phasor for the driving emf is the sum of the phasors for voltage across the elements R and L.

Complex Analysis: Complex analysis is a powerful technique that is the working engineer's basic tool for the analysis of circuits with time dependence. Complex analysis depends on two ideas. The first is that a *complex variable* z can represent two physical quantities through the two variables x and y. This is accomplished through the use of $i \equiv \sqrt{-1}$; z is then given the form $z = x + iy$. x and y are extracted from z by taking the real and imaginary parts of z—just the coefficients of i^0 and i^1, respectively. We say that $x = \text{Re}(z)$ and $y = \text{Im}(z)$. (Higher powers of i, which may appear through algebraic manipulation, reduce to i^0 or i^1; for example, $i^2 = -1 = -i^0$.) In Fig. 33–9, we locate z on the xy-plane. You can see that if we think of z as a vector, then it is just the phasor that we spoke of above. But the general use of complex variables is more algebraic than pictorial.

▲ **FIGURE 33–9** A complex number z is characterized either by its real and imaginary parts, x and y, respectively, or by a magnitude and phase, ρ and θ, respectively.

The second idea of complex analysis is one of the most remarkable relations in mathematics:

$$e^{i\theta} = \cos\theta + i \sin\theta.$$

This result follows from the series expansions of the sine, the cosine, and the exponential. Using this identity, we can write an input voltage like that of Eq. (33–1) as

$$V_0 \sin \omega t = \text{Im}(V_0 e^{i\omega t}),$$

where $\text{Im}(z)$ is the imaginary part of z, that is, the coefficient of i in the expression for z. We then represent all oscillating functions—currents, or potentials across individual elements—as exponentials rather than as sines or cosines, including possible phases. At the end, we take the imaginary part of the complex quantity that we have calculated. Using the relation $e^{i\theta} = \cos\theta + i \sin\theta$, one additional representation of z is useful in the procedure, namely

$$z = x + iy = \rho e^{i\theta},$$

where $\rho = \sqrt{x^2 + y^2}$ and $\tan\theta = y/x$. We refer to ρ as the magnitude of z and to θ as the phase of z. Figure 33–9 labels these alternative variables and makes clear the relation between (x, y) and (ρ, θ).

What is the advantage of this procedure? The answer is simple: Upon differentiation, exponentials remain exponentials. Therefore, the differential equations that describe the circuit behavior contain overall powers of exponentials that ultimately cancel. Accordingly, these differential equations reduce easily to algebraic equations, which are simpler to deal with. Problems 91 to 95 illustrate complex analysis. We present a simple example here.

EXAMPLE 33–6 Consider the AC circuit treated in Example 33–5: a driving emf $\mathcal{E} = V_0 \sin \omega t$ and an inductor and resistor in series. Find the current amplitude in the circuit as a function of V_0, R, L, and ω.

Strategy Let us use the subscript "C" to indicate complex quantities, and employ the rule that any physical quantity A is found from the imaginary part of its complex counterpart A_C: $A = \text{Im}(A_C)$. We therefore write the driving emf as $\mathcal{E}_C = V_0 \exp(i\omega t)$, as well as $I_C = I_0 \exp(i\omega t)$ for the current. We will want to use these expressions in the loop rule. We should find that after derivatives are taken, the loop rule becomes a very simple algebraic expression for I_0, the desired current amplitude.

Working It Out Referring to Fig. 33–8a, the loop rule reads $\mathcal{E}_C - L(dI_C/dt) - I_C R = 0$. With the explicit complex forms for $\mathcal{E}_C$ and I_C above, and with $\dfrac{d}{dt} e^{i\omega t} = i\omega e^{i\omega t}$, we have

$$V_0 \exp(i\omega t) - i\omega L I_0 \exp(i\omega t) - I_0 \exp(i\omega t) = 0.$$

The factor $\exp(i\omega t)$ cancels out, and we are left with an algebraic equation for I_0 whose solution is

$$I_0 = \frac{V_0}{R + i\omega L}, \quad \text{or} \quad I_C = \frac{V_0}{R + i\omega L} e^{i\omega t}.$$

We are asked to find the amplitude of the current; that is, a real quantity, the *magnitude* of I_C. But what is this magnitude? For that we write the combination $R + i\omega L$ that appears in the denominator of our expression for I_C as a magnitude and a phase:

$$R + i\omega L = \sqrt{R^2 + (\omega L)^2} \exp(i\phi),$$

so that

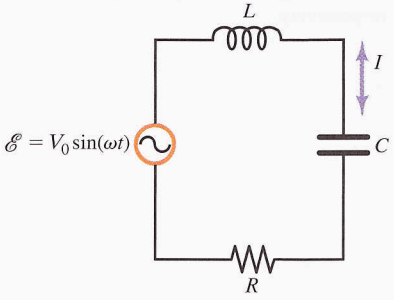
$$I_C = \frac{V_0 \exp(i\omega t - i\phi)}{\sqrt{R^2 + (\omega L)^2}}.$$

The magnitude of this quantity is the coefficient of the exponential, and that is the required relation. We have not written the phase explicitly, because that is not called for in the question. But we could have, and it would have given us the phase that was found in Example 33–5. The square root that appears in our answer is called the impedance—it plays the role of a resistance and will be discussed in more detail below.

The main thing to note here is the simplicity of the algebraic steps.

33–3 AC in Series *RLC* Circuits

In mechanics, a *driven harmonic oscillator* is a device in which a harmonic external force acts on, for example, a mass fixed to a spring. If the driving force has been acting for some time, the mass will move with the *driving frequency*—the angular frequency ω of the force—even though the mass is attached to a spring and undergoes some damping. As we saw in Section 13–8, this system illustrates the important physical phenomenon of *resonance*, characterized by a large amplitude motion when the driving frequency is near the natural frequency† ω_0, the frequency with which the mass would move if there were no driving force.



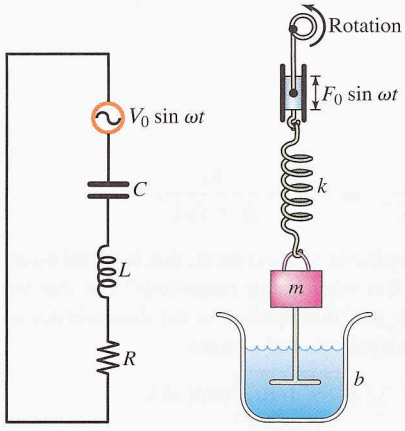
In Chapter 32, we noted the similarities between the damped mass-spring system and series *RLC* circuits without a driving term. If we add an AC source of emf to a series *RLC* circuit, the analogy is extended to a damped mass-spring system with a harmonic driving force. Using this analogy, we can expect such a circuit to exhibit *resonant behavior*.

Let us treat our circuit—the *RLC* circuit with an AC source of emf—more explicitly (Fig. 33–10). Applying the loop rule for the potential changes around the circuit gives

$$V_0 \sin \omega t - L\frac{dI}{dt} - \frac{Q}{C} - IR = 0. \tag{33–22}$$

Because $I = dQ/dt$, we can reexpress this result in terms of the single variable Q, the charge on the capacitor:

$$V_0 \sin \omega t - L\frac{d^2Q}{dt^2} - R\frac{dQ}{dt} - \frac{Q}{C} = 0. \tag{33–23}$$



▲ **FIGURE 33–10** An *RLC* circuit is driven by an AC emf.

The unknown quantity in this differential equation is Q, and the solution will give us Q as a function of time. Once we solve for Q, differentiation with respect to time will give the current. We can then find the voltage drops across the various circuit elements.

The analogy to the mechanical system is evident in the comparison between Eq. (33–23) and Eq. (13–52), which expresses Newton's second law for a driven harmonic oscillator with damping (Fig. 33–11). The equation for the mechanical system is rewritten here in the form

$$F_0 \sin \omega t - m\frac{d^2x}{dt^2} - b\frac{dx}{dt} - kx = 0, \tag{33–24}$$

where the first term is the driving force, with amplitude F_0. The structure of Eqs. (33–24) and (33–23) are identical, and once we recall the solution for the mechanical system, we can immediately make the substitutions summarized in Table 33–1 to find the solution for the driven *RLC* circuit. Now, as we described in Section 13–8, Eq. (33–24) for the

▲ **FIGURE 33–11** The *RLC* circuit and a damped mass-spring system are analogous. The analogies between the different elements of the two systems are understood in the vertical ordering of the elements.

TABLE 33–1 • Analogy Between Driven *RLC* Circuits and Driven Spring Motion

	Circuit	Mass–Spring
Variable	Charge Q	Position x
Coefficient of variable	$\frac{1}{C}$	k
Coefficient of $\frac{d(\text{variable})}{dt}$	R	b
Coefficient of $\frac{d^2(\text{variable})}{dt^2}$	L	m
Driving term	$V_0 \sin(\omega t)$	$F_0 \sin(\omega t)$
Natural frequency	$\frac{1}{\sqrt{LC}}$	$\sqrt{\frac{k}{m}}$

†When no confusion is possible, we use the term "frequency" rather than "angular frequency" for ω.

position $x(t)$ has a solution in which the position of the mass oscillates with the angular frequency of the driving force. This solution is given by Eq. (13–53); it is convenient to shift the phase of that solution and write it as

$$x = -A\cos(\omega t - \phi). \tag{33–25}$$

Not only is the frequency determined, but *the amplitude A and phase ϕ are also determined*. We find their values by direct substitution into the differential equation, with the results

$$A = \frac{F_0}{\sqrt{m^2(\omega^2 - \omega_0^2)^2 + b^2\omega^2}} \tag{33–26}$$

and

$$\tan\phi = \frac{1}{b}\left(\omega m - \frac{k}{\omega}\right). \tag{33–27}$$

Here, ω_0 is the natural frequency of the oscillator, given by $\omega_0 = \sqrt{k/m}$.

We also recall that for the mechanical oscillator, the force and the position are both harmonic with the same frequency but out of phase. For example, the function $\sin\omega t$—proportional to the force—rises from zero at $t = 0$, whereas the function $\cos(\omega t - \phi)$—proportional to the position—rises from zero when the argument of the cosine is $-90° = -\pi/2$ rad, that is, when $t = (\phi - \pi/2)/\omega$.

Now we can move on to the *RLC* circuit with an AC source of emf. The solution for the charge on the capacitor in the loop equation for this circuit [Eq. (33–23)] is found by making the formal substitutions of Table 33–1, which relates the parameters of the harmonic oscillator to the circuit parameters. The solution for the charge is

$$Q = -Q_{\max}\cos(\omega t - \phi) = -\frac{V_0}{\sqrt{L^2(\omega^2 - \omega_0^2)^2 + R^2\omega^2}}\cos(\omega t - \phi), \tag{33–28}$$

where $Q_{\max}$ is defined in comparing the second and third terms, and

$$\tan\phi = \frac{1}{R}\left(\omega L - \frac{1}{\omega C}\right). \tag{33–29}$$

The current is found from evaluation of dQ/dt:

$$I = \frac{dQ}{dt} = I_{\max}\sin(\omega t - \phi) = \frac{\omega V_0}{\sqrt{L^2(\omega^2 - \omega_0^2)^2 + R^2\omega^2}}\sin(\omega t - \phi). \tag{33–30}$$

Again $I_{\max}$ is directly defined here. Note that $I_{\max} = Q_{\max}\omega$.

As we would expect, all the results given here reduce to the cases we treated in Section 33–2, in which only one circuit element—the resistor, the capacitor, or the inductor—is present at a time. We need only replace the values of L, R, or $1/C$ by zero, as appropriate (keeping in mind that $\omega_0 = 1/\sqrt{LC}$).

When we dealt in Chapter 32 with *RLC* circuits without AC sources of emf, neither the amplitude nor the phase were determined; rather, they were a matter of initial conditions. What is different here? A clue is provided by the equation satisfied by the charge, Eq. (33–23). If the AC source is not present, then the equation is homogeneous in Q, meaning that if there is a solution for some charge, then a multiple of that charge is also a solution. The overall multiplicative constant would cancel from the equation. But once we add the AC emf, Eq. (33–23) is no longer homogeneous in Q, and the overall scale of Q is determined. The same reasoning applies to the phase, where without the AC source, any phase is possible. With the AC emf present, that emf "sets the clock" with its definite $\sin\omega t$ form that vanishes at $t = 0$, and the phase of the solution is no longer arbitrary. These remarks about amplitude and phase actually apply to long-time solutions—transient solutions do have properties set by initial conditions, but these solutions die away with time.

Impedance

We have already defined the reactances $X_L = \omega L$ and $X_C = 1/\omega C$ [Eqs. (33–15) and (33–20)]. They enter immediately into the phase [Eq. (33–29)] that appears in the driven *RLC* circuit according to

$$\tan\phi = \frac{1}{R}(X_L - X_C). \tag{33–31}$$

The reactances play the role of an effective resistance, dependent on frequency, for the single element circuits. As we shall see, the effective resistance of the *RLC* circuit is the **impedance** Z defined by

$$Z \equiv \sqrt{\left(\omega L - \frac{1}{\omega C}\right)^2 + R^2} = \sqrt{(X_L - X_C)^2 + R^2}. \tag{33–32}$$

The impedance has units of ohms.

In contrast to resistance, impedance depends on the frequency; we can understand this on physical grounds. Inductance opposes a change in current, and larger values of angular frequency mean more rapid changes in the current. However, an inductor is transparent to a static potential, corresponding to $\omega \to 0$. These properties are reflected in the frequency dependence of $X_L = \omega L$. A capacitor has just the opposite properties: No constant current can pass through a capacitor, but the capacitor has little effect when the current changes so rapidly that little charge can accumulate. These properties are reflected in the frequency dependence of $X_C = 1/\omega C$. The combination of the effects of both the inductance and the capacitance implies that the impedance is high in the limit of both large and small values of the frequency ω.

To see in more concrete terms how the impedance plays the role of a resistance, let's express the current in terms of it. It is a matter of a little algebra (see Problem 38) to show that, in terms of these quantities, the amplitude in Eq. (33–28) becomes $Q_{\max} = V_0/\omega Z$ and hence, with $I_{\max} = \omega Q_{\max}$, we have $I_{\max} = V_0/Z$. In other words,

$$I = I_{\max}\sin(\omega t - \phi) = \frac{V_0 \sin(\omega t - \phi)}{Z}. \tag{33–33}$$

The current takes the form of an AC emf divided by the impedance. This equation is analogous to the DC equation $I = V/R$. *Impedance thus plays the role of resistance in an AC circuit.* Note that $I_{\max} = V_0/Z$, but because of the phase, $I(t)$ is not generally equal to $V(t)/Z$.

EXAMPLE 33–7 The series *RLC* circuit in Fig. 33–10 is driven with an AC source of emf of the form $\mathcal{E} = V_0 \sin\omega t$, where V_0 is exactly 110 V and the frequency f is exactly 60 Hz. If $R = 20.0\ \Omega$, $L = 5.00 \times 10^{-2}$ H, and $C = 50.0\ \mu$F, find the potential drops across the inductor at $t = 0$ and at time t_1, the first time after $t = 0$ that $\mathcal{E}$ reaches a maximum.

Strategy We use $V_L = -L\,dI/dt$ to find the potential drop across the inductor, and utilize Eq. (33–33) for the current I in this circuit:

$$V_L = -L\frac{d}{dt}\left[\frac{V_0}{Z}\sin(\omega t - \phi)\right] = -\frac{LV_0\omega}{Z}\cos(\omega t - \phi).$$

This can easily be evaluated at $t = 0$. For the next part of the problem, we note that the first time after $t = 0$ that the source emf reaches a maximum is time t_1, determined by $\omega t_1 = \pi/2$, or

$$t_1 = \frac{\pi}{2\omega} = \frac{\pi}{4\pi f} = \frac{1}{4f}.$$

Again, V_L can be evaluated at this time.

Working It Out At $t = 0$, V_L takes the form

$$V_L = -\frac{LV_0\omega}{Z}\cos(-\phi) = -\frac{LV_0\omega}{Z}\cos\phi,$$

while at $t = t_1$ we have

$$V_L = -\frac{LV_0\omega}{Z}\cos\left(\frac{\omega}{4f} - \phi\right) = -\frac{LV_0\omega}{Z}\cos\left(\frac{\pi}{2} - \phi\right)$$
$$= -\frac{LV_0\omega}{Z}\sin\phi.$$

To evaluate these results numerically, note that $\omega = 2\pi(60\text{ Hz}) = 377$ rad/s. We insert the values of ω, R, L, and C to obtain $X_L = \omega L = 18.9\ \Omega$, $X_C = 1/\omega C = 53\ \Omega$, $Z = \sqrt{(X_L - X_C)^2 + R^2} = 39.6\ \Omega$, and $\tan\phi = -1.71$ [or $\phi = -1.04$ rad$(-59.7°)$]. Thus at $t = 0$,

$$V_L = -\frac{LV_0\omega}{Z}\cos\phi = -26.4\text{ V}.$$

At $t = t_1$,

$$V_L = -\frac{LV_0\omega}{Z}\sin\phi = 45.2\text{ V}.$$

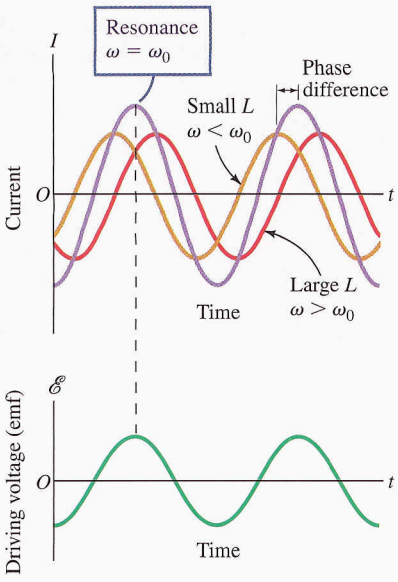
What Do You Think? At what time after t_1 will the voltage across the inductor first reach a negative maximum?

Resonance in Driven *RLC* Circuits

The current amplitude contained in Eq. (33–30) exhibits the phenomenon of resonance—as do the amplitude of the charge on a capacitor and the voltage amplitudes across any of the elements of a driven *RLC* circuit. The amplitudes are inversely proportional to the impedance. When Z is a minimum, these amplitudes reach a maximum—we say they are *peaked*, or *resonate*. This occurs when the driving frequency ω is at the undamped natural frequency ω_0, which as we know from Section 32–5 is given by $\omega_0^2 = 1/LC$ (Fig. 33–12). (This can be seen by setting the derivative of I_{max} with respect to ω equal to zero.) The amount and sharpness of the peaking depends on the damping factor, which is the resistance R. Without R, the amplitudes would be infinite when the driving frequency ω equals ω_0, something you can easily see from the form of the impedance, Eq. (33–32). However, there is always some resistance in real circuits. Figure 13–25 illustrates the resonance peak for several values of the damping parameter b of a mechanical oscillator. Similar plots apply to *RLC* circuits. The smaller the damping—the smaller the resistance—the larger and sharper the resonance peaks. The maximum in this peak occurs when $X_L = X_C$,

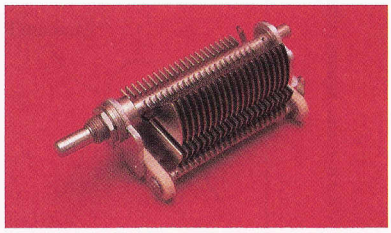
$$\omega L = \frac{1}{\omega C}.$$

This condition implies that



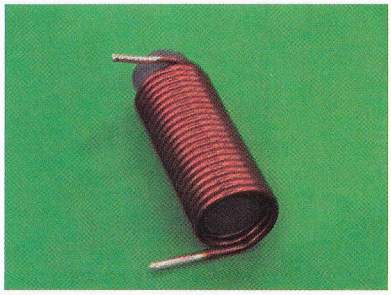
$$\omega^2 = \omega_0^2 = \frac{1}{LC}. \tag{33–34}$$

At this value of the angular frequency, $Z = R$. The current amplitude at this value of the driving frequency is given simply by



$$\text{at resonance: } I_{max} = \frac{V_0}{R}. \tag{33–35}$$

At resonance both *the maximum value of current amplitude and the sharpness of the resonance peak* increase as R decreases. It is useful to note one last feature: At resonance, the tangent of the phase [Eq. (33–29)], and hence the phase itself, is zero.



Resonance phenomena have many applications in circuits. The most familiar concern radio and television reception (Fig. 33–13). A receiver can be tuned by changing either an inductance or a capacitance, thus changing the resonant frequency. The receiver then preferentially picks up broadcast signals at that frequency.

▲ **FIGURE 33–12** Given the driving voltage shown, the current through an *RLC* circuit varies harmonically with the frequency of the driving voltage but differs from it in amplitude and phase in a way that depends on whether or not the driving frequency ω equals the undamped natural frequency ω_0. At resonance ($\omega = \omega_0$), the current amplitude is a maximum and the phase is that of the driving voltage. In the plot of current versus time, we have controlled the natural frequency by varying L.

(a)

(b)

▲ **FIGURE 33–13** Receiver tuners can be constructed by (a) rotating the overlapping areas of the plates to change the capacitance or by (b) moving an iron core in and out of a solenoid to vary the inductance.

33–4 Power in AC Circuits

Energy flows in an *RLC* circuit. The capacitor and inductor store this energy for some parts of the cycle and release it for others, but no energy is lost (dissipated) in these elements. Energy is, however, lost in the resistance of the circuit. The power dissipated in the circuit is accordingly

$$P = I^2R = \frac{[V_0 \sin(\omega t - \phi)]^2}{Z^2}R. \tag{33–36}$$

This power is always positive, oscillating between zero and a maximum of V_0^2R/Z^2. For engineering purposes, it is often sufficient to know the *average* power dissipated over time. Let's indicate time-averaged quantities with angle brackets, $\langle\ \rangle$. The average of a sine (or cosine) squared over one cycle is one-half:

$$\langle \sin^2(\omega t - \phi) \rangle = \frac{1}{2},$$

so

$$\langle P \rangle = \frac{V_0^2R}{Z^2}\langle \sin^2(\omega t - \phi) \rangle = \frac{1}{2}\frac{V_0^2R}{Z^2}. \tag{33–37}$$

If we substitute Eq. (33–32) for the impedance, we find an explicit form for the average power:

$$\langle P\rangle = \frac{1}{2}\frac{V_0^2 R}{[\omega L - (1/\omega C)]^2 + R^2} = \frac{1}{2}\frac{V_0^2 R\omega^2}{L^2(\omega^2 - \omega_0^2)^2 + \omega^2 R^2}. \quad (33\text{–}38)$$

The resonant behavior of AC circuits is evident in this result for the power dissipated—the denominator is smallest, and so the average dissipated power is largest, when the driving angular frequency ω is near the "natural" angular frequency $\omega_0 = \sqrt{1/LC}$. As the driving frequency ω increases through ω_0, the power dissipated has the typical peaked behavior of resonance. (We'll discuss this in more detail below around Fig. 33–14.) At resonance, the expression for power simplifies to

$$\langle P\rangle_{\text{res}} = \frac{1}{2}\frac{V_0^2}{R}. \quad (33\text{–}39)$$

The power displays the same resonant behavior as does the current.

Equation (33–33) shows that the current oscillates with time. Just as it is useful to characterize the power with average values, we can also work with an *rms (root mean square)* value for the current (and other harmonically varying quantities in AC). The rms value, x_{rms}, of any quantity x is defined as the square root of the time average of the square of that quantity:

$$x_{\text{rms}} \equiv \sqrt{\langle x^2\rangle}.$$

In particular, if x varies harmonically—if $x = x_0\cos(\omega t - \phi)$—we can use the fact that the time average of the cosine squared is one-half to show that

$$x_{\text{rms}} = \frac{x_0}{\sqrt{2}}. \quad (33\text{–}40)$$

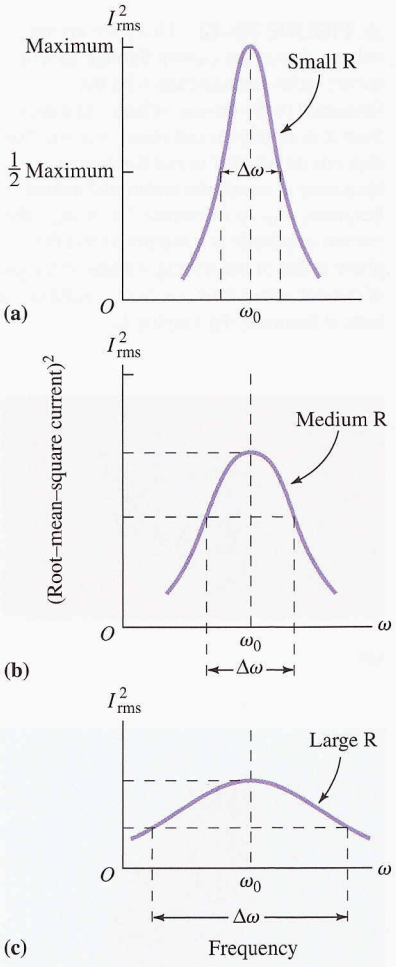
When we apply this concept to the AC current, we see from Eq. (33–33) that

$$I_{\text{rms}} = \frac{V_0}{(\sqrt{2})Z} = \sqrt{\frac{V_0^2\omega^2/2}{L^2(\omega^2 - \omega_0^2)^2 + \omega^2 R^2}}. \quad (33\text{–}41)$$

From Eq. (33–38), we can see that I_{rms} and the average dissipated power, $\langle P\rangle$, obey the same power–current relation that DC quantities obey, namely

$$\langle P\rangle = I_{\text{rms}}^2 R. \quad (33\text{–}42)$$

Figure 33–14 plots I_{rms}^2 as a function of the driving angular frequency ω for three values of resistance. The sharpness in the peak of the average power (or of I_{rms}^2) versus ω is characterized by the *width* of the peak or, more precisely, the *total width at half-maximum* $\Delta\omega$. This is commonly called the **bandwidth** in the context of AC. To calculate the bandwidth, we find the angular frequencies at which the power drops to half the peak value and take the difference between these angular frequencies. This calculation shows that, for small values of resistance, the bandwidth is given by



$$\Delta\omega = \frac{R}{L}. \quad (33\text{–}43)$$

The smaller the resistance and the larger the inductance, the smaller the bandwidth. We can understand the importance of a small bandwidth by thinking about a radio or television receiver whose tuning circuit depends on the resonance phenomenon. If the resonance is sharp, the receiver will more effectively pick out only the desired frequency over others nearby (Fig. 33–14a). Conversely, if the resonance is broad, the circuit will respond to frequencies in the AC signal far from the desired frequency (Fig. 33–14b, c).

Another measure of the sharpness is the ratio $\omega_0/\Delta\omega$. This quantity is defined as the *quality factor*, or *Q-factor*,

$$Q \equiv \frac{\omega_0}{\Delta\omega} = \frac{\omega_0 L}{R}. \quad (33\text{–}44)$$

This factor is often used by electrical engineers to represent the sharpness of a resonant circuit.

▲ **FIGURE 33–14** The rms current squared in a series *RLC* circuit with an AC source of emf such as the circuit of Fig. 33–10. (a) There is a resonance phenomenon when the driving frequency ω matches the natural frequency ω_0 of the circuit. The bandwidth $\Delta\omega$ measures the width of the rms current squared. (b, c) As R increases, the distribution of the current as a function of ω broadens.

EXAMPLE 33–8 Two FM radio stations broadcast at the same strength from the same nearby distance, one at a frequency of 91.3 MHz and the other at 91.1 MHz. You prefer the former broadcast over the latter, and you want to construct a simple series *RLC* circuit to act as a receiver that is unique to your favorite station. Given an inductor with an inductance L of exactly 1 μH and adjustable resistance and capacitance, what values should you choose for R and C in order to limit the power received from the unwanted station to 1 percent of the power received from the desired station?

Strategy There are two requirements for the R and C values in our circuit. First, it must be resonant at $\omega_0 = 2\pi f = 2\pi(91.3\text{ MHz}) = 5.74 \times 10^8\text{ s}^{-1}$, and second, the resonant peak must be sharp enough to limit the power from the station broadcasting at $\omega_1 = 2\pi(91.1\text{ MHz}) = 5.72 \times 10^8\text{ s}^{-1}$. The resonant frequency is determined from L and C alone; since the value of L is known, we use this to find C. The sharpness requirement determines R. The power delivered by the signal at resonance is given by Eq. (33–39), whereas the power delivered off resonance is given by Eq. (33–38).

Working It Out We use $\omega_0^2 = 1/LC$ to find C:

$$C = \frac{1}{\omega_0^2 L} = \frac{1}{(5.74 \times 10^8\text{ s}^{-1})^2(1\ \mu\text{H})} = 3.04 \times 10^{-12}\text{ F}.$$

For R, we look at the power delivered by the two stations. With signals arriving with the same strength, it is appropriate to use the same value of V_0. Thus

$$\frac{\langle P\rangle_{\omega_1}}{\langle P\rangle_{\text{res}}} = 0.01 = \left[\frac{1}{2}\left(\frac{V_0^2}{R}\right)\right]^{-1}\frac{1}{2}\frac{V_0^2 R\omega_1^2}{L^2(\omega_1^2 - \omega_0^2)^2 + \omega_1^2 R^2}$$
$$= \frac{R^2\omega_1^2}{L^2(\omega_1^2 - \omega_0^2)^2 + \omega_1^2 R^2}.$$

This gives

$$[L^2(\omega_1^2 - \omega_0^2)^2 + \omega_1^2 R^2](0.01) = R^2\omega_1^2.$$

To a good approximation, we can ignore $0.01\omega_1^2 R^2$ on the left compared to $\omega_1^2 R^2$ on the right. We then take the square root of both sides:

$$L(\omega_0^2 - \omega_1^2)(0.1) = L(\omega_0 - \omega_1)(\omega_0 + \omega_1)(0.1) = R\omega_1.$$

The factor $(\omega_0 + \omega_1)$ is, to a good approximation, equal to $2\omega_1$, so we have

$$2\omega_1 L(\omega_0 - \omega_1)(0.1) \cong R\omega_1.$$

Thus, canceling the factor ω_1,

$$R = 2L(\omega_0 - \omega_1)(0.1)$$
$$= 2(10^{-6}\text{ H})[(5.74 \times 10^8\text{ s}^{-1}) - (5.72 \times 10^8\text{ s}^{-1})](0.1)$$
$$= 0.4\ \Omega.$$

You can check with this value of R that our approximations were justified.

What Do You Think? Suppose instead of a factor 0.01 (1%), you wanted a "discrimination requirement" 100 times better, i.e. the power from the unwanted station is 0.0001 of that of the desired station. What value would you now choose for R?

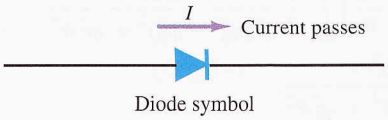
The Power Factor

The power in AC circuits is commonly given in a form other than that given in Eq. (33–38). We find this form with the aid of the trigonometric identity

$$\cos^2\phi = \frac{1}{\tan^2\phi + 1}.$$

If we now use Eq. (33–31) for $\tan\phi$, we find that

$$\cos^2\phi = \frac{1}{[(1/R)(X_L - X_C)]^2 + 1} = \frac{R^2}{(X_L - X_C)^2 + R^2} = \frac{R^2}{Z^2};$$
$$\cos\phi = \frac{R}{Z}. \qquad (33\text{–}45)$$



Then, using Eqs. (33–41) and (33–43), we see that Eq. (33–42) becomes

$$\langle P\rangle = I_{\text{rms}}^2 R = I_{\text{rms}}^2 Z\cos\phi. \qquad (33\text{–}46)$$

The term $\cos\phi$ in Eq. (33–46) is called the *power factor*. For a circuit without resistance, it is zero, whereas for a pure resistance it is a maximum, with a value of one.

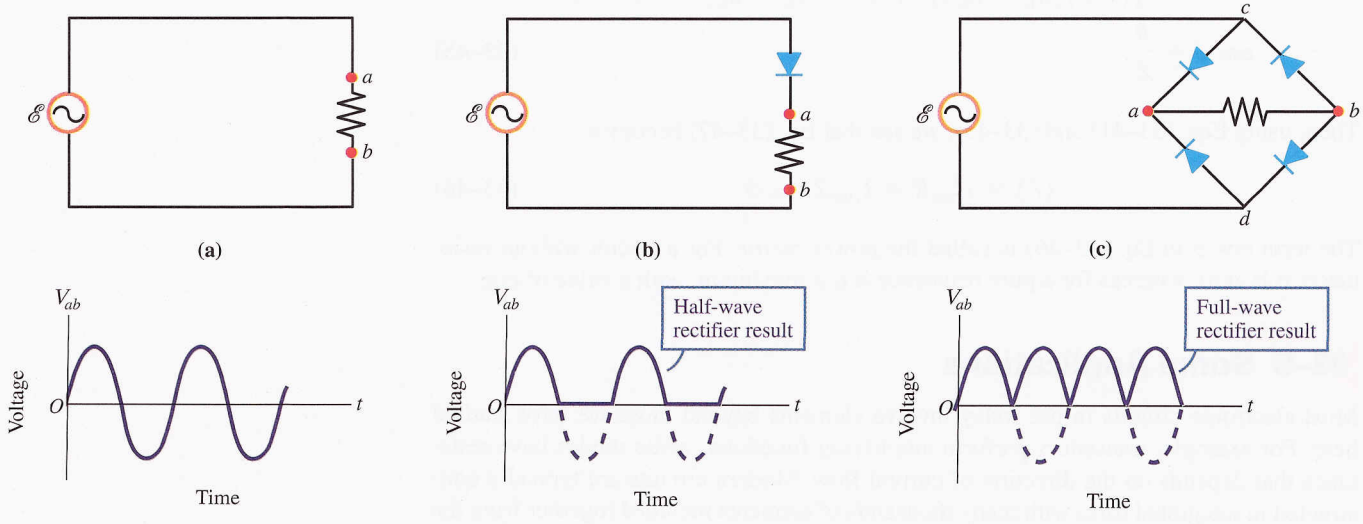
33–5 Some Applications

Most electronic circuits in use today involve elements beyond those we have studied here. For example, transistors perform amplifying functions, while diodes have resistance that depends on the direction of current flow. Modern circuits are typically constructed in integrated form with many thousands of elements included together from the start, and perform many complicated functions. Nevertheless, we can understand a good deal more with a small addition to the elements we have in place.

▲ **FIGURE 33–15** The symbol for a diode in a circuit diagram. Current can flow only in the direction shown.

Diodes and Rectifiers

While many sources of electric power supply AC voltage, many applications of that power require DC voltage. For example, rechargeable batteries require a DC current for charging but are charged with a device that plugs into household AC. A process called *rectification* transforms AC voltage to DC voltage using a diode. A **diode** is a semiconductor device with a high resistance to current that flows in one direction, but a low resistance to current that flows in the other direction—the direction of the arrow in the diode symbol (Fig. 33–15). In effect, the diode allows current flow only in one direction.



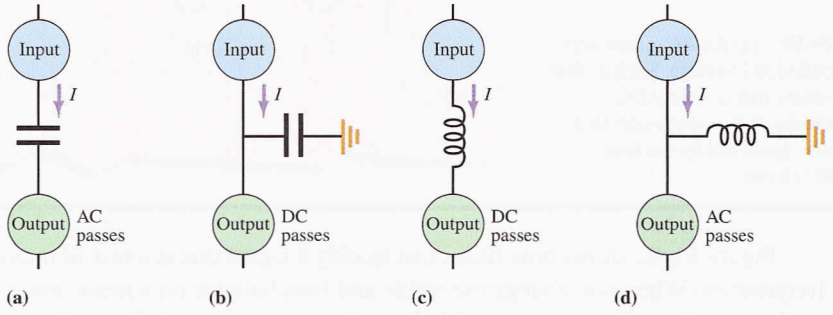
The diode can be used to construct a **rectifier**, a circuit element that changes AC into DC. Let's consider the circuit shown in Fig. 33–16a. The voltage across the load resistor can be negative or positive. When a diode is placed in the circuit, however, the negative voltages are blocked, leaving only positive voltages across the load resistor (Fig. 33–16b). Such a circuit is called a *half-wave rectifier*. This circuit can suffice as an approximation to a source of DC voltage although the voltage between points a and b, V_{ab}, is neither smooth nor constant.

We can improve the situation considerably with the circuit shown in Fig. 33–16c, called a *full-wave rectifier*. The diodes in this circuit are arranged such that *the voltage V_{ab} is always positive* even though the input voltage oscillates from positive to negative. When the emf produces positive voltage, positive current flows clockwise and passes through the path *cabd* in the direction of the rectifier arrows. The voltage V_{ab} is positive. When the emf produces negative voltage, positive current flows counterclockwise and the path of the current is *dabc*. In this case also, the voltage V_{ab} is positive. Note that now the voltage V_{ab} is positive for all half-cycles, and the rms voltage is higher than it is for the half-wave rectifier. The use of *filters* (see below) allows the voltage peaks to be smoothed, producing a voltage that is much closer to being constant.

THINK ABOUT THIS. . .

HOW DOES A CAR PRODUCE THE ELECTRICITY IT NEEDS?

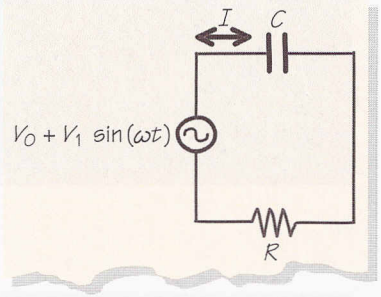
Although a car's battery is essential for starting, once the automobile engine is running, the engine itself produces the emf necessary to keep the engine running, to power the various "extras" such as lights or radio, and to recharge the battery. The mechanism involves an engine-driven belt that leads to the automobile's *alternator*. The belt runs over a pulley on whose shaft there is a wire coil rotating inside a magnetic field. We learned in Section 30–5 that such a device produces alternating current. But because AC current is not always suitable for the car's electrical system, and certainly not suitable for charging the battery, a rectifier circuit similar in principle to that in Fig. 33–16c is present to change the AC current to DC current.



▲ **FIGURE 33–16** (a) The AC voltage across a resistor. (b) A half-wave rectifier is applied. (c) A full-wave rectifier is applied.

Filters

A **filter** is a device that takes an input signal from one part of a circuit that may be a mixture of AC and DC and passes only the AC or only the DC signal to a different part of the circuit. More generally, a filter will change the balance of high and low frequency components in a signal that may contain many different frequencies. Our discussion of the capacitive and inductive reactances shows that either a capacitor or an inductor can act as such a filter. Consider Fig. 33–17, in which the current I from the input is a mixture of DC and AC,



$$I = I_0 + I_1 \sin \omega t.$$

Here I_0 and I_1 are constants. A constant current cannot pass across a capacitor, whereas the impedance of the capacitor goes to zero if ω becomes large. Thus for the capacitor in Fig. 33–17a, only the AC part of the current passes to the other side. For the capacitor in Fig. 33–17b, AC passes through the capacitor to ground, and the DC passes through to the output side of the circuit. An inductor works in just the opposite way: DC passes through without impedance ($X_L \to 0$ as $\omega \to 0$, and $\omega = 0$ corresponds to DC), whereas the impedance is large for AC with large ω. Thus for the inductor in Fig. 33–17c, DC passes through to the output; for the inductor in Fig. 33–17d, AC passes through to the output and DC passes through the inductor to ground.

◀ **FIGURE 33–17** AC and DC filters formed from capacitors or inductors. With a capacitor: (a) AC current passes through to the output side. (b) DC current passes to the output side. With an inductor: (c) DC passes through to the output side. (d) AC passes through to the output side.

EXAMPLE 33–9 The generator in the circuit shown in Fig. 33–18 produces a combination of DC and AC in the form $\mathcal{E} = V_0 + V_1 \sin \omega t$, where $V_0 = 0.10$ V, and $V_1 = 0.25$ V. The values of the capacitance and resistance in the circuit have the values $C = 1.0\ \mu$F and $R = 0.20\ \Omega$. What is the value of ω for which the voltage amplitude across the resistor is 50 percent of the value of the maximum voltage of the generator?

▲ **FIGURE 33–18**

Strategy We can apply the superposition principle by applying the loop rule that corresponds to the DC and AC terms separately, and then add the voltage drops. For the AC term, the current in the circuit is, from Eq. (33–33),

$$I_{AC} = \frac{V_1 \sin(\omega t - \phi)}{Z} = \frac{V_1}{\sqrt{(1/\omega C)^2 + R^2}} \sin(\omega t - \phi).$$

The voltage drop across the resistor from the AC is $I_{AC}R$ and therefore has the amplitude

$$\frac{V_1 R}{\sqrt{(1/\omega C)^2 + R^2}}.$$

For the DC term the capacitor acts as a perfect filter for the constant term in the input voltage because no constant current can pass. There is thus *no* voltage drop across the resistor associated with the V_0 term.

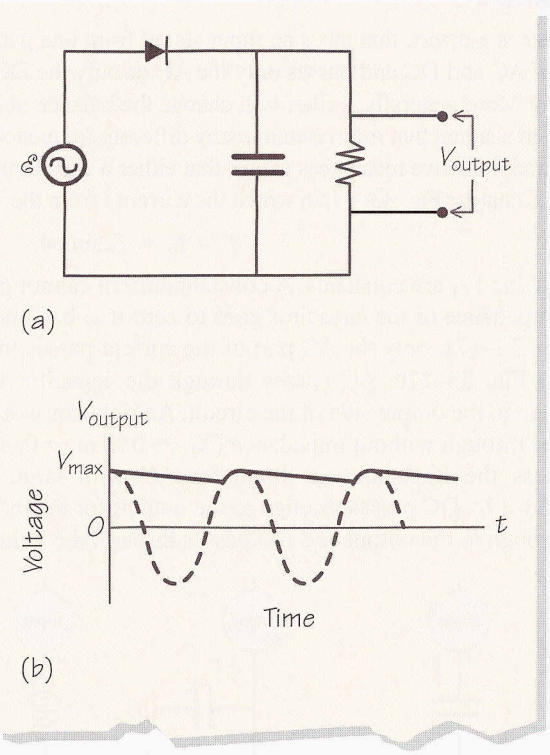
The maximum value of the input voltage is $V_0 + V_1$. We calculate the ratio of the voltage amplitude across the resistor to the maximum input voltage and set it equal to $\frac{1}{2}$. This equation determines ω.

Working It Out The equation for the ratio of potentials described above is

$$\frac{1}{V_0 + V_1} \frac{V_1 R}{\sqrt{(1/\omega C)^2 + R^2}} = 0.5.$$

We solve for ω:

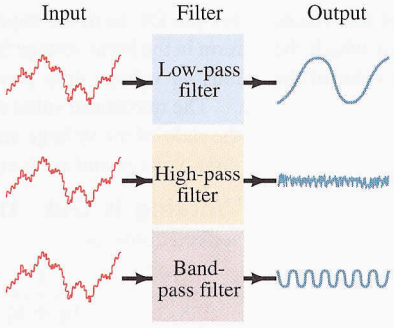
$$\omega = \frac{1}{RC\sqrt{\dfrac{V_1^2}{(V_0 + V_1)^2(0.50)^2} - 1}}$$



$$= \frac{1}{(0.20\ \Omega)(1.0 \times 10^{-6}\ \text{F})\sqrt{\dfrac{(0.25\ \text{V})^2}{(0.10\ \text{V} + 0.25\ \text{V})^2}\dfrac{1}{(0.50)^2} - 1}}$$

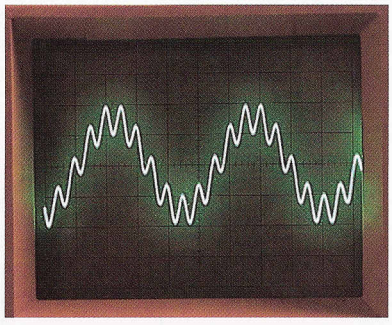
$$= 4.9 \times 10^6\ \text{s}^{-1}.$$

What Do You Think? At very high frequencies what becomes of the ratio of the voltage amplitude across the resistor to the maximum input voltage?



CONCEPTUAL EXAMPLE 33–10 Consider the *RC* circuit shown in Fig. 33–19a. The diode allows only the positive voltage to be passed through the circuit. Assume the values of R and C produce an RC time constant that is much longer than the period of the emf source voltage. What does the output voltage V_{output} across the resistor look like?

Answer During the rising voltage period of the source emf ($V = V_{max} \sin \omega t$), the capacitor will be charged to a full voltage V_{max}. As soon as the source voltage passes its peak and begins to decrease, the fully charged capacitor will start to discharge. Because the time constant is much greater than the period of the source voltage, the resulting voltage across the resistor will hardly decrease from its peak voltage V_{max} due to the capacitor discharging before the source voltage comes back to a peak again and recharges the capacitor. In effect, this circuit has rectified the AC voltage to one of full DC. We sketch the result in Fig. 33–19b. Application of a filter to the rectified voltage shown in Fig. 33–16b, for example, will further smooth out the peaks and valleys in the curve of voltage versus time.



▶ **FIGURE 33–19** (a) An *RC* circuit acts as a filter for rectified AC voltage. Such a filter can produce a voltage that is nearly DC. (b) The slow decrease of the nearly constant-voltage segments is governed by the time constant of the *RC* circuit.

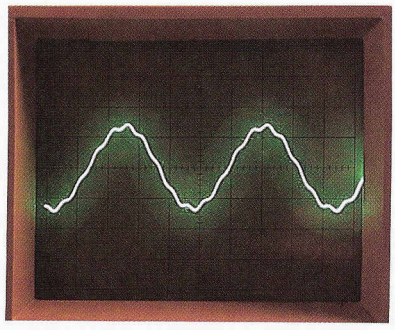


Figure 33–20 shows how filters can modify a signal that is a mix of many different frequencies. When you change the treble and bass balance on a music system you are applying filters. We can also add that when you sequentially apply a high- and low-pass filter, you are making a band-pass filter, one that allows a given band of frequencies to pass.

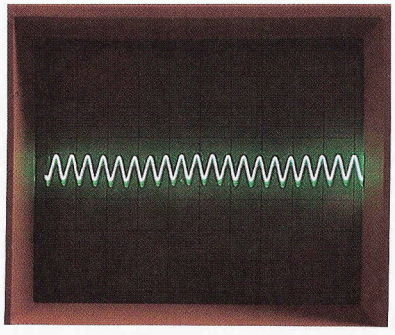


(a)

(b)

(c)

(d)

▶ **FIGURE 33–20** (a) Filters allow the low frequencies contained in an input signal to pass. (b) An input voltage containing both low and high frequencies. (c) The input voltage in part (b) has been sent through a low-pass filter, which eliminates the high frequencies. (d) The input voltage in part (b) has been sent through a high-pass filter, which eliminates the low frequencies.

*Impedance Matching

Another aspect of AC of practical importance concerns **impedance matching**, which refers, as in our discussion of filters, to the *connection* between different parts of a circuit. Figure 33–21a shows such a situation, in which some combination of circuit elements makes up circuit 1, connected at points a and b to circuit 2. The two circuits have impedances Z_1 and Z_2, respectively. We are not concerned here with the origin of currents in these circuits as much as we are with our ability to deliver power from circuit 1 to circuit 2. We therefore assume that the origin of these currents is within circuit 1 and break that circuit down as in Fig. 33–21b. The primary question is, if Z_1 is fixed, what are the requirements for Z_2 so that the power delivered to circuit 2 is a maximum? If, for example, a stereo amplifier is connected to a loudspeaker, what should the loudspeaker's impedance be in order that maximum power is delivered to it?

The answer is found by computing the average power $\langle P \rangle$ to circuit 2, which, from Eq. (33–42), is $I_{\text{rms}}^2 R_2$. The current in the loop of Fig. 33–21b is given by

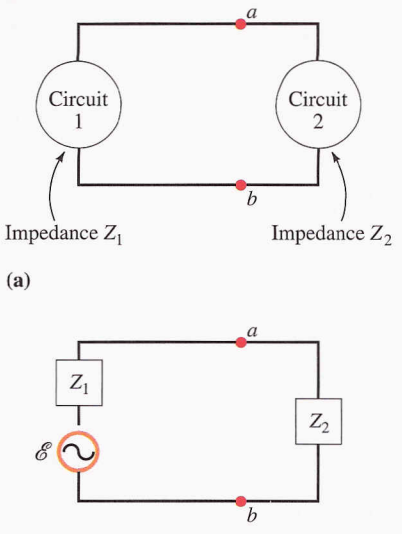
$$I_{\text{rms}} = \frac{\mathscr{E}_{\text{rms}}}{Z_{\text{total}}}. \tag{33–47}$$

Here, $\mathscr{E}_{\text{rms}}$ is the rms value of the generator, whose maximum voltage, or amplitude, is V_0. If the generator produces a sinusoidal emf of the form of Eq. (33–1), then Eq. (33–40) shows that $\mathscr{E}_{\text{rms}} = V_0/\sqrt{2}$. The total impedance Z_{total} is found by separately adding the capacitive reactances, inductive reactances, and resistances, a result that follows from our knowledge of how series combinations of C, L, and R add (see Problem 44):

$$Z_{\text{total}} = \sqrt{[(X_{L_1} + X_{L_2}) - (X_{C_1} + X_{C_2})]^2 + (R_1 + R_2)^2}. \tag{33–48}$$

Thus the average power delivered to circuit 2 is

$$\langle P \rangle = \frac{\mathscr{E}_{\text{rms}}^2 R_2}{Z_{\text{total}}^2} = \frac{\mathscr{E}_{\text{rms}}^2 R_2}{[(X_{L_1} + X_{L_2}) - (X_{C_1} + X_{C_2})]^2 + (R_1 + R_2)^2}. \tag{33–49}$$



That there is a value of the parameters of Z_2 that maximizes this power is clear: If Z_2 is too small, the factor R_2 will also be small and $\langle P \rangle$ will be small; if Z_2 is too large, its parameters will dominate the denominator of Eq. (33–49), and $\langle P \rangle$ will again be small. An intermediate value of the parameters of Z_2 will give a maximum value of $\langle P \rangle$. Two independent parameters are involved here: the resistance R_2 and the total reactance term for circuit 2, $X_{L_2} - X_{C_2}$. Formally, we find the value of the parameters that maximize $\langle P \rangle$ by taking the derivative of $\langle P \rangle$ with respect to these quantities and setting it equal to zero. From this exercise the power is maximized when

$$R_2 = R_1 \quad \text{and} \quad X_{L_2} - X_{C_2} = -(X_{L_1} - X_{C_1}). \tag{33–50}$$

The second condition—that the reactance term of Z_2 is equal but opposite to that of Z_1—follows because it means that the reactance terms in the denominator of Eq. (33–49) cancel, thus maximizing $\langle P \rangle$ whatever the value of the resistances. The first condition—that the resistances be equal—is perhaps less intuitive but nevertheless follows directly from the requirement that the derivative of $\langle P \rangle$ is zero (see Problem 72). When the conditions of Eq. (33–50) are met, the impedances are said to be matched.

Impedance matching is desirable when you wish to deliver maximum power to one part of a circuit. It is worth noting that we do not always wish to deliver maximum power. An AC voltmeter, for example, should have an impedance *mismatch* because we want it to draw as little current as possible.

The subject of circuit analysis is highly developed. We have been able to do no more than describe its principles, and this chapter will not have taught you to fix, much less design, TVs or computers. But the principles we have described here apply to all AC circuits.

▲ **FIGURE 33–21** (a) Circuit diagram to illustrate impedance matching. (b) Circuit 1 of part (a) is broken down into a source of emf $\mathscr{E}$ and an impedance Z_1. Circuit 2 is assumed to include only an impedance Z_2.

Summary

The presence of AC sources of emf in circuits with resistors, inductors, and capacitors introduces a variety of new possibilities of phenomena and applications. Transformers allow us to vary the voltage amplitude of AC emfs, of importance in power transmission on large and small scales.

The relation between the voltages and the numbers of turns of the primary and secondary coils of a transformer is

$$\frac{V_2}{V_1} = \frac{N_2}{N_1}. \tag{33–4}$$

Conservation of energy implies that the currents carried by the respective coils are related inversely:

$$\frac{I_1}{I_2} = \frac{N_2}{N_1}. \tag{33–6}$$

A series *RLC* circuit with an AC source of emf of frequency ω behaves like a damped harmonic oscillator driven by a harmonically varying force. Solutions for currents, voltages, and charges in such circuits can be found by using the solutions already developed for the driven harmonic oscillator. For such circuits the impedance Z is a quantity that plays the role of a resistance. The impedance is frequency dependent:

$$Z \equiv \sqrt{\left(\omega L - \frac{1}{\omega C}\right)^2 + R^2} = \sqrt{(X_L - X_C)^2 + R^2}. \tag{33–32}$$

where X_C is the capacitive reactance and X_L is the inductive reactance. The current in the driven circuit is then

$$I = I_{\max} \sin(\omega t - \phi) = \frac{V_0 \sin(\omega t - \phi)}{Z}, \tag{33–33}$$

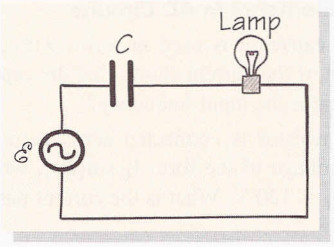
where $V_0 \sin \omega t$ is the driving emf. The phase ϕ is given by

$$\tan \phi = \frac{1}{R}\left(\omega L - \frac{1}{\omega C}\right). \tag{33–29}$$

Such circuits exhibit resonant behavior when the driving frequency is near the natural frequency $\omega_0 = \sqrt{1/LC}$. This type of behavior is most clearly seen in the power dissipated in driven *RLC* circuits. Averaged over time, the power lost is

$$\langle P \rangle = I_{\text{rms}}^2 R = I_{\text{rms}}^2 Z \cos \phi, \tag{33–46}$$

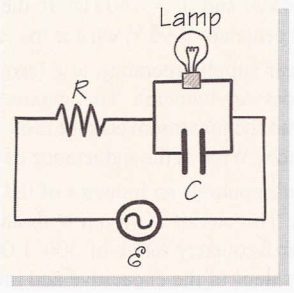
where $I_{\text{rms}} Z = V_0/\sqrt{2}$ gives the rms current. Near resonance, the power dissipated is a maximum, and the width of the peak of average power versus driving frequency has a width at half-maximum of



$$\Delta\omega = \frac{R}{L}, \tag{33–43}$$

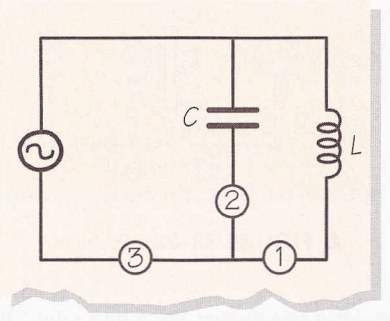
a result that holds as long as the resistance is not too large.

If we add diodes—devices that allow current to pass in one direction only—to our arsenal of circuit elements, we can construct a variety of electronic devices, including rectifiers, which produce a positive (or negative) emf from an AC source, and filters, which take a mixed AC and DC signal and pass predominantly either the constant (DC) part or the variable (AC) part of a given frequency. The term impedance matching refers to constraints that describe how different parts of a circuit can be connected together with minimal power loss.



Understanding the Concepts

1. Why is the material used to make the core of transformers so important?
2. What are some applications for step-up and step-down transformers?
3. Why does a capacitance act as a short circuit at high frequencies?
4. Without R, the current amplitude in a series *RLC* circuit would be infinite when the driving frequency ω equaled ω_0, but this possibility could never happen, because there is always some resistance in real circuits. How do you reconcile this statement with the existence of superconductors?
5. To find the rms current [Eq. (33–41)], we square the current, then take the time average, and then take the square root. Why do we not simply take the time average of the current?
6. Consider a lightbulb connected in series with an inductance L, a capacitor C, and an AC emf. The frequency ω of the power supply can be tuned. For what value of ω will the bulb be brightest?
7. In discussing AC current, we found it useful to describe its root mean square; why didn't we bother with this in our discussion of power?
8. In Example 33–9, we took the input emf to be a mixture of DC and AC, then treated the effect of the AC and DC parts separately and added the two parts. How is this procedure justified?
9. What is the distinction between which side of a transformer is the primary or secondary coil? Could it easily be switched around and operated the opposite way? What would change?
10. A capacitor and a lamp are connected in series with an AC generator of constant voltage but variable frequency (Fig. 33–22, see next page). Which of the following three statements is true? The lamp will (a) not light, because the capacitor is connected in series with the lamp; (b) burn brightest when the frequency is high; (c) burn with the same brightness for all frequencies.

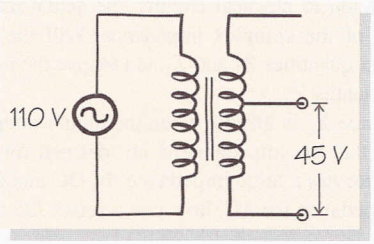


▲ **FIGURE 33–22** Question 10.

11. A capacitor, lamp, and resistor are connected to an AC generator of constant voltage but variable frequency (Fig. 33–23). Which of the following statements is true? The lamp will (a) not burn, because the capacitor shorts out the lamp; (b) burn brightest when the frequency is low; (c) burn brightest when the frequency is high; (d) burn with the same brightness for all frequencies.

▲ **FIGURE 33–23** Question 11.

12. A particular appliance or household circuit is rated for a maximum current. Why is that, and why must currents not exceed that maximum?
13. The purpose of a ballast in a fluorescent light is to start and control the lamp. A voltage at least three times as large as the steady state voltage is needed to start the lighting process, and current spikes must be controlled. Which of the three circuit elements (*R, L, C*) are you likely to find in a ballast? Explain what it might do.
14. The primary purpose of an electric heater is to produce heat. Why would such a heater require a 220-V socket rather than a 120-V socket?
15. In the complex analysis approach, two combinations of circuit elements have complex impedances Z_1 and Z_2, respectively. When these combinations are placed in series with one another, their (complex) total impedance is given by the addition $Z = Z_1 + Z_2$. For application to physical circuits, the actual impedance is the magnitude of the complex impedance. Will the magnitudes of the complex quantities Z_1 and Z_2 add to give the magnitude of the complex quantity Z?
16. The reactance X_C is infinite when the input voltage is DC. Does that mean that the impedance is not defined for this situation?
17. If a capacitor has a large impedance for DC and an inductor has a large impedance for AC, how can a series *LC* circuit pass any current?
18. If the frequency of an AC voltage across an inductance is doubled, the inductive reactance of the inductor is (a) increased by a factor of 4; (b) decreased by a factor of 4; (c) doubled, (d) none of these.
19. Television antenna wires normally have negligible resistance and an impedance of 75 Ω. Why is it important to use antenna wires with the same impedance throughout?
20. Some appliances that operate off a 120-V line and draw in excess of 20 A of current have different plugs than regular 120-V household devices have. Why are these plugs different? What might happen if they were not different?
21. Three lightbulbs, a capacitor, and an inductor are connected to an AC power supply as shown in Fig. 33–24. Under what circumstances do you expect bulbs 1 and 2 to be very bright, while 3 is quite dim?

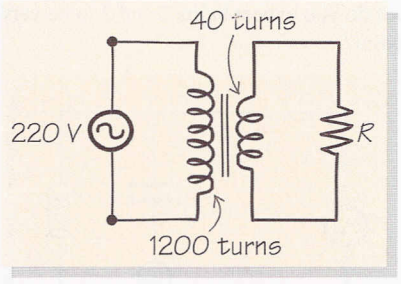


▲ **FIGURE 33–24** Question 21.

22. Do all CRT-based television sets have transformers? How might transformers be used in a television set?
23. If electricity is transported in power transmission lines at 200 kV to 500 kV, does the power have to be generated at these voltages? Why or why not?
24. In a capacitor, there is a gap between the two plates. Why then is there any current at all flowing in a circuit with a capacitor? Is this current carried by sparks?

Problems

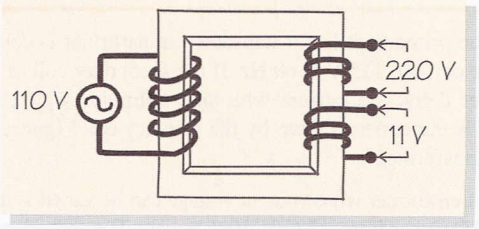
33–1 Transformers



1. (I) A transformer has 100 turns in the primary coil and 1,500 turns in the secondary coil. If the amplitude of the AC voltage in the primary coil is 600 V, what is the voltage amplitude in the secondary coil?
2. (I) Suppose that electric power costs 18 cents/kWH. Consider a transmission line that delivers 500 kW of power and has a resistance of 150 Ω. Calculate the dollars lost annually due to the transmission line if the power is delivered at (a) 750,000 V and (b) 1,440 V.
3. (I) Many electrical devices, such as doorbells or buzzers, operate on 12 V AC. A small transformer used to produce this voltage has a primary coil of 550 turns and takes an input of 110 V AC. How many turns must the secondary coil have?
4. (I) The primary coil of a step-down transformer is connected to house current, 115 V at 60 Hz. If the secondary coil of the transformer delivers a current with an amplitude of 2.0 A at 24 V, what is the current drawn by the primary coil? Ignore losses in the transformer.
5. (I) A transformer whose output voltage can be varied is used to obtain AC power from a 120-V, 10-A supply. The secondary coil consists of 1200 turns of wire. The variable transformer works by connecting different numbers of turns of wire on the secondary coil. The secondary voltage can thereby be regulated. When all 1200 turns act as the secondary coil, the output voltage has an amplitude of 120 V. How many turns of wire should be used to obtain 45 V (Fig. 33–25, see next page)? How much current will flow in this case?

▲ **FIGURE 33–25** Problem 5.

6. (I) A transformer has one coil with an inductance of 74 mH, area 35 cm^2, and length 20 cm. It is fully linked with another coil having the same area and length, but not the same number of turns. Their mutual inductance is 43.5 mH. How many turns does each coil have?



7. (II) Figure 33–26 shows an ideal transformer with 220 V on the primary coil supplying power to a resistor of resistance R. If the resistor dissipates 88 W, what is the current in the primary coil?

▲ **FIGURE 33–26** Problem 7.

8. (II) A step-down transformer has a turn ratio (N_1/N_2) of 15:1. (a) If the primary coil is connected across a 220-V oscillating-voltage generator, what voltage appears across the secondary coil? (b) Assuming that there are no power losses in the transformer, what current would have to flow through the primary coil so that a 15-Ω resistor placed across the secondary coil draws all the power of the circuit? (c) What resistance connected across the 220-V voltage generator would draw the same total power?

9. (II) The transformer shown in Fig. 33–27 has two secondary windings; one supplies 220 V, the other, 11 V. The input voltage at the primary coil is 110 V. If the 220-V secondary coil has 1000 turns, how many turns does the 11-V secondary coil have?

▲ **FIGURE 33–27** Problem 9.

10. (II) Suppose that a transformer consists of two separate windings of wire on the same core. The core material has a magnetic permeability μ. How does the ratio of the emfs in the two coils depend on μ?

33–2 Single Elements in AC Circuits

11. (I) A 12-μF capacitor is used in series with an AC generator. Measurement of the current shows that the capacitive reactance is 1.0 Ω. What is the input frequency?

12. (I) A 25-Ω resistor is connected across a power supply that produces a voltage of the form $V_0 \sin(\omega t)$, where $f = \omega/2\pi =$ 60 Hz and $V_0 = 130$ V. What is the current passing through the resistor?

13. (I) An alternating current of maximum value 2 A in a solenoid of self-inductance $L = 15$ mH induces an emf of maximum value 330 V. What is the angular frequency of the alternating current?

14. (I) An AC power supply with frequency 60 Hz is connected to a capacitor of capacitance $C = 40$ μF. The maximum instantaneous current that passes through the circuit is 2.26 A. What is the maximum voltage?

15. (I) A current flowing through a circuit that contains only a capacitor and an AC power supply has the form $I_0 \cos[2\pi ft - (\pi/6)]$, where $I_0 = 2.45$ A and $f = 180$ Hz. If the maximum voltage supplied by the generator is 95 V, what is the capacitance?

16. (I) An AC power supply operating at a frequency of 220 Hz is connected across an inductor. The maximum voltage of the source is 4 V, and the maximum current is 65 mA. What is the inductive reactance? What is the inductance of the circuit?

17. (I) An AC circuit contains an inductor of 0.3 H and capacitor of 2 μC in series. The circuit is driven with an AC source of emf with an angular frequency range of 300–1,000 rad/s. What are the maximum values of the capacitive and inductive reactances?

18. (II) A current $I = I_0 \sin(\omega t - \pi/3)$ flows in a circuit for which $I_0 = 2.3$ A and $\omega = 2\pi(60\text{ Hz})$. (a) At what times does the peak current flow? (b) If the current flows through an inductance of 0.25 H, what is the peak voltage on the inductor? At what times does this peak voltage occur?

19. (II) The average of the square of the voltage in an inductive circuit (a circuit with no capacitors and no resistors) driven by an AC emf is $(30\text{ V})^2$, and the average of the square of the current is $(2\text{ A})^2$. What is the inductive reactance? If the inductance is 25 mH, what is the frequency of the alternating current?

20. (II) The voltage across an inductor takes the form $V(t) = (0.3\text{ V}) \sin[(400\text{ s}^{-1})t] + (0.3\text{ V}) \sin[(2{,}700\text{ s}^{-1})t]$. Determine the current through the inductor if $L = 40$ μH.

21. (III) (a) Draw the phasor for the function $D \cos(\omega t + \phi)$ on the graph that contains the phasor for the function $C \sin(\omega t + \phi)$. Which phasor is more advanced in phase—that is, points in a direction corresponding to a larger angle, as measured from the $+x$-direction? (b) What is the angle between the two phasors on the plot you drew for part (a)? Which phasor leads? (c) Repeat the exercise for the function $f(t) = A \cos(\omega t) + B \sin(\omega t)$.

33–3 AC in Series *RLC* Circuits

22. (I) Consider an LC circuit driven by an AC source of emf. It differs from the one shown in Fig. 33–10 in that the inductor and the capacitor are in parallel, while there is no resistor. Given that the input voltage is $V_0 \sin \omega t$, determine the form of the current through the inductor without using Kirchhoff's rules.

23. (I) Consider a radio circuit with a fixed inductance of 14 μH. What is the value of the tunable capacitance for the reception of a 42-m radio wave?

24. (I) What is the range needed for a variable capacitor to be combined with a 12-mH coil so that a tuned circuit could be formed to cover the range of broadcast-band frequencies from 540 kHz to 1,600 kHz?

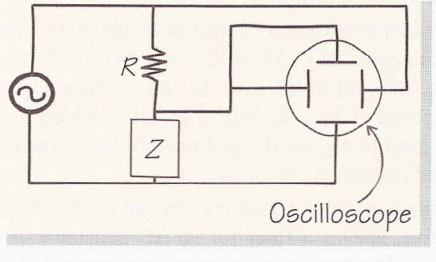
25. (I) The driving frequency in a driven *RLC* circuit is at the resonant frequency. The maximum current carried by the circuit is found to be insufficient for the desired application. By what factor should the resistance be changed to double the maximum current?

26. (I) An AC generator with a voltage amplitude of 50 V and a frequency of 750 Hz is built to drive a circuit meant to be resonant. The resistance of the circuit is 0.5 Ω, and the inductance is 5 mH. What must the value of the capacitance be?

27. (I) A series *RLC* circuit of frequency 60 Hz has a maximum current of 100 mA. What is the maximum charge on the capacitor? If the impedance is 40 Ω, what is the emf?

28. (I) FM radio stations operate at frequencies spaced at 0.2 MHz intervals from 88.1 to 107.9 MHz, but many radio tuners operate down to 87.9 MHz. However, TV channel 6 operates at 88.0 MHz, with the audio signal of TV channel 6 operating at 87.75 MHz. You have a *RLC* series tuning circuit with a 20 pF capacitor. What inductance do you need to receive the Channel 6 audio circuit?

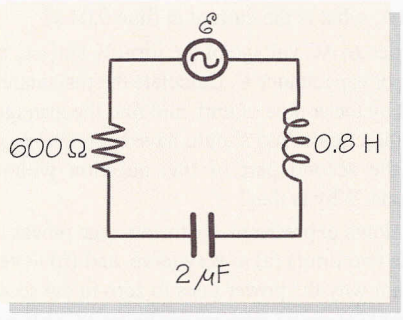
29. (II) An inductance is connected in series with a resistor of 150 Ω. When these are placed in series across an rms 110 V AC line with $\omega = 60$ radians/s, the voltage across the resistance is 40 V. Calculate the value of L and its resistance.



30. (II) A series *RLC* circuit has parameters $R = 18\ \Omega$, $L = 30.0$ mH, and $C = 15.0\ \mu$F. Find the capacitive reactance, inductive reactance, and impedance for the frequencies (a) 60 Hz, (b) 500 Hz, and (c) 20,000 Hz.

31. (II) A series *RLC* circuit consists of a 1200.0-Hz AC emf with $V_0 = 80$ V; $R = 500\ \Omega$, $L = 92$ mH, and $C = 2\ \mu$F. Find X_C, X_L, Z, Q_{max}, ϕ, and I_{max}.

32. (II) You want to build an AC series circuit with the smallest possible impedance. You have a fixed frequency generator with an angular frequency of 1000 rad/s, and the following circuit elements available: two capacitors, of 1 μF and 100 μF; two inductors, of 10 mH and 25 mH, and two resistors, of $10^3\ \Omega$ and $3 \times 10^3\ \Omega$. You may use only one of each type element. What is the lowest circuit impedance and which values of R, L, and C would you choose to make this circuit?



33. (II) Find the voltages across the capacitor and inductor in the AC circuit of Problem 31 at $t = 0.10000$ s if the emf is switched on at $t = 0$ s. All circuit elements initially have no charge or current.

34. (II) An unknown impedance Z is investigated with an oscilloscope. It is connected in series with a 12-Ω resistor, and connected to a 60-Hz AC power supply. The horizontal deflection plates of the oscilloscope are connected to the known resistor so that the horizontal deflection of the electron beam is proportional to the potential drop on the resistor. The potential drop on the impedance Z is measured by the vertical displacement of the electron beam (Fig. 33–28). (a) Sketch the shape of the figure on the oscilloscope's screen if Z consists of a coil with inductance $L = 0.95$ mH and resistance $r = 650\ \text{m}\Omega$. (b) Repeat the calculation if Z is a 0.5-mF capacitor in series with a resistance $r = 650\ \text{m}\Omega$. (c) How can you tell if Z is capacitive or inductive?

▲ **FIGURE 33–28** Problem 34.

35. (II) Given that the maximum voltage in the circuit shown in Fig. 33–29 is 110 V and the frequency of oscillation is 60 Hz, calculate the maximum current and the maximum potential drops across the resistor, capacitor, and inductor.

▲ **FIGURE 33–29** Problems 35 and 36.

36. (II) What is the resonant angular frequency ω_0 of the circuit in Problem 35? Suppose that the voltage generator has a variable angular frequency ω. For what values of ω will the current have half the value it has at resonance?

37. (II) An AC circuit consists of a parallel-plate capacitor and a long, cylindrical solenoid. Suppose that all the dimensions of the apparatus, including the wire sizes, are scaled down by a factor of 2. (Note that the turn density doubles.) How would the resonant frequency of the circuit change? Assume that there are changes in resistance.

38. (II) Show that $Q(t)$ in Eq. (33–28) satisfies Eq. (33–23) by direct substitution. Determine the maximum charge Q_{max} on the capacitor in terms of the impedance.

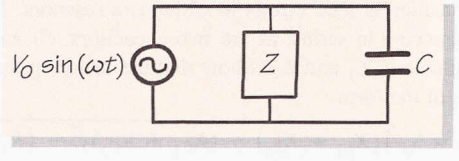
39. (II) Sketch the current and voltage for the following AC series circuits: (a) a pure capacitive circuit, (b) a pure inductive circuit, (c) an *RL* circuit, (d) an *RC* circuit, and (e) an *LC* circuit.

40. (II) A resistor draws 3 A when connected to a 80-V, 60-Hz line. A capacitor of what capacitance, when connected in series with the resistor, will drop the current to 1.5 A? What are the voltage drops across the capacitor and the resistor?

41. (II) A 16-μF capacitor is connected in series with a coil whose resistance is 30 Ω and whose inductance can be varied. The circuit is connected across a 12-V, 60-Hz generator. What is the potential difference across the capacitor and across the inductor–resistor combination when the frequency is the resonant frequency?

42. (II) Suppose that the maximum voltages across the resistor, capacitor, and inductor of a series *RLC* circuit driven by an AC generator of frequency f are identical. If the resistor has a resistance R, find the values of C and L in terms of R and f.

43. (II) A series *RLC* circuit contains a 70-nF capacitor and a 0.2-Ω resistor. If the circuit is resonant at a frequency of 180,000 Hz, what is the inductance?



44. (II) Consider an *RLC* circuit in which two resistors, R_1 and R_2, are connected in series, as are two capacitors, C_1 and C_2, and two inductors, L_1 and L_2. Show that the resulting total impedance is of the form

$$Z_{\text{total}} = \sqrt{[(X_{L_1} + X_{L_2}) - (X_{C_1} + X_{C_2})]^2 + (R_1 + R_2)^2}.$$

45. (III) There is an AC source of emf in a single-loop circuit that produces a potential drop in the form $V(t) = V_0 \sin(\omega t)$, while the current in the circuit takes the form $I(t) = I_0 \sin(\omega t - \phi)$. Make a phasor diagram for the current and potential drop across each element if the circuit contains (a) a resistor and a capacitor, and (b) a resistor and an inductor.

33–4 Power in AC Circuits

46. (I) What is the average power dissipated in the resistor for the circuit in Problem 12?
47. (I) An AC power supply with a frequency of 75 Hz dissipates energy at a rate of 150 W in a 12-Ω resistor. If the current at time 0 s is 5.0 A, what is the current at time 0.04 s?
48. (I) Consider an AC voltage of the form $V_0 \sin(\omega t)$ connected to a capacitor of capacitance C. Calculate the instantaneous power VI delivered by the source of emf, and find the average power dissipated in the circuit. You should have been able to obtain the answer to the second part of this question without doing any calculations. Why is that?
49. (I) Write down expressions for the average power in an RLC circuit in the two limits (a) ω very large, and (b) ω very small. Can you explain why the power goes to zero in the second case?
50. (I) A portable electric heater operating on AC voltage of amplitude 110 V is rated at a power of 800 W. (a) What is the resistance of the heater? (b) Find the rms current. (c) Find the maximum current.
51. (I) What are the power factors for (a) pure capacitive circuits, (b) pure inductive circuits, and (c) pure resistive circuits?
52. (II) Show that, on average, no power is dissipated in a purely inductive circuit (a circuit with neither capacitors nor resistors).
53. (II) What are the power factors for (a) RL circuits, (b) RC circuits, and (c) LC circuits?
54. (II) A coil draws a current with a peak amplitude of 0.4 A from a peak 170 V source operating at a frequency $f = 60$ Hz. The power consumed is 18 W. What are the impedance, the resistance, and the inductance?
55. (II) Consider an RLC circuit, with $L = 170\ \mu$F and $C = 24$ mH. (a) Calculate the resonant frequency. (b) How large should the resistance R be if a 1% shift in the frequency is to reduce the power received by a factor of 50?
56. (II) An AC source of emf operating at a frequency of 60 Hz produces an rms voltage of 78 V. Find the voltage amplitude. The source of emf is connected in series with an impedance of $Z = 20\ \Omega$. Find the rms current and the current amplitude.
57. (II) When a coil draws 200 W from a $V_{\text{rms}} = 110$-V, 60-Hz line, the power factor is 0.6. If the same coil with a capacitor added in series is to draw the same power from a $V_{\text{rms}} = 220$-V, 60-Hz line, what must the capacitance be? If the aim were to maintain the same power factor rather than the same rms power, how would your answer change?
58. (II) A machine shop uses 120 A from a 220-V, 60-Hz line. However, due to the primarily inductive load—motors—the voltage and current are out of phase by 40°, wasting a lot of heat in the cables. A large capacitor connected parallel to the machines can solve this problem (Fig. 33–30). (a) How large should the capacitance be? (b) What will be the current in the main cable with the capacitor attached? (c) What is the total power of the machines in the shop?

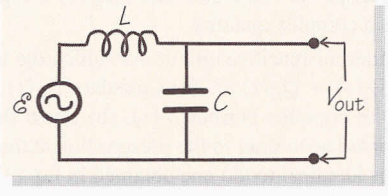
▲ **FIGURE 33–30** Problem 58.

59. (II) An electric motor consumes 5 kW of power at 220 V (voltage amplitude) with a power factor of 0.80. This motor is to be run at the end of a power transmission line with a total resistance of 2.5 Ω. What voltage and power must be supplied at the input end of the transmission line?
60. (II) An AC transmission line transfers energy to a device with a power factor of 0.85 at the rate of $\langle P \rangle = 4$ kW and a voltage of 220 V. If the transmission line has a resistance of 15 Ω, how much energy is lost to Joule heating in the transmission line?
61. (II) A 220-V generator has a current-carrying capacity of 80 A. What is the maximum rate at which energy can be taken from this generator by an impedance with a power factor of 0.55? for a power factor of 0.95?
62. (II) A 20-Ω resistor and a 4.5-μF capacitor are connected in series to a 110-V, 60-Hz power supply. What are the rms current, power, and power factor? How will these numbers change if an inductance of 0.035 H is connected in series with this circuit?
63. (II) An RLC circuit draws a peak 3.00 A from an rms 220 V AC power supply. The power consumed is 200 W. When the capacitor is short-circuited, the current falls to 2.20 A. Find the values of R, the capacitive reactance, and the inductive reactance, assuming that $X_L < X_C$.
64. (II) A series RLC circuit is known to have a resonance at 2.2 MHz. The half-power point is 3.0 KHz away from resonance. Given that the capacitance is 6.6 pF, what are L and R?
65. (II) House current, which has an rms voltage of 110 V and a frequency of 60 Hz, drives a resistor of a variable resistance set at $R = 50\ \Omega$, a capacitor of fixed capacitance $C = 20\ \mu$F, and an inductor of variable inductance, connected in series. (a) What is the power absorbed by the circuit if $L = 10$ mH? (b) What would the power drawn be if the resistance were halved without changing the setting of the inductance? (c) What is the maximum power drawn in part (b)?
66. (II) For a driven series RLC circuit, show that

$$\frac{R}{Z} = \frac{1}{\sqrt{1 + Q^2\left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega}\right)^2}}.$$

67. (II) Plot R/Z in Problem 66 for values of ω/ω_0 from 0.4 to 2.5 and values of Q of 1, 10, and 100. Use a computer program and graphics output, if available.
68. (II) For a driven series RLC circuit, show that Q is related to $\Delta\omega$ by the relation

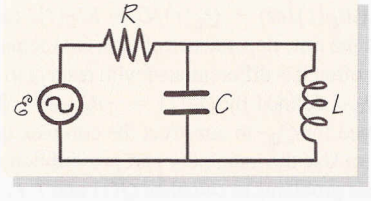
$$\frac{\Delta\omega}{\omega} = \frac{1}{Q}\frac{\omega_0}{\omega} \cong \frac{1}{Q}.$$



33–5 Some Applications

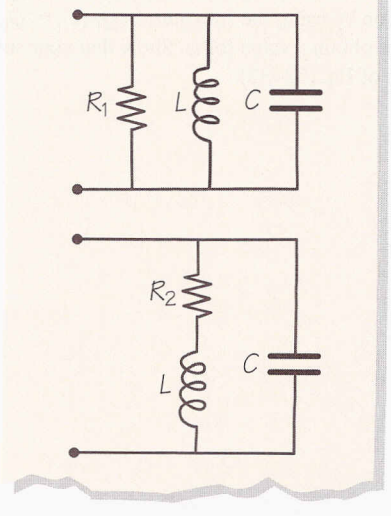
69. (II) Consider the circuit treated in Example 33–9 and drawn in Fig. 33–18. Take $C = 5$ nF and $R = 120\ \Omega$, but assume now that the input emf has the purely sinusoidal form $V_1 \sin(\omega t)$, where $V_1 = 0.20$ V. Calculate the potential across the capacitor for (a) $f = 100$ Hz, (b) $f = 10^5$ Hz, and (c) $f = 10$ MHz.
70. (II) Design a high-pass RC filter that will remove voltages with frequencies lower than 8 kHz.
71. (II) Design a high-pass RL filter for filtering out signals with frequencies lower than 8 kHz.
72. (II) The first condition for impedance matching is that the resistances are equal [Eq. (33–50)]. Show that this is true by starting with Eq. (33–49) in the case that the reactance terms are equal and opposite. Take a derivative of the resulting average power with respect to R_2, set it equal to zero, and show that this gives the equal resistance condition.
73. (II) A diode, through which current can flow only when the emf is positive, acts as a filter for an AC generator of angular frequency ω. The current has maximum magnitude I_0. Find its average and rms values.

74. (III) An *RC* filter circuit like that shown in Fig. 33–18 is called a *high-pass* filter circuit when the voltage output is taken across the resistor. Plot the ratio V_{out}/V_{in} as a function of frequency. Why does such a circuit block signals of low frequency but allow high-frequency signals to pass?



75. (III) An *RC* filter circuit like that shown in Fig. 33–18 is called a *low-pass* filter circuit when the voltage output is taken across the capacitor. Plot the ratio V_{out}/V_{in} as a function of frequency. Why does such a circuit block high-frequency signals but allow low-frequency signals to pass?

76. (III) Consider the *LC* filter of Fig. 33–31 with the emf $V_0 \sin(\omega t)$. Assume that $X_L \gg X_C$ (or $\omega \gg \omega_0$). (a) Show that $V_{out} = (X_C/X_L)V_0$. (b) Show that the circuit of Fig. 33–31 is generally effective in reducing the AC components, but not the DC components, of emf.

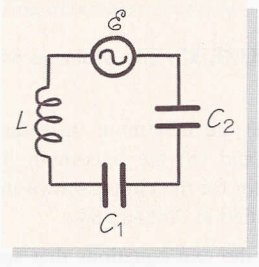


▲ **FIGURE 33–31** Problem 76.

77. (III) Given that the driving voltage of the *RLC* circuit shown in Fig. 33–32 is $V = V_0 \cos(\omega t)$, calculate the currents in the three elements. Is there a resonant frequency? [*Hint*: Write down the circuit equations, and substitute the trial solution $I = I_0 \cos(\omega t + \phi)$].

▲ **FIGURE 33–32** Problem 77.

78. (III) What is the relation between the resistances if the average power dissipated in them is the same at $\omega = 1/\sqrt{LC}$ (see Fig. 33–33)?

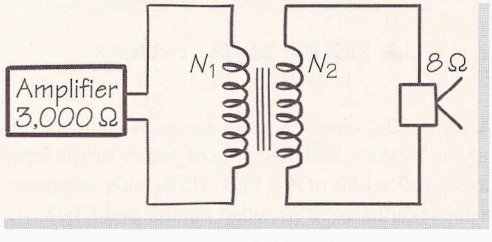


▲ **FIGURE 33–33** Problem 78.

General Problems

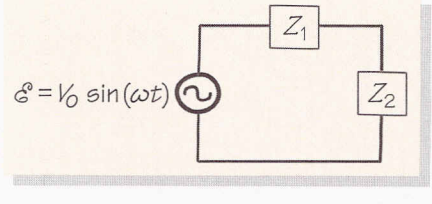
79. (II) Calculate (a) the maximum instantaneous voltage across each capacitor; and (b) the maximum instantaneous voltage across the inductor for the circuit shown in Fig. 33–34. Use the parameters specified in Problem 80.

80. (II) Consider the circuit shown in Fig. 33–34. The emf has an amplitude of $V_0 = 4$ V and a frequency of 600 Hz; $L = 70\ \mu$H, $C_1 = 4\ \mu$F, and $C_2 = 9\ \mu$F. Find (a) the maximum current; (b) the resonant frequency.



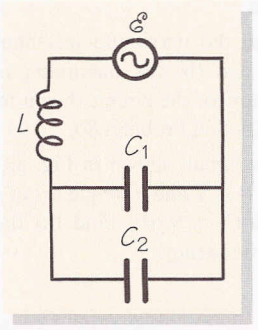
▲ **FIGURE 33–34** Problem 80.

81. (II) Show that Eq. (33–31) for the phase angle can be determined from



$$\tan\phi = \frac{(\omega^2 - \omega_0^2)L}{\omega R}.$$

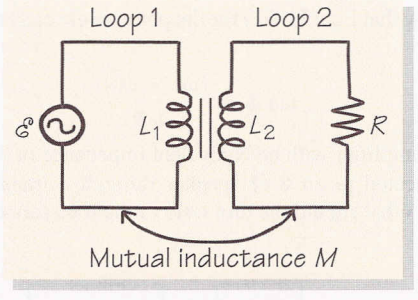
82. (II) An amplifier with an equivalent impedance of 3,000 Ω is to be connected to an 8-Ω speaker through a transformer (Fig. 33–35). What should the turn ratio of the transformer be?



▲ **FIGURE 33–35** Problem 82.

83. (II) The impedance Z_1 in Fig. 33–36 can be regarded as a pure resistance $R_1 = 15\ \Omega$, whereas the impedance Z_2 is associated with a series resistance $R_2 = 8\ \Omega$ and a capacitance $C = 2\ \mu$F. If $f = 3000$ Hz and $V_0 = 3$ V, what is the power dissipated in Z_2?

▲ **FIGURE 33–36** Problem 83.



84. (II) Consider the circuit shown in Fig. 33–37. The emf has an amplitude of $V_0 = 12$ V and a frequency of 400 Hz; $L = 10$ mH, $C_1 = 20\ \mu$F, and $C_2 = 30\ \mu$F. Find (a) the maximum current in each leg, and (b) the resonant frequency.

▲ **FIGURE 33–37** Problems 84 and 85.

85. (II) Calculate (a) the maximum instantaneous voltage across each capacitor; and (b) the maximum instantaneous voltage across the inductor for the circuit shown in Fig. 33–37. Use the parameters specified in Problem 84.

86. (II) Write down the two equations that specify the currents I_1 and I_2 in the two loops of the circuit shown in Fig. 33–38.

▲ **FIGURE 33–38** Problem 86.

87. (II) A series *RLC* circuit is to be designed to have a resonant frequency of 18 MHz, and the curve of power versus frequency f is to have a full width of 4.0 kHz. If the only capacitor available has a capacitance of 33 pF, what must R and L be?

88. (II) A resistor with $R = 62\ \Omega$ draws a current from a wall plug; a capacitor is connected in parallel with this resistor. The current source has an amplitude of 110 V and a frequency of 60 Hz, and the reactance of the capacitor is 3 Ω at this frequency. What is the current drawn by the parallel combination?

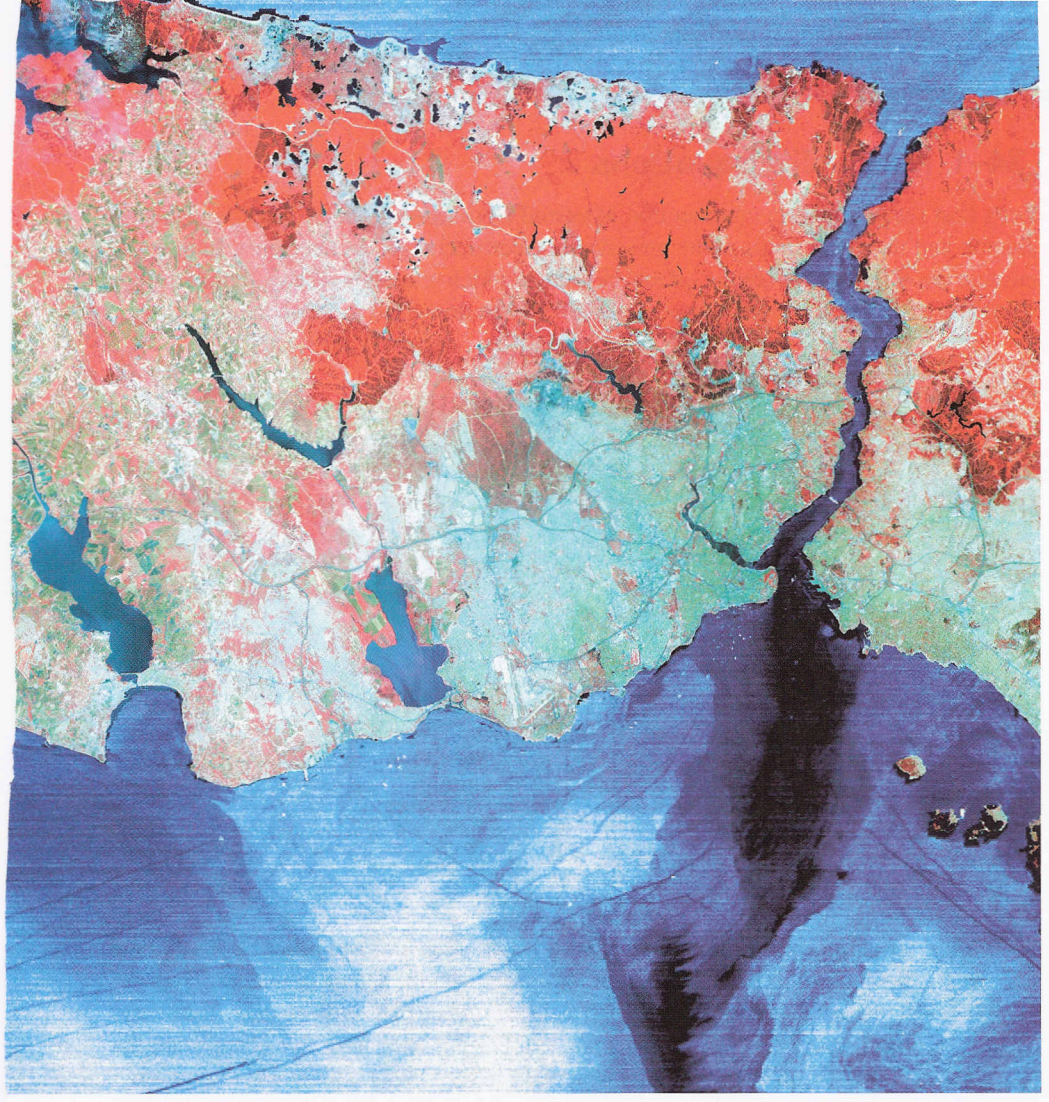
89. (II) A 15-μF capacitor connected in series with a resistor of variable resistance R is connected to a $V_{\text{rms}} = 110$-V, 60-Hz AC supply. Plot the variation of the rms current with R, and calculate the value of R for which the power delivered is maximum.

90. (II) An AC circuit supplies $V_{\text{rms}} = 220$ V at 60 Hz to a 10-Ω resistor, a 35-μF capacitor, and an inductor of variable self-inductance in the 30 mH to 300 mH range, all in series. The capacitor is rated to stand a maximum voltage of 1200 V. (a) What is the largest current possible that does no damage to the capacitor? (b) To what value can the self-inductance be safely set?

Problems with Complex Variables

In the following set of problems, we suppose there is an AC source of emf that produces a potential drop of the form $V_0 \sin(\omega t)$. In the complex variable technique, we work instead with the complex form $V_C(t) = V_0 \exp(i\omega t)$, with the instruction that the original potential drop is given by the imaginary part of this form, $\text{Im}[V_C(t)]$. All quantities with oscillating time dependence are given this treatment. Note: The subscript "C" here does not refer to a capacitor, but instead indicates a complex quantity.

91. (III) Consider a capacitive circuit, for which the loop rule takes the form $V_C(t) = Q_C(t)/C$. (a) Calculate $Q_C(t)$, and use it to calculate the complex current $I_C(t)$. (b) Show that the current $I(t)$ calculated according to the prescription at the head of these problems is identical to the one obtained in Eq. (33–12).



92. (III) Consider an inductive circuit, for which the loop rule takes the form $V_C(t) = L\, dI_C(t)/dt$. (a) Calculate $I_C(t)$ in two ways: (i) by direct integration of the equation; (ii) by noting that no matter how often the function $\exp(i\omega t)$ is differentiated with respect to time, the time dependence remains $\exp(i\omega t)$. (b) Show that the current $I(t)$ calculated according to the prescription at the head of these problems is the same as the one obtained in Eq. (33–18).

93. (III) In complex analysis, the loop rule for the series *RLC* circuit is $V_C(t) = L(dI_C(t)/dt) + Q_C(t)/C + RI_C(t)$. (a) Make use of the fact that the time dependence of $\exp(i\omega t)$ remains the same no matter how often it is differentiated with respect to time in order to calculate Q_{0C}, defined by $Q_C(t) = -iQ_{0C}e^{i\omega t}$. (b) Use the formula obtained for Q_{0C} to construct the complex quantities $Q_C(t)$ and $I_C(t)$. (c) Use the imaginary part prescription described at the head of these problems to calculate $Q(t)$ and $I(t)$.

94. (III) Consider the *RLC* circuit of Problem 93. Define the complex impedance Z_C to be $V_C(t)/I_C(t)$, and use the results of Problem 93 to show that Z_C is independent of time, with an absolute magnitude given by Eq. (33–32).

95. (III) Consider an *RLC* circuit without a driving emf, so that the loop rule reads $L(dI_C(t)/dt) + Q_C(t)/C + RI_C(t) = 0$. Solve this equation by using the substitution $Q_C(t) = Q_{0C}e^{i\omega t}$. Use the equation to obtain a value for ω. Show that your solution leads to the results of Eq. (32–32).

Maxwell's Equations and Electromagnetic Waves

Faraday's law shows that electricity and magnetism are fundamentally connected; James Clerk Maxwell's introduction in 1864 of the displacement current enhances this connection. We have a complete, consistent set of fundamental laws for electricity and magnetism, collectively known as Maxwell's equations. The individual experiments that led to the discovery and completion of each of these equations—Gauss' law for electric fields, Gauss' law for magnetic fields, Ampère's law, and Faraday's law—never hinted at the rich implications of Maxwell's equations taken *together*. The most dramatic prediction of the full set of Maxwell's equations is the existence of electromagnetic waves that propagate through empty space at a predictable speed—the speed of light. Light itself is such a wave. It is the intimate coupling between electric and magnetic fields that leads to these waves, with, in effect, one field generating the other in a self-sustaining way. In this chapter, we discuss the nature and properties of these *electromagnetic waves*: the orientation and relationship of the electric and magnetic fields contained in them, the energy and momentum they carry, and polarization. While these waves are described in terms of the mechanical waves we met in Chapters 14 and 15, they differ in a profound way in that they do not require a medium in which to propagate. This observation contains the seeds of Einstein's special relativity. We'll also see here how quantum physical phenomena intrude into the properties of classical electromagnetic waves.

▲ **FIGURE 34–1** An infinitesimal surface element $d\vec{A}$ on the closed surface S.

▲ **FIGURE 34–2** (a) A surface S bounded by the closed loop C. A current I passes through the surface. If the integration along C proceeds counterclockwise, (b) then the direction of the surface elements $d\vec{A}$ that make up S is given by a right-hand rule.

34–1 Maxwell's Equations

Let's first recall and then comment on **Maxwell's equations**, which fully describe the electric and magnetic fields in the presence of electric charges and currents. In this discussion we'll largely ignore the effects of matter, which although very well understood, would be a diversion from the important points to be described in this chapter.

I. Gauss' law for electric fields

$$\int_{\text{closed surface}} \vec{E} \cdot d\vec{A} = \frac{Q}{\varepsilon_0}. \tag{34–1}$$

II. Gauss' law for magnetic fields

$$\int_{\text{closed surface}} \vec{B} \cdot d\vec{A} = 0. \tag{34–2}$$

III. Generalized Ampère's law

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 I + \mu_0 \varepsilon_0 \frac{d}{dt} \int_{\text{surface}} \vec{E} \cdot d\vec{A}. \tag{34–3}$$

IV. Faraday's law

$$\oint \vec{E} \cdot d\vec{s} = -\frac{d}{dt} \int_{\text{surface}} \vec{B} \cdot d\vec{A}. \tag{34–4}$$

I. Gauss' law is equivalent to Coulomb's law in static situations and hence shows that the electric field due to a static charge varies inversely with the square of distance from the charge. It relates the electric flux through a closed surface (the surface can be imaginary) to the charge enclosed [see, for example, Eq. (23–7)] and states that charges are the sources of electric field. The surface element $d\vec{A}$ in Eq. (34–1) is normal to the surface S and is directed outward with magnitude dA (Fig. 34–1). The charge Q is the total charge contained within the closed surface. The factor ε_0 (the permittivity of free space) is associated with our choice of units. Gauss' law holds even for time-dependent electric fields.

II. Magnetic monopoles—which would be the magnetic analogues of electric charge—have never been discovered. Their nonexistence leads to Gauss' law for magnetic fields [Eq. (29–12)], which states that the flux of the magnetic field through a closed surface is zero, implying that magnetic field lines have no beginning or ending. This equation also holds even for time-dependent magnetic fields.

III. Ampère's law states that magnetic fields arise from currents or changing electric fluxes. The left-hand side of this equation is the expression for the integral of the magnetic field's tangential component along an arbitrary closed loop C (Fig. 34–2). The right-hand side has two contributions: One is the total current flowing through any surface S bounded by the closed loop C; the other is the rate of change of the electric field flux through such a surface, the displacement current contribution. As we described in Chapter 29 [see Eq. (29–31)], Maxwell was responsible for introducing the displacement current. As you can review in Chapter 29, he did this to fill a gap in the logic of Ampère's law. The presence of the parameter μ_0 (the permeability of free space) is a consequence of SI units.

IV. Faraday's law describes the induced electric field loop generated by a changing magnetic flux [see Eq. (30–2)] and shows that the electric field encircles any area in which the magnetic flux is changing. The left-hand side is the integral of the tangential component of the induced electric field around an arbitrary closed loop C. The right-hand side measures the rate of change of the magnetic flux through any surface S bounded by C, just as in Fig. 34–2. Equation (34–4), as well as Eq. (34–3), implies a sign convention given by a right-hand rule. The minus sign is very important: It represents the fact that the induced electric field, were it to act on charges, would give rise to an induced current that opposes the change in the magnetic flux (Lenz's law).

The four Maxwell equations display a degree of symmetry between electric and magnetic fields. This symmetry is not perfect, because magnetic monopoles apparently do not exist. Faraday's law contains no term like the $\mu_0 I$ term in Ampère's law, because there is no free magnetic charge to form a magnetic current. In a vacuum there are neither currents nor charges, and then the symmetry between $\vec{E}$ and $\vec{B}$ is complete. This is a situation in which the propagation of electromagnetic waves occurs.

In the presence of matter, Maxwell's equations are modified. Assuming that we don't have to deal with boundaries between different materials, then for most types of materials we can simply replace ε_0 by $\varepsilon = \kappa\varepsilon_0$, where κ is the dielectric constant. Except for ferromagnetic materials, μ is very close to μ_0, so that the additional rule that the permeability of the vacuum (μ_0) is to be replaced by the material's permeability (μ) does not much affect things.

34–2 Electromagnetic Waves

Equations (34–3) and (34–4) clearly show that time-dependent electric and magnetic fields influence each other; they are said to be *coupled*. As a consequence of this coupling, electric and magnetic fields can transport energy (and momentum) over much larger distances than might be suggested by the $1/r^2$ falloff of the electric field in Coulomb's law or the magnetic field in the Biot–Savart law. As we shall see, the coupled fields transport energy through traveling waves called **electromagnetic waves**. These waves are all around us in the form of radio, television, and cell phone signals, microwaves, visible light, and X rays, for example. In fact, electromagnetic waves can be produced with essentially an unlimited range of wavelength or frequency, and the examples listed above just correspond to different wavelength or frequency ranges.

The following argument conveys the physical mechanism by which the electric and magnetic fields couple and electromagnetic waves propagate. Consider a straight wire that is aligned with the x-axis and carries a time-varying current I (Fig. 34–3a). A magnetic field encircles the wire; if the current changes with time, so does the magnetic field. As the current increases, so does the magnetic field. As the magnetic field increases, so does the magnetic flux through an area A_1 in the xz-plane. According to Faraday's law, Eq. (34–4), a changing magnetic flux induces an emf around the boundary of this area. This emf is associated with the induced electric field shown in Fig. 34–3b. Lenz's law determines the orientation of the field. (Note that while we have drawn electric fields in this figure, all that Faraday's law really tells is that an induced electric field is present whose integral along the boundary is given. The drawn electric fields are simply present to help you follow this argument more closely. Later we'll see how to tighten up the argument.)

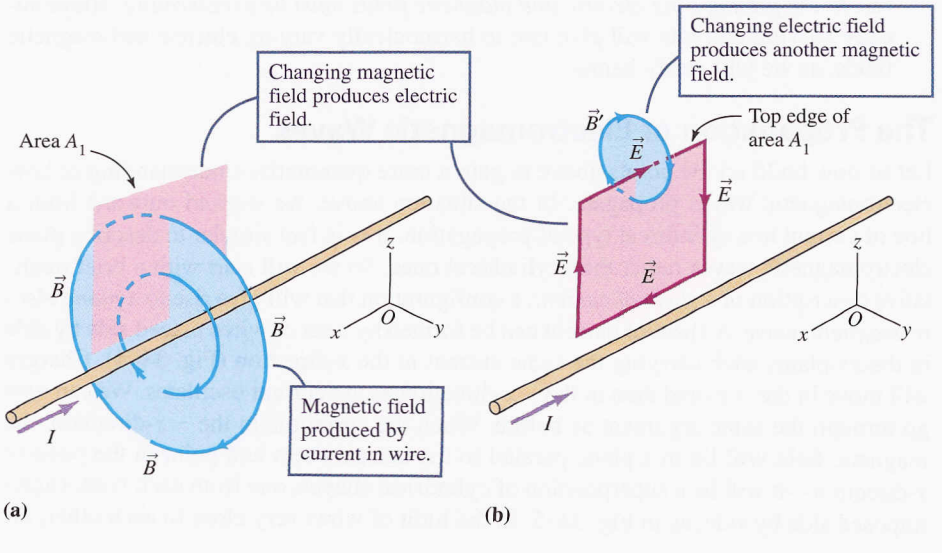

FIGURE 34–3 (a) As we know from Ampère's law, a current-carrying wire aligned in the x-direction has a magnetic field that forms circles in the yz-plane. (b) If the current in the wire changes with time, the magnetic field it produces changes with time, inducing a changing electric field, which in turn induces a changing secondary magnetic field, and so forth.

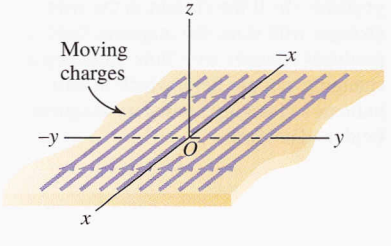
Let's consider now the top edge of area A_1. Along that edge, the electric field has been induced in the $-x$-direction. This induced electric field is time varying because it is due to a changing magnetic field; at the instant shown in our example, the electric field is increasing. Now, according to the generalized Ampère's law, Eq. (34–3), we do not need flowing charges to induce a magnetic field. *A changing electric field also produces a magnetic field by giving rise to a displacement current* (Section 29–5). The displacement current in this case is along the direction of the changing electric field, which is the direction of the original current. The displacement current, however, is spread through space rather than localized at the wire like the original current. In particular, there is a displacement current away from the location of the original current. At this point, we can begin to see how the propagation works: The displacement current produces a secondary magnetic field $\vec{B}'$ at still larger values of z (Fig. 34–3b). The field $\vec{B}'$ is perpendicular to the xz-plane. Because the displacement current varies with time, $\vec{B}'$ is also changing. Therefore this secondary magnetic field produces an induced emf aligned in the x-direction at still larger values of z, and the process repeats itself to larger and larger z values.

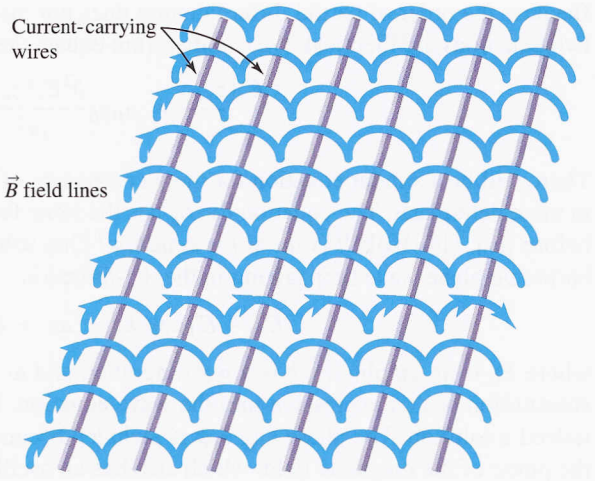


We could have taken our plane area A_1 to intersect the cylinder around the wire at any angle relative to the z-axis, since our picture is symmetric about the x-axis. The same sequence of events results from the coupling however we rotate our figure about the x-axis. This means that when we use the words "larger value of z," we really mean "larger value of the perpendicular distance from the wire." As the current changes with time, so do the secondary fields $\vec{B}'$. We therefore have electric and magnetic fields that *propagate* on the surface of an ever growing cylinder whose axis lies along the wire.

CONCEPTUAL EXAMPLE 34–1 Suppose the current oscillates for a while and is then turned off. What happens to the fields?

Answer If you look at the discussion above, you can see that to learn about a field farther from the wire, we discuss the fields closer to the wire, not the current itself. The induced electric field, the secondary magnetic field whose source is the displacement current due to this induced electric field, and all their successors have acquired a life of their own. While they were initially created by the current in the wire, the fields have detached themselves from their original source and are propagating "alone." If the current is turned off at some time $t = T$, then from that moment on, no new fields are produced, but the fields produced earlier continue their cylindrical propagation outward.

What qualitative conclusions can we can draw from this discussion?



1. With the changing current *restricted to a line*, the fields propagate with cylindrical symmetry outward from the current line. The electric field is aligned parallel to the current, and the magnetic field is aligned perpendicular to both the electric field and to the direction of propagation. *These are general features of electromagnetic waves.*
2. The current must change in time if it is to give rise to propagating fields, as a steady current merely produces a static magnetic field. We can translate this into a statement about the charges whose flow gives rise to the current: *The charges that give rise to the propagating electric and magnetic fields must be accelerating*. Harmonically varying currents will give rise to harmonically varying electric and magnetic fields, as we will verify below.

▲ **FIGURE 34–4** Current flows in a sheet along the $-x$-direction. It can be approximated by aligning wires side by side in the x-direction. If the current is oscillatory, charges move first in the $-x$-direction, then in the $+x$-direction.

The Propagation of Electromagnetic Waves

Let us now build on the points above to gain a more quantitative understanding of how electromagnetic waves propagate. In the situation above, we worked outward from a line of current to a cylindrical type of propagation. It is in fact simpler to describe plane electromagnetic waves rather than cylindrical ones. So we will start with a brief qualitative description of a *sheet of current*, a configuration that will give rise to a *plane electromagnetic wave*. A sheet of current can be formed by a set of wires placed side by side in the xy-plane, each carrying the same current in the x-direction (Fig. 34–4). Charges will move in the $+x$- and then in the $-x$-direction as the current oscillates. We can now go through the same argument as before. When the current is in the $-x$-direction, the magnetic field will lie in a plane parallel to the current sheet and point in the positive y-direction—it will be a superposition of cylindrical shapes, one from each wire, superimposed side by side, as in Fig. 34–5. In the limit of wires very close to each other, the

◀ **FIGURE 34–5** In the limit that the wires carrying the current are close to one another, the magnetic field of a series of closely spaced and parallel currents forms planes parallel to the plane of the currents.

field lines of the net magnetic field form a corrugated surface; taking the wires still closer to one another, the field forms two planes, one above the current sheet and the other the same distance away below the current sheet. The electric field will also lie in a plane parallel to the current sheet, and point in the direction of the current. These fields in turn lead to other fields, and if you follow the same argument that we made for the single wire, you will find that these fields will propagate in the z-direction (both + and −), perpendicular to the sheet. These fields will depend on time in a way that mirrors the time dependence of the current. The electromagnetic fields form *plane waves*, which we recall from Chapters 14 and 15 refers to waves that advance along planar wave fronts—in this case, planes parallel to the xy-plane.

To understand quantitatively how we can get fields that behave like this, we assert that Maxwell's equations—in particular, Faraday's law and the generalized Ampère's law—are equivalent to a set of differential equations for the components of these fields. Not surprisingly, these are *coupled* differential equations—how the magnetic field changes determines how the electric field changes and vice versa. We derive these equations in the Appendix to this chapter on p. 967. Here, in order to get directly to plane waves propagating in the z-direction, we write them down for the special case of fields that are independent of x and y, but which do depend on z and, of course, on the time t. The components B_y and E_x in particular satisfy

$$-\frac{\partial B_y(z,t)}{\partial z} = \mu_0\varepsilon_0\frac{\partial E_x(z,t)}{\partial t} \tag{34–5}$$

and

$$-\frac{\partial B_y(z,t)}{\partial t} = \frac{\partial E_x(z,t)}{\partial z}. \tag{34–6}$$

Although a changing current was necessary to produce the initial changing fields, these equations are not directly dependent on that current—this is what we meant when we said that the fields take on "a life of their own." The field components B_y and E_x both depend on the value of z and on the time t. (Recall that partial derivatives appear whenever quantities such as fields depend on two or more variables. In taking a partial derivative with respect to one variable, the other variables are held fixed.)

Equations (34–5) and (34–6) lead directly to wave equations for the field components. These two equations couple the two fields. We can combine and simplify them by a straightforward procedure. The partial derivative of Eq. (34–5) with respect to time gives

$$-\frac{\partial^2 B_y(z,t)}{\partial t\,\partial z} = \mu_0\varepsilon_0\frac{\partial^2 E_x(z,t)}{\partial t^2}.$$

Similarly, the partial derivative of Eq. (34–6) with respect to z gives

$$-\frac{\partial^2 B_y(z,t)}{\partial z\,\partial t} = \frac{\partial^2 E_x(z,t)}{\partial z^2}.$$

Because the order of partial differentiation does not matter, the left-hand sides of these two equations are identical. We can therefore equate the right-hand sides:

$$\frac{\partial^2 E_x(z,t)}{\partial z^2} = \mu_0 \varepsilon_0 \frac{\partial^2 E_x(z,t)}{\partial t^2}. \tag{34–7}$$

There will be a similar equation for the y-component of the magnetic field, as we'll see in more detail later. The equation for E_x has the same form as an equation we have seen before [Eq. (14–10)]: *It is the wave equation!* One solution of this wave equation is a harmonic plane wave propagating in the $+z$-direction:

$$E_x = E_0 \cos(kz - \omega t + \phi), \tag{34–8}$$

where E_0 is an amplitude, k is a wave number, and ω is an angular frequency. Direct substitution of this expression into the wave equation, Eq. (34–7), will verify that it is indeed a solution. The phase angle ϕ is included because we shall want to look at how the phase of the magnetic field, which also has an oscillating solution, is related to that of the electric field. It is important to understand what this equation means: the electric field has an x-component (always aligned along the x-axis), and that component changes as one looks at different values of z and t.

The Propagation Speed of Electromagnetic Waves

We recall from our discussion in Chapter 14 of wave motion that Eq. (34–8) represents a wave of wavelength $\lambda = 2\pi/k$ and frequency $f = \omega/2\pi$. The propagation speed is $v = \lambda f = \omega/k$. This speed is found immediately from the wave equation itself, as comparison with the original form of the wave equation, Eq. (14–10), shows. We have

$$v^2 = \frac{1}{\mu_0 \varepsilon_0}. \tag{34–9}$$

When we use the numerical values for μ_0 and ε_0, we find

$$v^2 = \frac{1}{(1.257 \times 10^{-6}\ \mathrm{T \cdot m/A})(8.854 \times 10^{-12}\ \mathrm{C^2/N \cdot m^2})} = 8.999 \times 10^{16}\ \mathrm{m^2/s^2}$$
$$= (3.00 \times 10^8\ \mathrm{m/s})^2.$$

Maxwell recognized that the magnitude of v is the *speed of light c!* One of the most commonplace of all the physical phenomena around us, light, was now explained in terms of the laws of electricity and magnetism, or more properly, electromagnetism. This surely represents one of the greatest discoveries of science, equal in every way to Newton's understanding of gravitation. (And there was more, much more, to come from Maxwell's equations, including special relativity and a great portion of today's technology.) Equation (34–9) tells us that the speed of light is determined by constants of the equations of electromagnetism:

$$c = \frac{1}{\sqrt{\mu_0 \varepsilon_0}}. \tag{34–10}$$

ELECTROMAGNETIC WAVE SPEED IN EMPTY SPACE

What distinguishes *visible* light? The wavelengths of electromagnetic waves are not restricted to any particular value or set of values. The kinds of experiments with optics that we'll be discussing later in the book show that what we call visible light corresponds to a limited range of wavelengths for which, through evolutionary adaptation, our eyes have become particularly good detectors. This range of wavelength is one in which the Sun emits radiation strongly and for which the waves pass easily through the atmosphere. Within this visible spectrum, we interpret different wavelengths as colors. The shortest wavelengths of the visible spectrum are violet; the longest wavelengths are red. The speed which Maxwell confirmed was the speed of visible light, because that was the phenomenon that to that point had been, quite literally, visible and whose speed

had been measured. But Maxwell's discovery opens a door onto the full spectrum of electromagnetic radiation, a subject we'll discuss more fully later in this section.

Keep in mind the important relation $v = \lambda f$ between speed, wavelength, and frequency. If the speed of propagation is fixed, as it is in empty space, then wavelength and frequency have an inverse relation, with large wavelengths corresponding to small frequencies and vice versa.

The Relation Between *E* and *B* in an Electromagnetic Wave

To see how E and B for an electromagnetic wave are related, we can start with Eqs. (34–5) and (34–6) and show that B_y also obeys a wave equation similar to that of E_x; namely,

$$\frac{\partial^2 B_y(z,t)}{\partial z^2} = \mu_0\varepsilon_0 \frac{\partial^2 B_y(z,t)}{\partial t^2}.$$

Like the x-component of the electric field, the y-component of the magnetic field forms a wave that propagates at speed c in the z-direction. However, because Eqs. (34–5) and (34–6) couple the fields, the waves of B_y do not propagate independently from those of E_x. If we have a wave solution for E_x, Eq. (34–8), then from Eq. (34–5),

$$\begin{aligned}\frac{\partial B_y}{\partial z} &= \mu_0\varepsilon_0 \frac{\partial E_x}{\partial t} = -\mu_0\varepsilon_0 \frac{\partial}{\partial t}[E_0 \cos(kz - \omega t + \phi)] \\ &= -\mu_0\varepsilon_0\omega E_0 \sin(kz - \omega t + \phi).\end{aligned} \tag{34–11}$$

Equation (34–6) becomes

$$\frac{\partial B_y}{\partial t} = -\frac{\partial E_x}{\partial z} = -\frac{\partial}{\partial z}[E_0 \cos(kz - \omega t + \phi)] = kE_0 \sin(kz - \omega t + \phi). \tag{34–12}$$

From these two expressions for the derivatives of B_y, it is easy to check that the following equation has the correct spatial and time dependence:

$$B_y = B_0 \cos(kz - \omega t + \phi). \tag{34–13}$$

Relations Between Amplitudes: The amplitude B_0 of the magnetic field wave is not independent of the amplitude E_0 of the electric field wave, as Example 34–2 shows.

EXAMPLE 34–2 Consider the electromagnetic traveling wave for which the electric and magnetic fields are given by Eqs. (34–8) and (34–13). Use the derivative relations we have found to show that the amplitudes are related by $E_0 = cB_0$.

Setting It Up Here we are proving a relation between the two coupled quantities E and B, so we must use the equations that couple them.

Strategy Equation (34–11) relates a derivative of B_y to a derivative of E_x. With E_x given by Eq. (34–8), and B_y given by Eq. (34–13), we can compute the partial derivative of B_y with respect to z using Eq. (34–11), and we can compute it directly. Comparing these two results will give us information about the magnitude of the amplitudes as well as the phases.

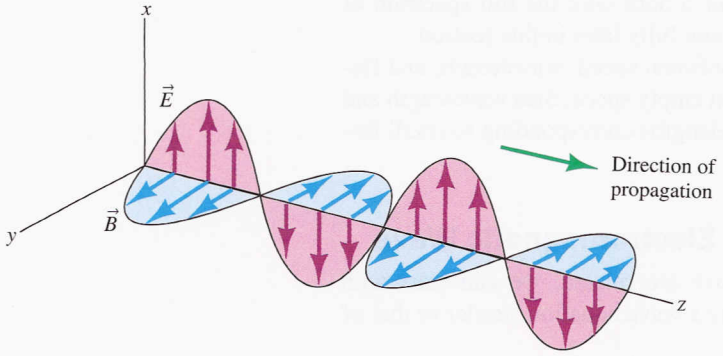
Working It Out We have from Eq. (34–11) with E_x given by Eq. (34–8)

$$\frac{\partial B_y}{\partial z} = -\mu_0\varepsilon_0\omega E_0 \sin(kz - \omega t + \phi).$$

With B_y given by Eq. (34–13), we can compute the partial derivative directly:

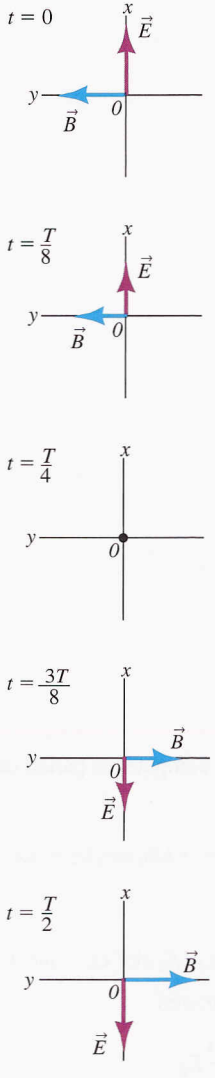
$$\frac{\partial B_y}{\partial z} = \frac{\partial}{\partial z}[B_0 \cos(kz - \omega t + \phi)] = -kB_0 \sin(kz - \omega t + \phi).$$

We equate these two results:



$$-kB_0 \sin(kz - \omega t + \phi) = -\mu_0\varepsilon_0\omega E_0 \sin(kz - \omega t + \phi).$$

The sine factor cancels, and we are left with



$$B_0 = \frac{\mu_0\varepsilon_0\omega}{k} E_0.$$

The factor $\omega/k = c$, whereas $\mu_0\varepsilon_0 = 1/c^2$, so we are left with $B_0 = E_0/c$, the relation we needed to show.

What Do You Think? Suppose the wave in this example impinges on a metal sheet in which there are free electrons. Will it be the electric field or the magnetic field that predominantly determines the motion of the electrons? [*Hint:*Think about the size of B_0.] *Answers to* ***What Do You Think?*** *questions are given in the back of the book.*

(a)

(b)

▲ **FIGURE 34–6** (a) A view at one particular time of the transverse electric and magnetic fields that propagate along the z-axis. (b) A view downward from the $+z$-direction of the electric and magnetic fields of an electromagnetic wave in an xy-plane at one particular z-value over time.

In the example above, we did not mention the currents that set up the original wave, and in fact the relation between the electric and magnetic field amplitudes in an electromagnetic wave is independent of those currents. We have, in general,

$$E = cB, \tag{34–14}$$

RELATION OF FIELD AMPLITUDES

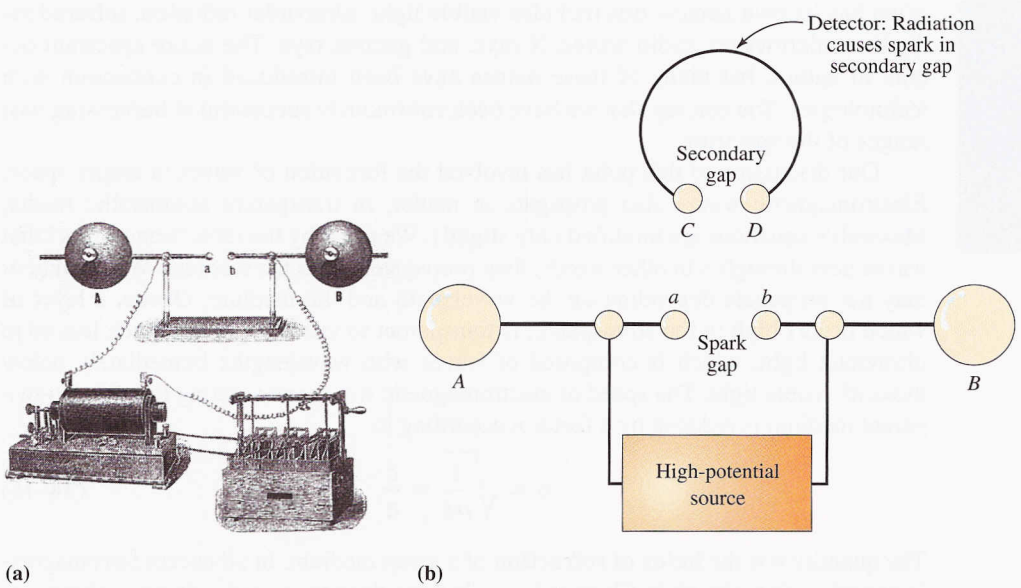
where E and B are the amplitudes of the fields in an electromagnetic wave.

The Transversality of Electromagnetic Waves: The fields described by Eqs. (34–8) and (34–13) and pictured in Fig. 34–6 form traveling waves that propagate in the z-direction. Even though the fields are oriented in the x- and y-directions, they do not depend on x or y—we are describing plane waves, as we stated earlier. The currents that we used to set up the waves in the first place guarantee that the waves will be plane waves, and by changing the originating current, we can form other configurations of waves. In particular, there is nothing special about the x- and y-directions. If we had set up our currents to run in the y- rather than the x-direction, we would have found another set of solutions, with $\vec{E}$ in the y-direction and $\vec{B}$ in the x-direction. The wave propagation would still have been in the z-direction. It is generally true that *the electric field and the magnetic field in an electromagnetic wave are perpendicular to each other*,

$$\vec{E} \cdot \vec{B} = 0. \tag{34–15}$$

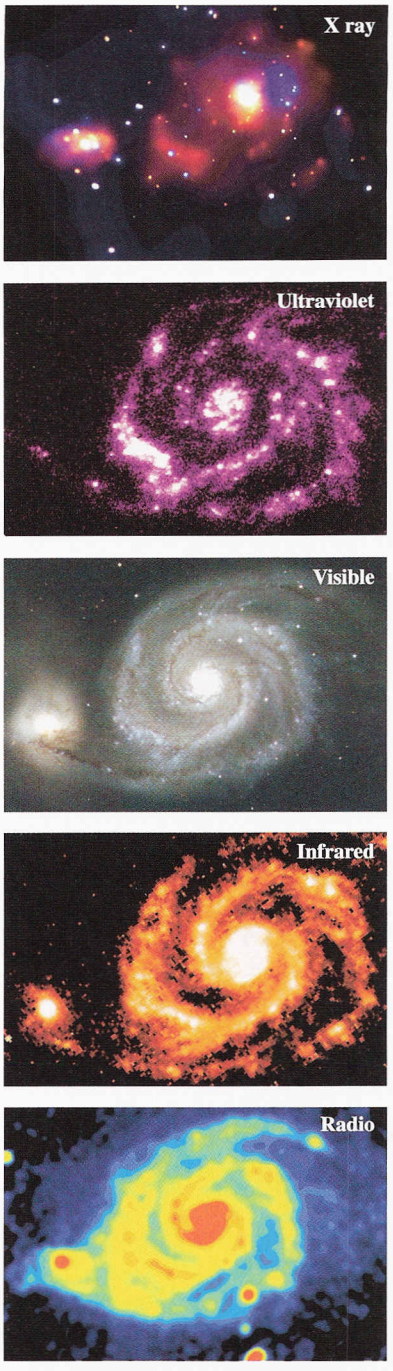
ORTHOGONALITY OF FIELDS

Moreover, an electromagnetic wave is *transverse* because the direction of the fields involved is perpendicular to the direction of wave propagation. *Neither the electric field nor the magnetic field has a component in the direction of propagation of the wave* (Fig. 34–6). We saw that both of these properties hold for the cylindrical wave emanating from the wire at the beginning of this discussion. We will limit ourselves to the plane and cylindrical wave discussions, but it is not difficult to see that these properties hold generally.



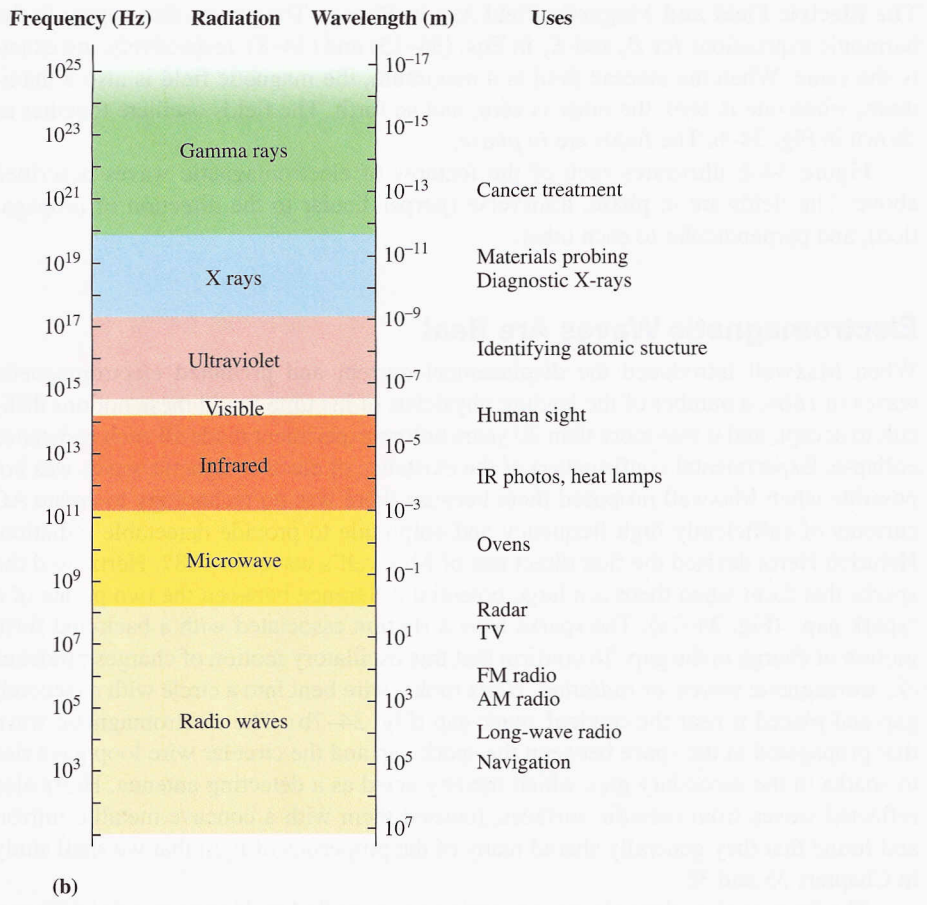
The Electric Field and Magnetic Field Are in Phase: The phases that appear in the harmonic expressions for B_y and E_x in Eqs. (34–13) and (34–8), respectively, are exactly the same. When the electric field is a maximum, the magnetic field is also a maximum; when one is zero, the other is zero, and so forth. The fields oscillate together as shown in Fig. 34–6. The fields are *in phase*.

Figure 34–6 illustrates each of the features of electromagnetic waves described above: The fields are in phase, transverse (perpendicular to the direction of propagation), and perpendicular to each other.



Electromagnetic Waves Are Real

When Maxwell introduced the displacement current and predicted electromagnetic waves in 1864, a number of the leading physicists of his time found these notions difficult to accept, and it was more than 20 years before experiment made all such resistance collapse. Experimental confirmation of the existence of electromagnetic waves was not possible when Maxwell proposed them because there was no technology to create AC currents of sufficiently high frequency and amplitude to provide detectable radiation. Heinrich Hertz devised the first direct test of Maxwell's waves in 1887. Hertz used the sparks that form when there is a large potential difference between the two points of a "spark gap" (Fig. 34–7a). The sparks have a rhythm associated with a back-and-forth motion of charge in the gap. To confirm that this oscillatory motion of charges produces electromagnetic waves, or *radiation*, Hertz took a wire bent into a circle with a (second) gap and placed it near the original spark gap (Fig. 34–7b). The electromagnetic wave that propagated in the space between the spark gap and the circular wire loop gave rise to sparks in the secondary gap, which thereby acted as a detecting antenna. Hertz also reflected waves from metallic surfaces, focused them with a concave metallic mirror, and found that they generally shared many of the properties of light that we shall study in Chapters 35 and 36.



The frequencies of the electromagnetic waves studied by Hertz are quite different from the frequencies of the waves that form visible light. The wave equation for electromagnetic waves admits solutions for *any* frequency, and the collection of all frequencies is known as the **electromagnetic spectrum**. In the century since Hertz's

▲ **FIGURE 34–7** (a) Hertz's apparatus for the detection of electromagnetic radiation. (b) Schematic diagram of Hertz's apparatus. The radiation propagates from the region between the oscillating spark *ab* to the gap *CD*, which detects the radiation produced at gap *ab* by forming its own sparks.

(a)

(b)

▲ **FIGURE 34–8** (a) These spectacular photos taken of the Whirlpool galaxy reveal different details, because they record radiation in different frequency ranges. (b) Different frequency regions of the full spectrum of electromagnetic radiation have specific names, as well as uses.

work, the electromagnetic spectrum has been explored across an enormous range of frequencies (Fig. 34–8). The radiation corresponding to a given part of the spectrum often has its own name—this includes visible light, ultraviolet radiation, infrared radiation, microwaves, radio waves, X rays, and gamma rays. The entire spectrum occurs in nature, but many of these names have been introduced in connection with technologies. You can say that we have been enormously successful at harnessing vast ranges of the spectrum.

Our discussion to this point has involved the formation of waves in empty space. Electromagnetic waves also propagate in matter. In transparent nonmetallic media, Maxwell's equations are modified only slightly. We mean by the term "transparent" that waves pass through—in other words, they propagate within the medium. Waves may or may not propagate depending on the wavelength and the medium. Ozone, a layer of which occurs high in the atmosphere, is transparent to visible light but much less so to ultraviolet light, which is composed of waves with wavelengths immediately below those of visible light. The speed of electromagnetic waves propagating through a transparent medium is reduced by a factor n according to

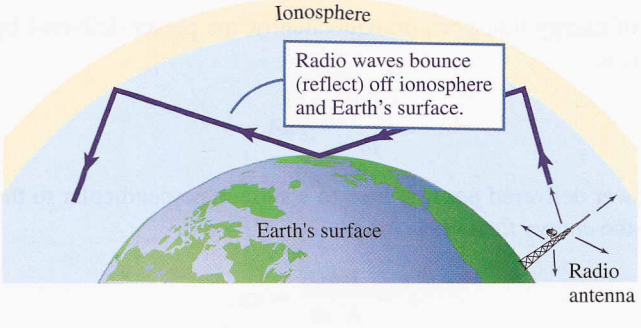
$$v = \sqrt{\frac{1}{\mu\varepsilon}} \equiv \frac{c}{n}. \tag{34–16}$$

The quantity n is the **index of refraction** of a given medium. In all except ferromagnetic materials (introduced in Chapter 31), μ is very close to μ_0 and $\varepsilon = \kappa\varepsilon_0$, where κ is the dielectric constant of the medium. Thus

$$v = \sqrt{\frac{1}{\mu_0\varepsilon_0\kappa}} = \frac{c}{\sqrt{\kappa}}; \tag{34–17}$$

in other words, the index of refraction $n = \sqrt{\kappa}$. It should be noted that the dielectric constant, and hence the wave speed, can depend on the frequency of the electromagnetic wave. When the speed of the wave depends on the frequency, the medium is said to be *dispersive*. The rainbow is an example of a phenomenon associated with dispersion.

THINK ABOUT THIS. . .



HOW DO RADIO WAVES TRAVEL AROUND THE GLOBE?

Driving at night in northern Minnesota, you may well hear a clear AM radio broadcast emanating from Florida. But the horizon seen from the antennas that produce these radio waves, which are electromagnetic radiation with wavelengths measured in tenths of kilometers, is substantially less than 100 km. The AM radio waves that you receive from so far away must travel through the atmosphere in what is effectively a curved path around Earth. The mechanism for this process lies in the *ionosphere*. This is a complex region of the atmosphere that extends from about 50 km to about 300 km from the ground. Short-wavelength radiation from the Sun and cosmic-ray particles that strike the upper atmosphere are energetic enough to separate some electrons from the atoms in this region, and this process of *ionization* leads to the presence of some *free electrons* in the ionosphere, forming a gas of electrons and ions known as a *plasma*. The structure of the ionosphere is that of a series of layers, with the most persistent ionization in the upper layers.

Radio waves that arrive at the ionosphere cause the free electrons to oscillate, and we have already pointed out that an accelerating charge produces radiation. This reradiation makes waves whose frequency matches the frequency of the oscillating charge. It sends back radio waves like those that have impinged on the plasma—we can refer to this as reflection. Through a process that involves the group behavior of large numbers of free electrons in the plasma, strong reflection occurs over a limited range of frequencies: Only radiation with a frequency below what is called the *plasma frequency* is reflected, or, in other words, radiation with wavelengths above a certain limit. The plasma is transparent to waves above that frequency. Now the plasma frequency varies with the density of free electrons n_e as $\sqrt{n_e}$, and for typical numbers in the ionosphere the plasma frequency is of the order of 10^7 Hz. This frequency is in the range of FM radio transmission but a factor of 100 above the frequency range of AM transmission. Thus AM radio signals are well reflected by the ionosphere, whereas FM signals pass through it. This allows AM signals to "bounce" their way to other locations through successive reflections from the bottom of the ionosphere and Earth's surface (Fig. 34–9).

Where, then, does the day–night difference come in? During the day, the Sun's radiation creates ionization. At night, when there is no ionizing radiation from the Sun, electrons recombine with their parent ions, and the ionosphere's composition changes. In particular, the lowest layer of the ionosphere, the layer from 50 km to 100 km high, essentially disappears as a plasma. The layer from which the radio waves reflect is now at a much higher altitude than during the day, and many fewer bounces are needed to reach a distant location. Since some energy is lost from the wave with each bounce, the distance the wave will travel at night is greatly increased over the distance it travels during the day.

The entire subject of the relation between the ionosphere and different communication bands (ranges of wavelength) is a rich one, and today's technologies make extensive use of knowledge about these effects.

▲ **FIGURE 34–9** For a certain range of frequencies the waves emitted by an antenna will be reflected back toward Earth by the ionosphere. That range includes AM radio waves.

34–3 Energy and Momentum Flow

The Energy of Electromagnetic Waves

We can get sunburned because electromagnetic waves carry energy. We can calculate the energy in electromagnetic waves from our earlier results, in particular Eq. (32–17), on the energy density in electric and magnetic fields:

$$u = \frac{1}{2}\left(\frac{B^2}{\mu_0} + \varepsilon_0 E^2\right) = \frac{\varepsilon_0}{2}\left(\frac{B^2}{\mu_0\varepsilon_0} + E^2\right) = \frac{\varepsilon_0}{2}(c^2B^2 + E^2). \quad (34\text{–}18)$$

Let's apply this result to an electromagnetic wave traveling in the z-direction. The fields are given by Eqs. (34–8) and (34–13):

$$E_y = E_0 \cos(kz - \omega t + \phi) \quad \text{and} \quad B_x = -B_0 \cos(kz - \omega t + \phi),$$

where $E_0 = cB_0$. For this wave, the energy density is

$$u = \frac{\varepsilon_0}{2}(c^2B_0^2 + E_0^2)\cos^2(kz - \omega t + \phi). \quad (34\text{–}19)$$

In this expression, the two terms are the contributions of the magnetic and electric parts of the wave, respectively. Because $E_0 = cB_0$, *the energy contained in an electromagnetic wave is shared equally between the magnetic field and the electric field.* Equivalently, we could take the contribution of either the electric or the magnetic terms and multiply by 2 to find the total energy density in an electromagnetic wave:

$$u = \varepsilon_0 E^2 = \frac{1}{\mu_0}B^2. \quad (34\text{–}20)$$

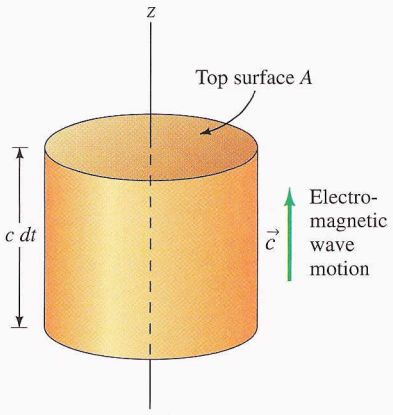
For practical purposes, the oscillations in electromagnetic waves are so rapid that we can simply consider the average of the energy density over one period, which we write as $\langle u \rangle$. The average of the cosine-squared factor in Eq. (34–19) over one period is one-half, so that

$$\langle u \rangle = \frac{\varepsilon_0}{2}E_0^2 = \frac{1}{2\mu_0}B_0^2. \quad (34\text{–}21)$$

The Transport of Energy

The $\cos^2(kz - \omega t + \phi)$ time and space dependence of the energy density in Eq. (34–19) shows that the energy in an electromagnetic wave is itself *transported* as a wave; it travels at speed $v = \omega/k = c$ in the z-direction. The amount of energy dU_t transported across a surface of area A perpendicular to the transport direction in a time interval dt is the energy contained in the volume of area A times the distance $c\,dt$ (Fig. 34–10); that is, the energy density u times this volume,

$$dU_t = u(Ac\,dt).$$



Thus the rate of energy transport, or, equivalently, the power delivered by the electromagnetic wave, is

$$\frac{dU_t}{dt} = cuA.$$

Finally, the power delivered per unit area to a surface perpendicular to the direction of propagation—the *energy flux*—is given by

$$S = \frac{1}{A}\frac{dU_t}{dt} = cu. \quad (34\text{–}22)$$

This flux has a direction associated with it and is more properly described as a vector. The vector $\vec{S}$ that describes the energy flux is the **Poynting vector**, given by

▲ **FIGURE 34–10** Electromagnetic energy contained in a volume $Ac\,dt$ is delivered in time dt to the area A.

$$\vec{S} = \frac{1}{\mu_0}\vec{E} \times \vec{B}. \qquad (34\text{–}23)$$

THE POYNTING VECTOR

Let's check that the magnitude and direction of the vector $\vec{S}$ are indeed correct. Because the fields $\vec{E}$ and $\vec{B}$ are at right angles to each other, we notice that the magnitude of $\vec{S}$ is just EB/μ_0. This can be rewritten in terms of the electromagnetic energy density, $u = \varepsilon_0 E^2$, as

$$S = \frac{1}{\mu_0}EB = \frac{\varepsilon_0}{\varepsilon_0\mu_0}E\left(\frac{E}{c}\right) = \varepsilon_0 c^2\frac{E^2}{c} = c\varepsilon_0 E^2 = cu. \qquad (34\text{–}24)$$

This is the same magnitude we found in Eq. (34–22). As for the direction, recall that the vector product of two vectors is perpendicular to both of them. From Fig. 34–6, we see that the direction of the vector product $\vec{E} \times \vec{B}$ is the $+z$-direction, the direction of wave propagation. More generally, the transversality of the electromagnetic wave will always lead to a Poynting vector that lies along the direction of propagation.

The energy density and the magnitude of the Poynting vector each vary with time. The value of the magnitude of $\vec{S}$ time-averaged over one cycle of the electromagnetic wave is called the **intensity** I of the radiation. Equation (34–24) allows us to relate the intensity to the amplitude E_0 of the electric field in the wave:

$$I = \langle S \rangle = c\varepsilon_0\langle E^2 \rangle = \frac{1}{2}c\varepsilon_0 E_0^2. \qquad (34\text{–}25)$$

Note from Eq. (34–21) that the intensity is also related to the average energy density in the wave, $I = c\langle u \rangle$.

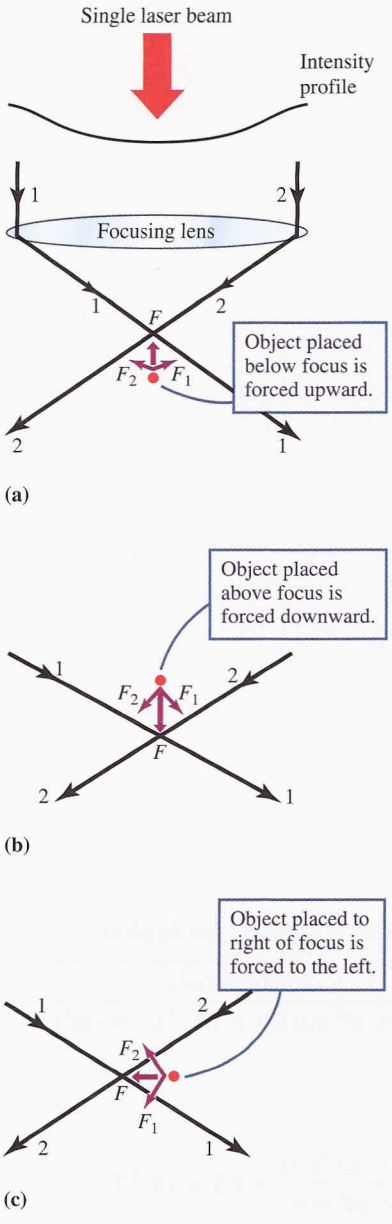
EXAMPLE 34–3 A characteristic number for the rate per unit area at which solar energy is delivered to a spot on Earth's surface is 1000 W/m^2. (This energy consists mainly of electromagnetic radiation in the visible range of wavelengths.) Use this number to estimate the amplitude of the electric and magnetic fields in the waves that deliver this energy.

Strategy We use the fact that the power (energy per unit time) delivered by an electromagnetic wave per unit area is S, whose average value is simply related to the square of the amplitude of the electric field. This result is independent of the wavelength of the radiation. More particularly, the equation $I = \langle S \rangle = \frac{1}{2}c\varepsilon_0 E_0^2$ gives the electric field amplitude in terms of the power delivered per unit area—we can solve this for E_0. Once this is calculated, we can easily obtain B_0 using $B_0 = E_0/c$.

Working It Out The relation between I and E_0 gives

$$E_0 = \sqrt{\frac{2I}{c\varepsilon_0}} = \sqrt{\frac{2(1000\ \text{W/m}^2)}{(3 \times 10^8\ \text{m/s})(9 \times 10^{-12}\ \text{C}^2/\text{N}\cdot\text{m}^2)}}$$
$$= 0.9 \times 10^3\ \text{V/m}.$$

In turn,



$$B_0 = \frac{E_0}{c} = \frac{0.9 \times 10^3\ \text{V/m}}{3 \times 10^8\ \text{m/s}} = 0.3 \times 10^{-5}\ \text{T}.$$

What Do You Think? An inventor seeking financing claims that he can block just the electric field in a light wave, leaving all the power in the magnetic field. Should you invest?

CONCEPTUAL EXAMPLE 34–4 Compare the electric field in sunlight to the electric field in the beam of a 0.1-W laser that covers an area of 1 cm^2. (The laser rating is the power in the beam.)

Answer The field is proportional to $\sqrt{I}$. For sunlight I is known to be 1000 W/m^2, and for the laser it is (0.1 W)/(1 cm^2) = 10^3 W/m^2. The fields will be comparable.

Lasers with much higher power than the one in the example above can generate fields strong enough to rip atoms apart! On a less dramatic level, an interesting device makes direct use of the electric fields in light for manipulation of large molecules and nanostructures. In the *optical tweezers*, a laser beam is focused to a very sharp point; the rms electric field is largest at that point and falls off away from it. When the focal point is near a tiny piece of dielectric material that may be chemically attached to a large molecule such as DNA, a dipole moment is induced in the material and in the same way that bits of paper with induced dipole moments are attracted to larger values of nonuniform

▲ **FIGURE 34–11** The focal point of an intense beam of light, a location where the beam is concentrated, acts to attract objects within which the electric field associated with the beam induces a dipole moment. When a laser provides the beam, the focal point can be so "tight" that the forces it exerts make a kind of optical tweezer that can manipulate nanoscale objects such as DNA molecules.

fields, it is attracted to the focal point of the nonuniform rms electric field of the laser beam. Figure 34–11 describes the action of the tweezers in schematic form. Once the system has been "gripped," the laser beam can be moved, moving the system with it.

Momentum in Electromagnetic Waves

An electromagnetic wave carries momentum as well as energy. To see this qualitatively, let's reconsider a plane wave that travels in the z-direction, with the electric and magnetic fields along the x- and y-directions, respectively. When such a wave impinges on a particle (you can think of an electron if you like, although we'll assume for simplicity that the charge is positive) with charge $+q$, the fields exert forces on the particle. Suppose that, at a given time, the oscillating electric field of the wave points in the $+x$-direction so there is a force qE in the $+x$-direction. The charge accelerates and moves with some velocity $\vec{v}$ in the $+x$-direction. If $\vec{E}$ points in the $+x$-direction, then $\vec{B}$ (which oscillates in phase with $\vec{E}$) must point in the $+y$-direction. The magnetic force $q\,\vec{v} \times \vec{B}$ on the charge acts in the $+z$-direction and pushes the charge in that direction. When the electric field later reverses sign, the electric force on the charge acts in the $-x$-direction, and the velocity then has a component in the $-x$-direction. The magnetic field has also reversed sign, but the magnetic force *continues to act in the $+z$-direction*. All the forces in the x- and y-directions average to zero, but the force in the z-direction is always positive, and there is a net force in the $+z$-direction. The charge has an increased momentum in the $+z$-direction; by momentum conservation, this momentum had to have been supplied by the electromagnetic wave.

By evaluating the amount of momentum the charged particle above picks up in a period of time dt, and recalling that the wave advances with speed c, so that a length $c\,dt$ of wave impinges on the particle in that time, we can show that the **momentum density** of an electromagnetic wave—the amount of momentum carried by the wave per unit volume—is $\vec{S}/c^2$. The magnitude of the momentum density is given by

$$\frac{S}{c^2} = \frac{u}{c}, \tag{34–26}$$

and the direction is that of $\vec{S}$, along the direction of wave propagation.

Radiation Pressure: When electromagnetic waves are absorbed or reflected as they enter into matter, they transfer momentum to the material on which they impinge. The particle upon which the wave fell above is an example. The rate at which momentum is transferred per unit area is a force exerted per unit area; that is, a pressure: **radiation pressure**. When an electromagnetic wave is absorbed, which happens when light falls on a black surface, all the momentum carried by the wave is transferred to the surface. The amount of radiation-produced momentum that falls perpendicularly on a surface A in a time interval dt is given by the momentum density multiplied by the volume $A(c\,dt)$. Thus the momentum dp transferred is

$$dp = \left(\frac{S}{c^2}\right)(Ac\,dt) = \frac{S}{c}A\,dt.$$

The force per unit area (radiation pressure) is given by

$$\frac{F}{A} = \frac{1}{A}\frac{dp}{dt} = \frac{1}{A}\frac{S}{c}A = \frac{S}{c} = u, \tag{34–27}$$

where we have used Eq. (34–22). This expresses the radiation pressure when radiation is totally absorbed. When the electromagnetic wave is reflected, which happens when it falls on a shiny, metallic surface, then the momentum of the wave is reversed upon reflection. Thus the momentum density transferred to the metallic surface is double the previous result, $2u/c$, and the radiation pressure is $2u$. (As we remarked above, a microscopic view of reflection is that the wave imparts momentum to a charged constituent, which then in turn reradiates and recoils in the process. This accounts for the factor of two.)

CONCEPTUAL EXAMPLE 34–5 Above we assumed that when light falls on a mirror and is reflected, the energy reflected is equal to the incident energy. Is this reasonable?

Answer Reflection is actually the reradiation of the wave by free electrons in the material. Metallic reflectors contain some free electrons, and that is why they make mirrors. (As for the shiny surface, that is another story, to be discussed in Chapter 35.) But the motion of these electrons is a local current, and there will be some small resistance, ohmic heating, and associated energy absorption. This means that the reflected energy will be slightly lower than the incident energy. This is typically a small effect.

EXAMPLE 34–6 Consider a 10^4-W searchlight that projects a cylindrical beam 0.6 m in diameter. What is the radiation pressure on a metallic mirror placed at right angles to the beam? Ignore the spreading of the beam.

Strategy The power delivered by the electromagnetic wave to a surface at right angles to the beam is given by

$$P = (\text{energy flux})(\text{area}) = SA = cuA,$$

where u is the energy density in the beam at the surface and A is the area of the beam. Given the area of the beam $A = \pi r^2$, we can calculate the energy density u and therefore the radiation pressure.

Working It Out The area is $A = \pi r^2 = \pi(0.3\text{ m})^2 \cong 0.3\text{ m}^2$. Thus

$$u = \frac{P}{Ac} = \frac{10^4\text{ J/s}}{(0.3\text{ m}^2)(3 \times 10^8\text{ m/s})} \cong 10^{-4}\text{ J/m}^3.$$

In turn, the radiation pressure is

$$\frac{F}{A} = 2u \cong 2 \times 10^{-4}\text{ N/m}^2.$$

What Do You Think? Just how small is this pressure? What thickness of a water layer on the ground would exert this kind of pressure?

EXAMPLE 34–7 The intensity (average energy flux) of solar radiation that falls on Earth is $1.4 \times 10^3\text{ W/m}^2$. Compare the force exerted by solar radiation on a totally absorbing dust particle of diameter 10^{-6} m and mass density $3 \times 10^3\text{ kg/m}^3$ with the gravitational force on the particle due to the Sun. The particle is located at a distance from the Sun equal to the Earth–Sun distance, $R = 1.5 \times 10^{11}$ m. The mass of the Sun is $M_{\text{Sun}} = 2 \times 10^{30}$ kg.

Strategy We are given the intensity $I = uc$, so that we have the data to find the radiation pressure, just u for an absorbing object like the dust particle. (We assume time averages throughout.) Since we can work out the area A of the dust particle, the radiation force F on the particle is pressure × area $= uA = IA/c$. Knowing the size of the particle and its density, as well as the mass of the Sun, and the distance from the Sun, Newton's law of gravitation determines the gravitational force on it, magnitude F_g.

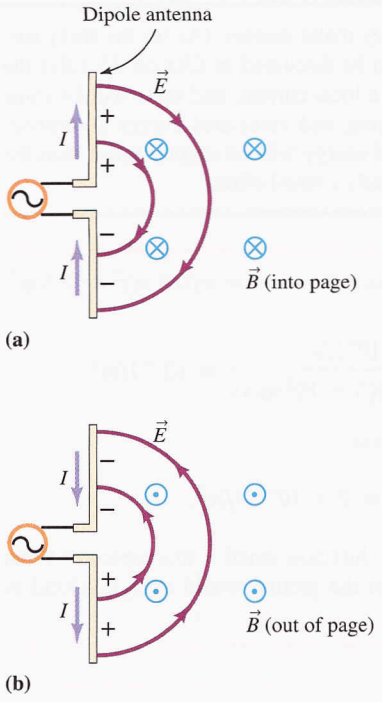
Working It Out The area presented by the dust particle is $A = \pi(d/2)^2 = \pi(0.5 \times 10^{-6}\text{ m})^2 = 0.8 \times 10^{-12}\text{ m}^2$. This gives for the radiation force

$$F = uA = \frac{IA}{c} = \frac{(1.4 \times 10^3\text{ W/m}^2)(0.8 \times 10^{-12}\text{ m}^2)}{3 \times 10^8\text{ m/s}}$$
$$= 0.4 \times 10^{-17}\text{ N}.$$

As for the gravitational force on the particle, the mass of the dust particle is $m = \rho V$, and the force of gravity is $F_g = \dfrac{GmM_{\text{sun}}}{R^2}$. Numerically, the mass m of the dust particle is

$$m = \rho V = \frac{4}{3}\pi\left(\frac{d}{2}\right)^3\rho = \frac{4}{3}\pi(0.5 \times 10^{-6}\text{ m})^3(3 \times 10^3\text{ kg/m}^3)$$
$$= 1.6 \times 10^{-15}\text{ kg},$$

hence the gravitational force on it is



$$F_g = \frac{GmM_{\text{sun}}}{R^2}$$
$$= \frac{(6.67 \times 10^{-11}\text{ N}\cdot\text{m}^2/\text{kg}^2)(1.6 \times 10^{-15}\text{ kg})(2 \times 10^{30}\text{ kg})}{(1.5 \times 10^{11}\text{ m})^2}$$
$$= 0.9 \times 10^{-17}\text{ N}.$$

We see that the two forces are comparable, so the radiation pressure can keep the dust particle at its current location. It is therefore no coincidence that this kind of dust grain is typical of those found in interplanetary space.

34–4 Dipole Radiation

Accelerating charges produce electromagnetic waves. For waves with wavelengths much longer than light (radio, TV, cell phones, etc.), we refer to the systems in which accelerating charges initiate electromagnetic waves as *broadcasting antennas*; we refer to the systems in which we detect the response of charges to the fields of an electromagnetic wave as *receiving antennas*. Here, we shall describe one of the simplest systems that can act as an antenna, the *dipole antenna*. Radiation emitted with the characteristic pattern of this antenna is called **dipole radiation**.

A dipole antenna is formed by charges that move back and forth in harmonic motion along a line. The charge configuration within the antenna is that of a set of electric dipoles, with one or both of the two charges making up each dipole oscillating (Fig. 34–12). Such an antenna is easy to construct using an AC generator. When the dimensions of the antenna are small compared with the wavelength of the radiation, the current

▲ **FIGURE 34–12** Pairs of equal but opposite charges move in simple harmonic motion along a line (vertical, here). These pairs of charges form a dipole antenna. In (a) the current is moving in one direction and in (b) it is moving in the opposite direction. As a result in (a) and (b) the two sides of the antenna are oppositely charged, and the field directions are reversed.

throughout the antenna is in phase, and the resulting electric and magnetic fields are oriented as shown in Fig. 34–12. They form an outgoing electromagnetic wave whose frequency is that of the oscillating charges.

How the Intensity of Radiation from an Antenna Decreases with Distance

Because electromagnetic waves are so often used for communication, it is clear that one of the most important characteristics of the electromagnetic waves radiated by an antenna is the rate at which the intensity decreases with increasing distance from the antenna. To understand this feature, we can consider any radiator—it is not important that the antenna be a dipole antenna. Let us consider an antenna that radiates electromagnetic waves symmetrically in all directions, such as the Sun or a lightbulb. From a distance, the electromagnetic waves emitted by the Sun appear to come from a point source, and we can use this fact to study the magnitudes of the electric and magnetic field strengths. As we learned in Section 34–3, the energy flux (the rate of flow of energy per unit area) is given by $S = cu = c\varepsilon_0 E^2$. The total energy flow per unit time (the power) across any surface is

$$P = \int_{\text{surface}} \vec{S} \cdot d\vec{A}.$$

If the magnitude of the electric field is independent of direction, as we would expect for a point source, then the total rate of energy flow across a sphere of radius R centered on the source is

$$P = c\varepsilon_0 E^2 (4\pi R^2). \tag{34–28}$$

But all the radiation emitted must eventually pass through any sphere that surrounds the source, whatever its radius, so P does not depend on R. From our expression for P, we see that this is possible only if the electric field decreases as $1/R$. The magnetic field must similarly fall off as $1/R$, because the magnetic and electric fields only differ by a factor of c in an electromagnetic wave. Contrast this result with the typical $1/R^2$ behavior of static electric fields (Chapter 22).

We can express the result of Eq. (34–28) in terms of intensity. The quantity $c\varepsilon_0 E^2$ is the magnitude of the Poynting vector, and its average value, which is defined as the intensity I, is one-half this value [Eq. (34–25)]. Thus

$$P = 2I(4\pi R^2). \tag{34–29}$$

Because P is independent of R, the intensity of the electromagnetic wave from a point source decreases as $1/R^2$. The next two examples illustrate this important property.

CONCEPTUAL EXAMPLE 34–8 In Example 34–7 we studied the balance of radiation pressure from sunlight with the gravitational force from the Sun for a dust particle as distant from the Sun as is Earth. We found that these forces balanced, suggesting that this is a mechanism for holding these particles at their current location. How would the argument change if the dust particle were as far away from the Sun as Jupiter?

Answer There is no change; the forces would still balance. Both the intensity of the Sun's radiation and the gravitational force due to the Sun have inverse square dependence on the distance from the Sun. If they balance at Earth's orbit, they will balance at Jupiter's.

EXAMPLE 34–9 A 100-W lightbulb emits electromagnetic radiation equally in all directions. Assume that 10 percent of the 100 W is converted into radiation in the visible spectrum. What is the intensity of the visible radiation 1.5 m from the bulb?

Setting It Up We are given the total power P and the power P_0 that appears as visible light, as well as the radius R of the sphere over whose surface the power is distributed. The desired intensity is denoted as I.

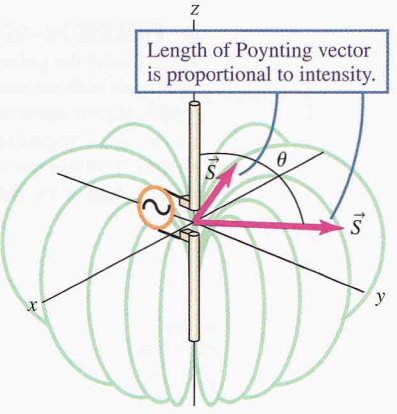
Strategy We may then use the relation $P = 2I(4\pi R^2)$ to calculate I as a function of R.

Working It Out We have $P_0 = 10\%$ of 100 W, so that $P_0 = 10$ W. This gives

$$I = \frac{P_0}{8\pi R^2} = \frac{10\text{ W}}{8\pi(1.5\text{ m})^2} = 0.2\text{ W/m}^2.$$

Compare this value to the 1400 W/m^2 in sunlight incident at the top of Earth's atmosphere, or to the 1000 W/m^2 of solar energy that reaches Earth's surface. About half this solar energy is in light in the visible part of the spectrum, whereas the lightbulb emits most of its energy in the infrared region of the spectrum.

What Do You Think? Does the fact that a lightbulb radiates equally in all directions mean that it is not an antenna?

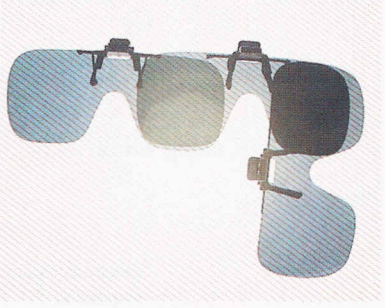


In our discussion of static electric fields due to a point source, we used symmetry considerations to argue that the *electric field vector points in a radial direction*. This cannot be the case for electromagnetic waves emitted from a point source, however, because we showed that the fields for such waves are transverse to the direction in which they travel. When the waves come from a point source, they travel outward radially. So given the symmetry, how does the electric (or magnetic) field "know" in what direction to point for a point source? The resolution to what appears to be a paradox is simple: *There are no truly pointlike sources of electromagnetic radiation*. The Sun is not a point; it radiates because charges within it move and accelerate. As far as this discussion is concerned, we can think of the Sun as a large collection of dipole antennas with random orientation.

The Angular Pattern of Dipole Radiation

The variation of the intensity of electromagnetic radiation with the angle of observation is an important property of radiation from an antenna. Such patterns are an important element of the design of real antennas. No broadcaster wants to use expensive electric power to send a signal where nobody lives. In our simple dipole antenna (Fig. 34–12), charges execute simple harmonic motion along the antenna direction (we shall call this the z-axis). The motion of the charge determines a preferred direction—along the z-axis. An observer looking along the z-axis would see no motion. An observer looking along a line perpendicular to the z-axis would see the full range of motion of the charges. An observer at an angle θ to the z-axis would see the charges move harmonically with an amplitude reduced from the full amplitude by a factor $\sin\theta$. The electric field that the observer sees is thus proportional to $\sin\theta$. Because the intensity is proportional to the square of the electric field in the wave, the intensity of the radiation emitted by a dipole antenna along the direction of θ is proportional to $\sin^2\theta$:

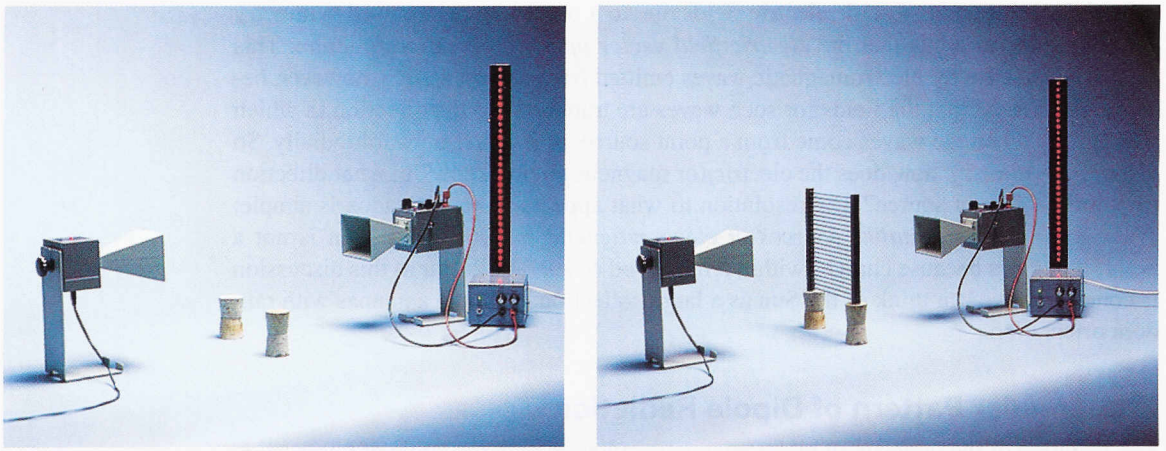
$$S \propto \frac{\sin^2\theta}{R^2}. \tag{34–30}$$



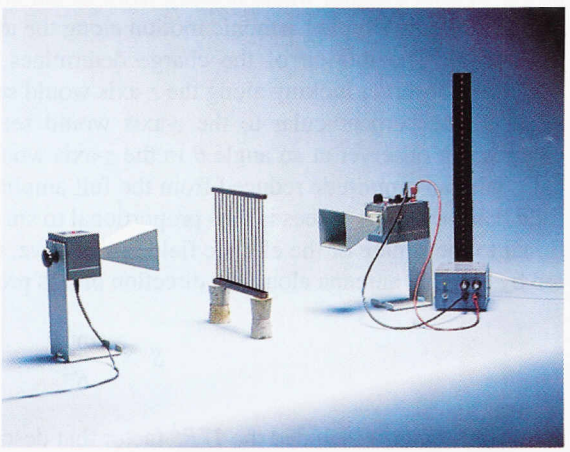
Here we have also included the $1/R^2$ factor that describes how the intensity varies with the distance R from the antenna. This intensity pattern describes the **angular distribution** of the power emitted by charges oscillating along a line (Fig. 34–13): no signal along the direction of the antenna and a maximum signal perpendicular to it.

▲ **FIGURE 34–13** The intensity distribution S for a radiating dipole antenna. The curve illustrates the relative amount of power emitted as a function of the angle θ. The Poynting vectors for two different positions are drawn.

34–5 Polarization



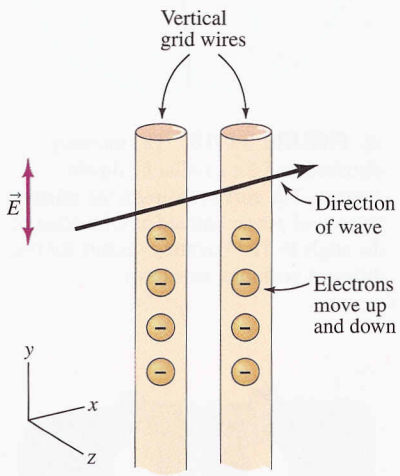
A little experimentation with *polarizing* sunglasses at the seashore shows that a change in the orientation of the glasses' axis results in a change of the intensity of the light transmitted. This occurs because the sunglasses are made of a material that is sensitive to the direction of the electric field. As we shall see, light reflected from water or sand is **polarized**, meaning that its electric field is oriented in a particular way; the glasses "detect" the polarization of the electromagnetic wave (light). These sunglasses also have the effect of passing light whose electric field is aligned in a certain direction, and if two pairs of glasses are aligned in a "crosswise" fashion, no light passes the pair (Fig. 34–14).



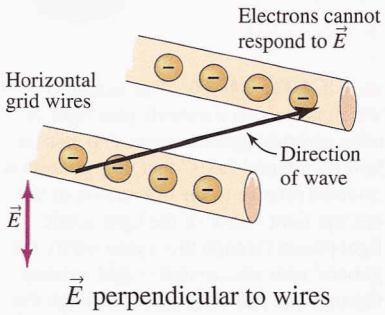
▲ **FIGURE 34–14** The extent to which polarizing materials pass light or other electromagnetic waves depends on how an internal "axis" that they possess is oriented relative to the orientation of the electric field vector of the light. Little light passes through the region where the glasses' axes are crossed—light passing through one pair cannot pass through the second pair. But when the axes are aligned, the same amount of light passes as for a single lens.

If polarized light contains its electric field oriented in a particular direction, what is unpolarized light? Unpolarized light consists of a mixture of light waves with their electric fields aligned in different directions—always perpendicular to the propagation direction. The alignment must be such that *no* direction of $\vec{E}$ is preferred. In sampling a beam of unpolarized light, one would be just as likely to find the electric field aligned in one transverse direction as in another.

Let us reconsider a charge that oscillates along the z-axis, as in Fig. 34–13. We found that, if we look along the x-direction, we would detect an electromagnetic plane wave that propagates along the x-direction, with an electric field aligned along the z-direction: $\vec{E} = E_z\hat{k}$, with $E_z = E_0\cos(kx - \omega t)$. (Setting the phase $\phi = 0$ won't



(a) (b)



(c)

▶ **FIGURE 34–15** (a) A receiver and detector for determining the polarization of microwave radiation. The red lights indicate the presence of a signal. (b) A horizontal grid is placed between them, oriented so that the radiation passes. (c) The grid is now oriented vertically so that the radiation cannot pass. The grid's orientation reveals the polarization of the radiation, which is vertical.

(a)

(b)

change anything here.) We say that the light, or indeed electromagnetic radiation of any wavelength, is **linearly polarized** along the direction of the electric field vector—in this case, the light propagating along the x-direction is polarized along the z-direction. Suppose that a dipole antenna emits radiation with a wavelength in the centimeter range. The polarization can be detected as follows: A current is induced in a receiving antenna, and the rms current detected can be measured (Fig. 34–15). Place a metal grid (such as an oven rack) between the transmitter and the receiver. The diameter of the wires in the grid should be much less than the wavelength of 1 cm, and the grid spacing should be on the order of 1 cm or less. Then, the intensity of the radiation at the receiver depends on the orientation of the metal grid, and we say that the grid acts as an **analyzer** for the polarization.

Here is why the grid acts as an analyzer. The electrons in the grid wires are accelerated by the electric field of the wave along the field direction. When the wires in the grid are parallel to the electric field, the electrons in the grid wires can move in response to the field (Fig. 34–16a). Because they are set into motion, they *absorb large amounts*

◀ **FIGURE 34–16** (a) When the grid wires are oriented in the direction of the electric field of an incoming wave, the electrons of the grid wires can respond and absorb energy from the wave. The transmitted wave is reduced in amplitude. (b) When the wires are perpendicular to the electric field of the wave, the electrons of the grid wires are constrained and cannot respond. Little energy is absorbed, and the wave passes through with little attenuation.

of energy from the field. This energy is lost in ohmic heating. The electric field of the radiation that passes through is reduced in magnitude because energy has been removed from the incident wave. In effect, the grid is opaque to the polarized radiation when it is oriented along the electric field vector. When the wires in the grid are perpendicular to the z-direction (Fig. 34–16b), the electrons in the metal are accelerated across the diameter of the wire. But, because the diameter is small, the electrons in the grid wires cannot respond fully and cannot absorb large amounts of energy from the incident wave. The energy remains in the transmitted wave. The grid acts as if it were transparent when it is oriented perpendicular to the polarization direction of the wave.

Certain materials, such as Polaroid, are analyzers for visible light. They are made of long molecules aligned parallel to each other. Electrons can easily move along the molecules but not across them and, because the molecular spacings are appropriate to the wavelengths of visible light, these materials behave like the microwave grid does.

A microwave grid or a piece of Polaroid is not simply an analyzer; it is also a **polarizer**: The microwave radiation that passes through the grid becomes polarized perpendicular to the grid wires. This is easily understood. Suppose that unpolarized microwave radiation approaches the grid. *Unpolarized radiation* is radiation that consists of a mixture of waves whose electric field vectors are as likely to point in any one direction as in another, as long as the direction is perpendicular to the direction of wave propagation. As we have seen, only those waves with the electric field oriented perpendicular to the grid can pass through, whereas the waves with the electric field parallel to the grid are absorbed. Thus the radiation that passes through the grid has become polarized perpendicular to the direction of the grid.

Malus's Law

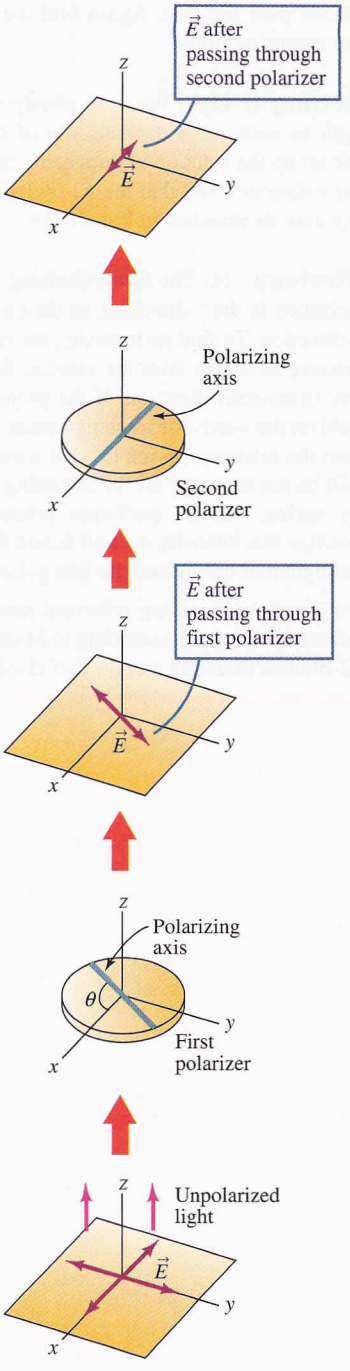
When unpolarized radiation moving in the z-direction falls on a polarizer whose polarizing axis (the axis perpendicular to the "grid wires" within the polarizing material) makes an angle θ with the x-axis, for example, then only the component of any electric field along the polarizing axis will pass through. What emerges is radiation that is linearly polarized along a line that makes an angle θ with the x-axis. We take the magnitude of the electric field that has passed through the polarizer to be E_0. The corresponding intensity is then

$$I_0 = \langle S \rangle = (\text{a constant})E_0^2. \tag{34–31}$$

Let's now place a second polarizer so that its axis lies along the x-axis (Fig. 34–17). The amplitude for the electric field in the wave incident on the polarizer is

$$\vec{E}_0 = (E_0 \cos\theta)\hat{i} + (E_0 \sin\theta)\hat{j}. \tag{34–32}$$

Only the component that is parallel to the axis of the second polarizer—the x-axis—passes through. Thus the field behind the second polarizer (which acts here as an analyzer) is given by $E_0 \cos\theta\, \hat{i}$. The intensity of the transmitted light is therefore



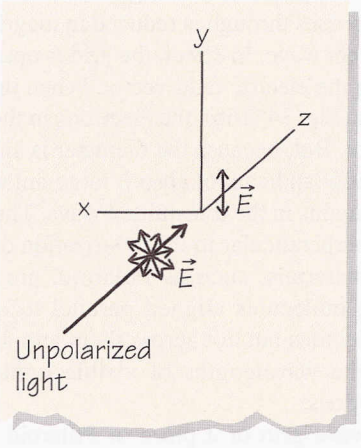
$$I = (\text{a constant})(E_0 \cos\theta)^2, \tag{34–33}$$

and the intensity of the light is reduced:

$$I = I_0 \cos^2\theta. \tag{34–34}$$

Equation (34–34) is known as **Malus's law**. In particular, when the axes of the polarizer and analyzer are perpendicular to each other ($\theta = \pi/2$), radiation is not transmitted. This case is illustrated well for the sunglasses of Fig. 34–14.

One of the important consequences of Malus's law is that when unpolarized light passes through a polarizer, it has *half* its original intensity (see Example 34–10).



▲ **FIGURE 34–17** An unpolarized beam passes first through a polarizer whose axis makes an angle θ with the x-axis, and the beam is then polarized linearly in this direction. A second polarizer aligned with the x-axis allows only the component of the electric field aligned along the x-axis to pass.

EXAMPLE 34–10 Light passes through the glass plate of a transparency projector and emerges unpolarized with intensity I_0. (a) A Polaroid sheet is placed on the glass plate with its polarizing axis aligned with the 12-o'clock position. What are the polarization and intensity of the emerging light? (b) A second Polaroid sheet, with its polarizing axis along the 2-o'clock position, is placed over the first. Again find the polarization and intensity of the emerging light.

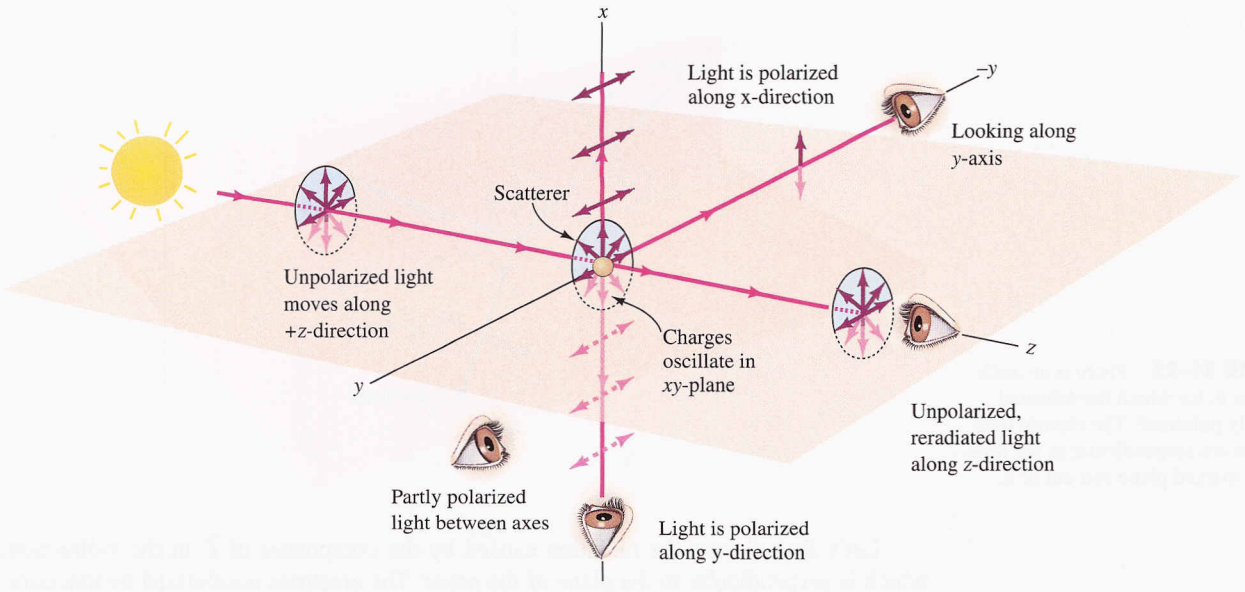
Setting It Up We must clarify what is meant by *unpolarized* light to understand the intensity of the emerging light in part (a). We set up the solution by supposing that the light wave propagates in the z-direction and that the 12-o'clock position is aligned along the $+y$-axis, as sketched in Fig. 34–18.

Strategy (a) The first polarizing sheet passes light with its polarization in the y-direction, so the emerging light is polarized in the y-direction. To find its intensity, we recall that unpolarized light is a mixture of waves with the electric field equally likely to lie along any (tranverse) direction. If the projection of the incoming electric field on the y-axis for some particular wave in the mixture is $E\cos\theta$, then the intensity passed for that wave is $I = I_0\cos^2\theta$. Note that I_0 will be the same for all the incoming waves—that is what we mean by saying that no particular orientation is preferred. We must *average* this intensity over all θ, and that will give us the intensity of the light that has passed the first polarizer.

(b) The light emerging polarized along the 12-o'clock axis will be reduced in intensity according to Malus's law. The angle between the 12-o'clock direction and the 2-o'clock direction is $\pi/3$ radians.

▲ FIGURE 34–18

Working It Out The average value of $\cos^2\theta$ is $1/2$, giving the following answers for part (a): The polarizer is aligned with the x-direction, so that the light will be polarized in the x-direction, and the intensity of the light will be $I = I_0\langle\cos^2\theta\rangle = \frac{1}{2}I_0$.
(b) From Malus's law we get the intensity



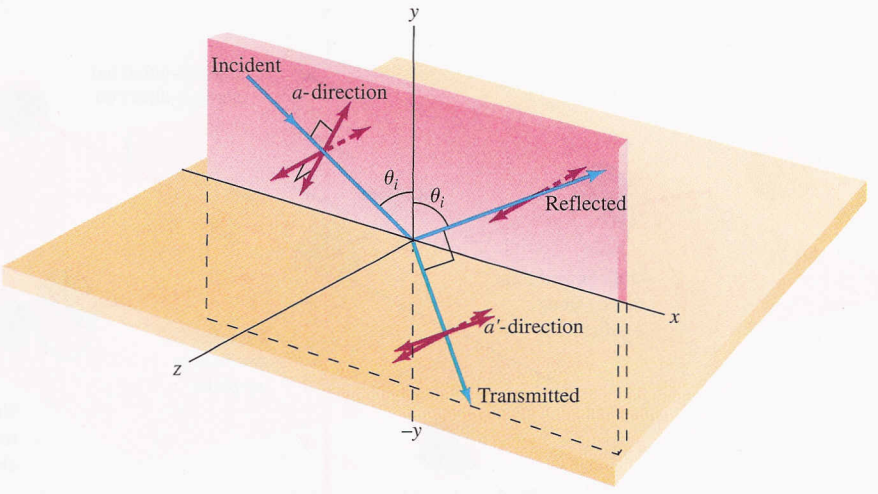
$$I_1 = I\cos^2(\pi/3) = \frac{I_0}{2}\frac{1}{4} = \frac{I_0}{8}.$$

What Do You Think? Both Polaroid sheets will experience some heating due to absorption of light. In what ratio do you expect the two sheets to acquire thermal energy?

How to Produce Polarized Radiation

We have already described two ways to produce polarized radiation: by accelerating charges in an oriented dipole antenna and by passing unpolarized radiation through a polarizer. Two more ways are important in many situations.

Polarization by Scattering: If you look at the beam of an automobile headlight from the side in a rainstorm or a snowstorm, it is quite visible, because there is a pronounced scattering of the light. The light beam is much less visible from the side on a dry night. Nevertheless, even in the absence of water droplets or dust particles, light and other forms of electromagnetic radiation are scattered by air molecules. The scattering mechanism is quite different from the mechanism that operates when the light scatters from droplets, because the size of the droplets is much larger than the wavelength of the light. It can be described as follows: The oscillating electric field $\vec{E}$ of the incoming radiation sets in motion the electrons in the air molecules. The electrons act like oscillators subject to an external harmonic force and oscillate with the frequency of the incoming field. The electrons move in a plane perpendicular to the incident radiation and, if the incident wave is unpolarized, then there is no preferred direction to the electron motion as long as it occurs in the plane. An observer looking at an electron from a direction close to that of the incident radiation will see a radiated field that is unpolarized because there is no preferred direction. In contrast, an observer looking at the electron from a direction perpendicular to the direction of the incident radiation will see the electron moving in just one direction (and will not see the component of the motion toward or away from him or her). This observer thus sees 100 percent linearly polarized light (Fig. 34–19). The polarization is partial for angles between these directions. If you live where the atmosphere is clear, you can easily observe this by holding a piece of Polaroid and looking 90° away from (*but not at*) the Sun. The light intensity will change when the Polaroid is rotated, showing that the light scattered by the air molecules is polarized.



▲ **FIGURE 34–19** The polarization of radiation by scattering. An electromagnetic wave can propagate through a material because the wave's electric and magnetic fields cause electrons in the material to oscillate at the radiation frequency; these electrons in turn radiate new waves of the same frequency. The electric field of these new waves is aligned with the electrons' motion. Here, unpolarized radiation is perpendicularly incident on the *xy*-plane in a gas; the electric fields of the radiation lie in that plane but are otherwise unrestricted. An observer along the *z*-axis sees the full range of motion of the electrons in that plane and hence sees unpolarized light. An observer at 90° to the original wave direction can see a side view of the plane from which the light is radiated and hence sees light fully polarized; the polarization direction is parallel to the plane's edge. At intermediate angles, the reradiated light is partly polarized.

Polarization by Reflection: When unpolarized radiation is reflected from a surface such as glass, the reflected light is partly polarized (Fig. 34–20a). When the angle of incidence is just right, the reflected light is fully polarized (Fig. 34–20b). This is for much the same reason that scattered light is polarized (Fig. 34–19). Unpolarized light incident at an angle θ_i (*the angle of incidence*) impinges on a surface. In general, we may decompose the electric field of the incident wave into two components—each perpendicular to the direction of propagation. As Fig. 34–21 illustrates, one of these directions, the *z*-direction, is perpendicular to the surface of the page and parallel to the reflecting surface; we label the other the *a*-direction. When the wave arrives at the surface, its electric field accelerates electrons. These accelerated charges reradiate and give rise to both the transmitted and the reflected wave.

(a) (b)

◀ **FIGURE 34–20** Radiation is polarized by reflection. (a) Here we see a shop window with oblique reflections, which are partially polarized. (b) The same scene, but with the camera lens fitted with a polarizing filter. The reflected light passing through the filter is greatly reduced.

▶ **FIGURE 34–21** There is an angle of incidence θ_i for which the reflected wave is fully polarized. The electric field components are perpendicular to the rays, both in the marked plane and out of it.

Let's first discuss the radiation caused by the component of $\vec{E}$ in the z-direction, which is perpendicular to the plane of the paper. The electrons accelerated by that component of the incoming electric field move at right angles to the direction of the reflected wave. An observer looking back along the line of the reflected wave sees the full motion of these electrons. Thus there is strong reflection of this part of the incident wave. Next, let's consider the radiation induced by the component of the electric field of the incident wave in the a-direction. The electrons that absorb this incident radiation move parallel to the a-direction. An observer who looks along the line of the reflected wave sees a foreshortened motion of the electrons and thus only a limited amount of reflected radiation. Thus there is a preferential polarization direction for the reflected light. In the special case that the direction of the reflected wave is along the a'-direction (perpendicular to the direction of the transmitted radiation), there is no reflected radiation polarized along the a'-direction because the motion of the absorbing and reradiating electrons along the a'-direction cannot be seen. *The reflected radiation is plane-polarized with an electric field in the z-direction, parallel to the plane of the reflecting surface.* For this special angle, the reflected and transmitted waves must be at 90° to one another.

The angle of incidence for which the reflected and transmitted (or refracted) rays are perpendicular to one another are easily found once the rules for these rays (Snell's law) are developed, which we will do in Chapter 35. We give the result here: When the *angle of incidence* is the angle θ_B, known as **Brewster's angle**, the reflected ray is linearly polarized. This angle, which is the incident angle in Fig. 34–21, is given by

$$\tan \theta_B = \sqrt{\frac{\varepsilon}{\varepsilon_0}} = n. \tag{34–35}$$

As we have already noted, the effect is present but less dramatic for other angles. An analyzer whose polarizing axis is oriented in a direction perpendicular to the z-direction (the direction of polarization of the reflected wave) will absorb most of the reflected radiation. Thus Polaroid sunglasses, worn to cut down the glare of reflected light from roads, beaches, car hoods, and other horizontal surfaces, must have their polarizing axis aligned in a vertical direction.

*34–6 Electromagnetic Radiation as Particles

In one of the most astonishing discoveries of the early part of the twentieth century, we learned that *electromagnetic radiation consists of particles*. The research of Max Planck, of Albert Einstein, and of Arthur Compton established that what we call an electromagnetic wave consists of a large number of individual particles called **photons**. These particles are indivisible: It is not possible to have 0.3 photons, for example. For radiation characterized by a frequency $f = \omega/2\pi$, the energy carried by a single photon is

$$E = hf, \tag{34–36}$$

where $h = 6.63 \times 10^{-34}\ \text{J}\cdot\text{s}$ is Planck's constant. A photon also carries momentum, given by

$$p = \frac{E}{c} = \frac{hf}{c} = \frac{h}{\lambda}. \tag{34–37}$$

The particle nature of electromagnetic radiation was established through Compton's experiments on the scattering of radiation by free electrons in carbon. Photons scattered through a given angle have energy that can be calculated by treating each photon as a relativistic billiard ball that collides elastically with an electron at rest. The momentum of the outgoing photon depends on the collision angle. Equation (34–37) then implies that the frequency of the scattered radiation also depends on the collision angle in a way that can easily be calculated.

That h is small explains why we think of light as a continuous phenomenon rather than a series of individual photons. Someone standing under Niagara Falls wouldn't feel as if he or she is being bombarded by droplets of water! We now have instruments that can routinely detect individual photons. Had the evolutionary history of the human eye been somewhat different—so that the eye could easily respond to a single photon—the notion of radiation as consisting of particles would have been obvious to everyone.

EXAMPLE 34–11 At what rate does a 60-W lightbulb emit photons? For simplicity, assume that the light is emitted with a single wavelength of 590 nm.

Strategy We are given the wavelength, and therefore the frequency of the light, from which we can calculate the energy per photon, namely $E = hf = h(c/\lambda)$. The given wattage P of the bulb is the energy emitted per second, and P is the number of photons per second N times the energy per photon, $P = NE$. We can then solve for N.

Working It Out We have

$$E = h\frac{c}{\lambda} = \frac{(6.6 \times 10^{-34}\ \text{J}\cdot\text{s})(3 \times 10^{8}\ \text{m/s})}{(590 \times 10^{-9}\ \text{m})} = 3.4 \times 10^{-19}\ \text{J}.$$

From this we learn the number of photons per second,

$$N = \frac{P}{E} = \frac{60\ \text{W}}{3.4 \times 10^{-19}\ \text{J}} \cong 1.8 \times 10^{20}\ \text{photons/s}.$$

This is a very large number, one that would not permit you to sense the presence of individual photons.

What Do You Think? Do you expect photons to carry momentum? What do you think is the momentum of a photon with frequency f?

THINK ABOUT THIS. . .

WHEN PHOTONS GET REFLECTED BY A MIRROR, DO THEY DROP IN FREQUENCY?

We argued earlier that when electromagnetic waves are reflected by a mirror, a little of the energy that sets the electrons in motion is absorbed by ohmic heating, so that a little of the incident energy is absorbed, and the energy reflected is a little smaller than the incident energy. In terms of photons, which for monochromatic incident waves each have the same energy hf, a loss of energy would imply a drop in the frequency, and therefore an increase in the associated wavelength ($f = c/\lambda$). Since color of radiation is associated with frequency, does this mean that the reflected light is somewhat redder than the incident light? This is certainly not what is observed. A charge that is set into oscillation by an external field will reradiate with the same frequency, which is what we *do* observe. The loss in energy is not due to a loss of energy for individual photons, but rather in the reflection of *fewer* photons. Some of the photons emitted by individual oscillators are absorbed in the medium and their energy goes into kinetic energy of the atoms that make up the medium—causing ohmic heating.

Summary

Maxwell's equations—which comprise Gauss' laws for electric and magnetic fields, the generalized Ampère's law, and Faraday's law [Eqs. (34–1) to (34–4)]—imply that it is possible to have propagating electric and magnetic fields even in the absence of currents and charges. In the absence of free charges, the electric and magnetic fields obey the wave equation, which has the generic form, here written for the x-component of the electric field,

$$\frac{\partial^2 E_x(z,t)}{\partial z^2} = \mu_0\varepsilon_0\frac{\partial^2 E_x(z,t)}{\partial t^2}. \tag{34–7}$$

In the case that $E_z = 0$ and $B_z = 0$, the waves propagate along the z-direction. Whatever the direction, the speed of propagation is given by

$$v^2 = \frac{1}{\mu_0 \varepsilon_0}. \tag{34–9}$$

This speed is the speed of light, $v = c \cong 3 \times 10^8$ m/s. In material media characterized by the dielectric constant κ, the speed of propagation is $c/\sqrt{\kappa} = c/n$, where $n = \sqrt{\kappa}$ is the index of refraction. There are solutions of the wave equation (electromagnetic waves) in which the fields have the harmonic form

$$E_x = E_0 \cos(kz - \omega t + \phi), \tag{34–8}$$

and

$$B_y = B_0 \cos(kz - \omega t + \phi). \tag{34–13}$$

These waves propagate in the z-direction. More generally, electric and magnetic fields of waves that propagate in a given direction are transverse to that direction. The electric and magnetic field amplitudes are related by

$$E = cB, \tag{34–14}$$

and the fields are perpendicular to each other:

$$\vec{E} \cdot \vec{B} = 0. \tag{34–15}$$

Electromagnetic waves carry energy with energy density

$$u = \frac{\varepsilon_0}{2}(c^2 B^2 + E^2). \tag{34–18}$$

This energy is carried in equal amounts by the electric and magnetic fields. Electromagnetic waves also carry momentum, with momentum density $\vec{S}/c^2$, where $\vec{S}$ is the Poynting vector, given by

$$\vec{S} = \frac{1}{\mu_0}\vec{E} \times \vec{B}. \tag{34–23}$$

Thus radiation can transfer momentum; when a material absorbs radiation, there is a radiation pressure on the material, given by

$$\frac{S}{c} = u. \tag{34–27}$$

Charged particles radiate when they are accelerated. For a charge q undergoing an acceleration along the z-direction, the energy flux is proportional to

$$S \propto \frac{\sin^2 \theta}{R^2}, \tag{34–30}$$

where θ is the angle with the z-axis and R is the distance from the charge. Radiation with a $\sin^2 \theta$ angular dependence is called dipole radiation.

The polarization of an electromagnetic wave is the direction of the transverse electric field vector. It can be measured because polarizers transmit electromagnetic waves only along a particular polarization axis. Polarizers may be used to detect as well as to polarize electromagnetic waves. If a second polarizer is placed with its axis making an angle θ with the first one, then the electric field E of the transmitted wave is reduced in magnitude from the electric field E_0 of the incident wave according to $E = E_0 \cos \theta$. Thus the intensity I (the average of the energy flux) of the transmitted light is reduced from the incident intensity I_0 according to Malus's law:

$$I = I_0 \cos^2 \theta. \tag{34–34}$$

Waves can be polarized by reflection. If light falls on a medium of dielectric constant κ at an angle θ_B (Brewster's angle), for which

$$\tan \theta_B = n, \tag{34–35}$$

(n is the material-dependent index of refraction), then the reflected light is polarized in a direction perpendicular to both the incoming direction and the reflected direction of the wave. Light can also be polarized by scattering.

Appendix Getting Maxwell's Equations in Differential Form

Starting from a set of accelerating charges and Maxwell's equations, let's derive the equations that lead us directly to electromagnetic waves. The particular set of charges that we use form currents in the xy-plane, oscillating back and forth in the x-direction, as in Fig. 34–4. As in the qualitative discussion of Section 34–2, we know that the moving charges will give rise to changing electric and magnetic fields. We concentrate on time-dependent fields that vary with z but not with x and y. This implies that for a given z, the fields are the same out to infinity in the x- and y-directions. This cannot strictly be true in a physical situation; thus, we shall keep in the back of our minds that somewhere, for large enough values of x and y, the fields actually taper off to zero.

Let's draw an imaginary loop C in the yz-plane (at $x = 0$) that goes from $y = b$ to $y = -b$ at some value of z and returns from $y = -b$ to $y = b$ at $z + dz$ (Fig. 34A–1). We are going to apply the generalized Ampère's law to the loop. Sides at $y = \pm b$, going from z to $z + dz$, are very short. We shall ignore the contribution from the short sides because we can make these sides infinitesimally short. Moreover, our qualitative argument in Section 34–2 gives us no reason to believe that there is a field B_z. (This can be verified with the help of Gauss' law.) Application of the generalized Ampère's law, Eq. (34–3), now becomes easy. All we need to calculate for the line integral in Ampère's law are the contributions from the long (horizontal) sides of the loop. We have

$$B_y(z + dz, t)(2b) - B_y(z, t)(2b) = \mu_0\varepsilon_0 \frac{d}{dt} \int_{\text{loop area}} \vec{E} \cdot d\vec{A}. \tag{34–A1}$$

From the definition of a derivative, the difference $B_y(z + dz, t) - B_y(z, t)$ is the rate of change of B_y with respect to z times dz, so

$$2b[B_y(z + dz, t) - B_y(z, t)] = 2b\left(\frac{\partial B_y}{\partial z}\, dz\right). \tag{34–A2}$$

The partial derivative appears because we keep t constant in $B_y(z, t)$.

Now let's consider the right-hand side of Eq. (34–A1). In using Ampère's law, a right-hand rule dictates that for loop C in the direction shown in Fig. 34A–1, the surface element $d\vec{A}$ is oriented in the $-x$-direction, so $\vec{E} \cdot d\vec{A} = -E_x\, dA$. In addition, the area $A = 2b\, dz$ is infinitesimally small, so we can assume that E_x does not vary over the surface and we can remove it from the integral. Finally, the time derivative on the right-hand side of Eq. (34–18) acts only on E_x, because the surface is itself fixed. Thus

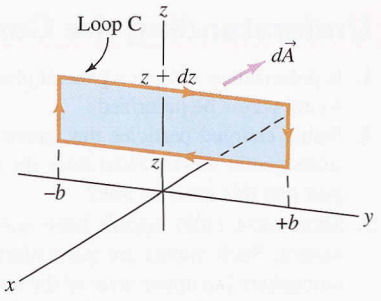
$$\mu_0\varepsilon_0 \frac{d}{dt} \int_{\text{loop area}} \vec{E} \cdot d\vec{A} = -\mu_0\varepsilon_0 \frac{\partial}{\partial t} E_x \int_{\text{loop area}} dA = -\mu_0\varepsilon_0 \frac{\partial E_x}{\partial t} A$$

$$= -\mu_0\varepsilon_0 \frac{\partial E_x}{\partial t} (2b)\, dz. \tag{34–A3}$$

We have used a partial derivative because z is a second variable that is held fixed. We now equate the two right-hand sides of Eqs. (34–A2) and (34–A3):

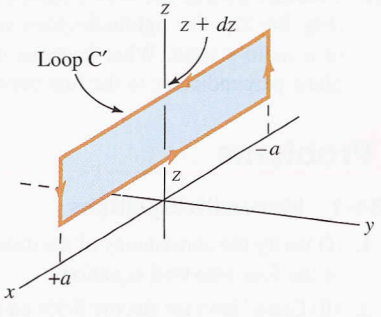
$$2b\left(\frac{\partial B_y}{\partial z}\, dz\right) = -\mu_0\varepsilon_0 \frac{\partial E_x}{\partial t} 2b\, dz;$$

that is,



$$\frac{\partial B_y}{\partial z} = -\mu_0\varepsilon_0 \frac{\partial E_x}{\partial t},$$

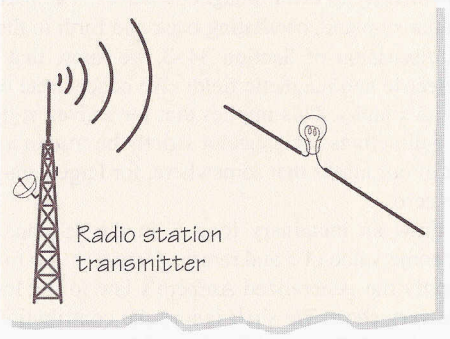
which is Eq. (34–5).



We next make use of Faraday's law, Eq. (34–4), the fourth of Maxwell's equations. We apply it to a loop C' that goes from $x = a$ to $x = -a$ at some value of z and returns from $x = -a$ to $x = a$ at $z + dz$ (Fig. 34A–2). Then, a nearly identical derivation to the one that led us to Eq. (34–5) leads us to Eq. (34–6),

$$\frac{\partial B_y}{\partial t} = -\frac{\partial E_x}{\partial z}.$$

Equations (34–5) and (34–6) are the ones we use in Section 34–2 to find the wave equation for electromagnetic waves.



▲ **FIGURE 34A–1** A loop used to derive a relation between $\partial B_y/\partial z$ and $\partial E_x/\partial t$ using Ampère's law.

▲ **FIGURE 34A–2** A loop used to derive a relation between $\partial B_y/\partial t$ and $\partial E_x/\partial z$ using Faraday's law.

Understanding the Concepts

1. Is polarization of light a general phenomenon for all waves? Can sound waves be polarized?
2. Stable charged particles that move uniformly produce no electromagnetic waves. How does the conservation of energy suggest that this must be true?
3. Short-wave radio signals have wavelengths of several tens of meters. Such waves are particularly well reflected by Earth's ionosphere (an upper layer of the atmosphere that contains many free charges). Why would Earth's ionosphere reflect, rather than absorb, these waves?
4. Two identical wires with identical lightbulbs connected to the middle of each wire are placed in an electromagnetic plane wave moving out of the plane of the page. The two wires make an angle of 30 degrees with each other. Bulb B1 is totally dark, bulb B2 is not. Can bulb B1 be made to shine brightly, and if so, how?
5. The production and detection of polarization depends on the electric field vector. Can there be, in principle, a polarization associated with the magnetic field vector?
6. Can there be standing electromagnetic waves as well as traveling ones? Recall that mechanical standing waves on a string are possible when certain boundary conditions are satisfied, such as the ends of the string being fixed. How can we control the values of electric or magnetic fields on fixed boundaries?
7. You have a series of simple polarizers that you can orient as you choose in succession along a beam. Can you arrange them so that if the beam were polarized to start with it would be unpolarized when it has passed through your succession of polarizers?
8. Would the presence of magnetic monopoles analogous to electric charges change the nature of electromagnetic waves in free space?
9. A *solar sail* is a large surface on which the radiation pressure of the Sun's radiation can act and thereby push the sail along. Solar sails have been proposed for spaceships to travel throughout our solar system. What properties must such a sail have, and what difficulties do you see in the proposal?
10. Rockets are propelled forward when mass is ejected backward from them. Could a source of light (or other electromagnetic radiation) be used in place of the mass?
11. How can you tell whether or not light is linearly polarized?
12. Incident light is linearly polarized along the x-axis. We would like to rotate the direction of polarization so that it lies along the y-axis. Can this be done with one polarizer? Can it be done with two? What is the minimum reduction in intensity when two polarizers are used? Can there be even less intensity reduction with three polarizers?
13. Consider a metal rod with a lightbulb connecting the two halves (Fig. 34–22). The lightbulb glows when the rod is in the vicinity of a radio station. What happens when the rod is rotated in a plane perpendicular to the line between the rod and the station?

▲ **FIGURE 34–22** Question 13.

14. In Hertz's test of the existence of electromagnetic waves, sparks appear in a secondary gap as the result of an AC current in a primary circuit. Hertz interpreted these sparks as due to the effect of electromagnetic waves and not to the effects of Faraday induction. What sort of checks did Hertz need to make in order to rule out Faraday induction?
15. A 100-W lightbulb hangs from the ceiling of a windowless and thermally isolated room with the door closed. How much of the 100 W goes into heating the room?
16. Can you use the example and the arguments given in Section 34–2 to prove in a more general way than was done there that electromagnetic waves are transverse? Are there any pitfalls?
17. We showed that electromagnetic radiation carries momentum by thinking about its effect on a free charge. Consider its effect on an electric dipole to see whether it might carry angular momentum as well. Start by orienting the dipole with its axis along the direction of the electric field vector of the electromagnetic wave.
18. Consider the electromagnetic wave shown in Fig. 34–6(a). Suppose the green arrow showing the direction of the propagation of the wave were missing. Could you figure out how to replace it?
19. Consider the solar sail described in Question 9. Is it better to make a solar sail reflective (shiny) or absorbing (black)?
20. In the subsection on momentum in electromagnetic waves, we mentioned that an electromagnetic wave will accelerate a charged particle, giving it momentum at the same time. Does this mean the wave loses energy and momentum? In other words, if we sit behind a receiving antenna, do we pick up less radiation because of the presence of the antenna?
21. When electromagnetic radiation interacts with matter—for example, when light propagates in a crystal—it is always the electric and not the magnetic field that determines the behavior. Can you explain this, recalling the role of the two fields in the Lorentz equation?
22. How is it possible to clearly hear a 50,000-watt radio station that is 375 miles away, but not possible to clearly hear a local 5000-watt radio station that is 5 miles away?

Problems

34–1 Maxwell's Equations

1. (I) Verify the consistency of the dimensions of both sides of each of the four Maxwell equations.
2. (II) Gauss' laws for electric fields and for magnetic fields differ due to the lack of magnetic charges. Assume that magnetic monopoles (magnetic charges) exist; denote them by the symbol M. Rewrite Gauss' law for magnetic fields, and give the SI units of M.
3. (II) Ampère's and Faraday's laws differ due to the lack of a currentlike term in Faraday's law. Assume that magnetic monopoles exist (call them M), and rewrite Faraday's law. Discuss the physical significance of any new terms added.
4. (II) A region is bounded by an imaginary closed surface. Cut the region into two subregions with an arbitrary surface. Show that if Maxwell's first and second equations (which involve the surface

integrals) are valid for both subregions, they are also valid for the whole region. Show that the validity of the third and fourth equations (which involve line integrals) for the two parts of the surface of the regions created by the cut implies the validity of these equations for the full region.

34–2 Electromagnetic Waves

5. (I) If the electric field for a plane wave is given by $E_x = 0$, $E_y = E_0 \cos(kz + \omega t)$, what are $\vec{B}$ and the direction of propagation of the wave?
6. (I) Use dimensional analysis to show that $1/\sqrt{\mu_0 \varepsilon_0}$ has the dimensions of speed, $[LT^{-1}]$.
7. (I) An FM radio station announcer identifies the station as "Q94;" the number 94 stands for the frequency in some units. What is the wavelength and frequency of the waves emitted by the radio station?
8. (I) What is the relation between the amplitudes of the electric and magnetic fields in an electromagnetic wave propagating in a medium whose dielectric constant is κ? Assume the magnetic permeability of the medium is that of the vacuum.
9. (I) A superposition of electromagnetic waves traveling in the $+z$-direction and electromagnetic waves traveling in the $-z$-direction gives rise to standing waves. Check that a standing wave whose x-component of electric field has the form $E_0 \sin(kz) \cos(\omega t)$ satisfies the wave equation [Eq. (34–7)].
10. (II) Find the approximate wavelength, wave number, frequency, and angular frequency for electromagnetic waves associated with (a) your favorite AM station; (b) your favorite FM station; (c) a microwave oven; (d) yellow light; (e) X rays.
11. (II) Use Gauss' law to show that electromagnetic waves must be transverse. [*Hint*: Choose as your Gaussian surface a pill-box, with one of the plane surfaces chosen such that $\vec{E}$ or $\vec{B}$ vanishes on it.]
12. (II) Starting from Eqs. (34–5) and (34–6), derive a wave equation for the y-component of the magnetic field. What is the speed of the resulting wave?
13. (II) Write the counterparts of Eqs. (34–5) and (34–6) for electromagnetic fields B_y and E_z that lie in the yz-plane and propagate in the x-direction. [*Hint*: Start with Figs. 34A–1 and 34A–2. Then relabel the axes according to $x \rightarrow y \rightarrow z \rightarrow x$.]
14. (II) A plane harmonic wave of electromagnetic radiation with wavelength λ is propagating in the $-x$-direction. The z-component of the electric field has magnitude E_0, and there is no y-component. (a) Write an expression for the electric field. (b) Use this expression and the result of Problem 13 to calculate the magnetic field. What vector components will this field have?
15. (II) A plane wave propagates along the direction in the xy-plane that makes an angle θ with the x-axis. Show that the electric field is given by $\vec{E}_0 \cos(kx \cos\theta + ky \sin\theta - \omega t + \phi)$. What directions can $\vec{E}_0$ have?
16. (II) A plane wave of wavelength 17 m propagates in the z-direction. The electric field points in the y-direction and has an amplitude of 0.16 V/m. Write an expression for the magnetic field, including its amplitude in SI units. Assume that the electric field is at its maximum at $z = 0, t = 0$.
17. (II) An electromagnetic wave of wavelength 600 nm propagates in the z-direction. The magnetic field points in the y-direction, and has a magnitude of 10^{-8} T. Write an expression for the electric field, including numerical values and units. Assume that the magnetic field is maximum at $z = 0$ m, $t = 0$ s.
18. (II) An electromagnetic traveling wave is generated at the left-hand end of a tube oriented in the z-direction; the wave travels in the $+z$-direction. At the ends of the tube, $z = 0$ and $z = L$, are highly reflective mirrors. The electric field of the incident wave is $\vec{E} = E_1 \cos(kz - \omega t)\hat{i}$, and the electric field of the wave reflected at $z = L$ is $\vec{E} = E_1 \cos(kz + \omega t + \phi)\hat{i}$. Show that the net electric field forms a standing wave and, by computing B_y, that the associated magnetic field B_y also has the form of a standing wave.
19. (II) Consider the standing electromagnetic wave in Problem 9. If the standing wave is confined to a region lying between $z = 0$ and $z = L$ by two metallic plates, what is the relation between the allowed wavelengths of the radiation and L? (Recall from Chapter 22 that the electric field along a conducting surface must vanish on that surface.)
20. (III) A pulse of electromagnetic radiation travels in the $-z$-direction. The electric field is oriented in the x-direction and is given by $\vec{E} = E_0 \exp(-(z + ct)^2/a^2)\hat{i}$. What is the orientation of the magnetic field? Make a guess of the space–time dependence of the magnetic pulse, and use Eqs. (34–5) and (34–6) to find a form for $\vec{B}$ that satisfies Maxwell's equations.

34–3 Energy and Momentum Flow

21. (I) The intensity of an electromagnetic wave is 6×10^6 W/m^2. What is the amplitude of the magnetic field in this wave?
22. (I) A radio station emits a signal with a power of 18 kW. What are the values of the electric field and magnetic field at distances of 3.5 km and 10.5 km? Assume that the signal far from the antenna is transmitted with equal intensity in all directions. (Real radio stations cannot afford to transmit their energy in this way, and their antennas distribute energy with a high degree of directionality.)
23. (I) The electric field for a given electromagnetic wave has a peak value of 140 mV/m. What is the intensity of the wave?
24. (I) A laser emits a beam with an intensity of 0.40×10^{13} W/m^2 across an area of 1.5 mm^2. What force would the laser beam exert on a black (perfectly absorbing) object?
25. (I) A harmonic plane wave of wavelength 0.45 μm and an electric field amplitude of 3 V/m impinges on a totally reflecting surface of area 200 cm^2. What is the radiation pressure exerted by the wave?
26. (I) A plane electromagnetic wave with maximum electric field amplitude of 120 V/m is incident on a perfectly absorbing surface perpendicular to the direction of propagation. What is the rate of energy absorption per unit area of the surface?
27. (I) The rate at which the Sun emits energy in the form of radiation is 3.8×10^{26} W. (a) Calculate the magnitude of the Poynting vector at a distance of 1.5×10^{11} m from the Sun. (b) What is the radiation pressure exerted on a totally absorbing surface perpendicular to the direction of the radiation?
28. (II) (a) Sketch on the same graph $\sin x$ and $\cos x$ as a function of x. (b) On a separate graph sketch $\sin^2 x$ and $\cos^2 x$. Observe that the periodic functions $\sin^2 x$ and $\cos^2 x$ are identical to one another, except that one is displaced from the other by an interval $\pi/2$. (c) Use your sketch from part (b) to show that the area under the $\sin^2 x$ curve in the interval $0 \leq x \leq 2\pi$ is the same as the area under the $\cos^2 x$ curve in the same interval. (d) Given the fact that $\sin^2 x + \cos^2 x = 1$, use the results obtained in parts (a)–(c) to show that the averages $\langle \sin^2 x \rangle$ and $\langle \cos^2 x \rangle$ are equal to each other and thus equal to 1/2.
29. (II) The magnetic field for a given electromagnetic wave has an rms value of 7×10^{-9} T. What is the intensity of the wave? How much energy is transported per minute through a 0.1-m^2 area?

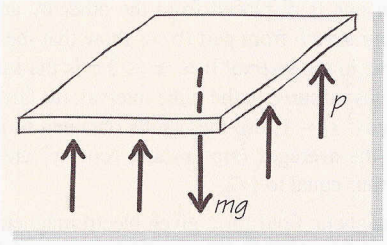
30. (II) A typical lecture-demonstration laser of power 0.75 mW has a beam of diameter 0.90 mm. (a) What are the peak values of the electric and magnetic fields? (b) Suppose—as is in fact possible—that the beam is focused to a circular area with diameter of one wavelength. What is the peak value of the electric field, given that $\lambda = 650$ nm?

31. (II) Assume that a 75-W lightbulb emits light equally in all directions. What are the peak and rms values of the electric and magnetic fields at a distance of 0.50 m?

32. (II) A 75-W lightbulb radiates uniformly in all directions, and 9 percent of this energy is emitted as electromagnetic radiation in the visible light range. What is the electromagnetic energy density of visible light at a distance of 130 cm from the bulb? What are the rms values of the corresponding electric and magnetic fields there?

33. (II) The total electromagnetic power emitted by the Sun is 3.8×10^{26} W. What is the radiation pressure exerted on a totally reflecting surface a distance $r = 1.0 \times 10^{10}$ m from the Sun?

34. (II) What are the dimensions and SI units for the Poynting vector? Reduce your answer to the dimensions and units of mass, length, and time, then reexpress it in terms of watts and meters.

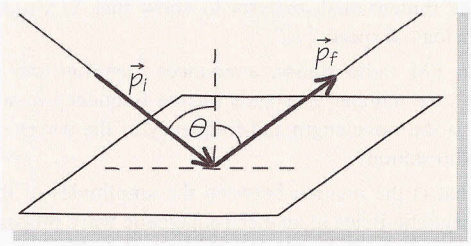


35. (II) Solar energy delivered to a horizontal surface in Washington, D.C., averaged over a full year is 160 W/m^2. Assuming that this radiation is fully absorbed on a particular square meter of ground, what is the approximate total momentum delivered to this area in 1 y? Compare this number to an estimate of the momentum absorbed by a baseball catcher in catching a single pitch.

36. (II) The radiation pressure of a beam of electromagnetic radiation is equal to atmospheric pressure. Calculate the intensity, energy density, and rms electric and magnetic fields of this beam. Assume that the beam is totally absorbed.

37. (II) Sunlight exerts an average radiation pressure of 5×10^{-6} N/m^2. Consider a rectangular mirror of dimensions 20 cm $\times$ 500 cm attached to a vertical wire, so that it is oriented perpendicular to the sunlight. How should you attach it to get the maximum torque exerted by the sunlight? What is the torque?

38. (II) What is the radiation pressure on the walls of a microwave oven in which the rms electric field is 500 V/m? Assume that the waves are traveling waves of the sort we have studied in this chapter, and if it is necessary to know the frequency, estimate the appropriate value.

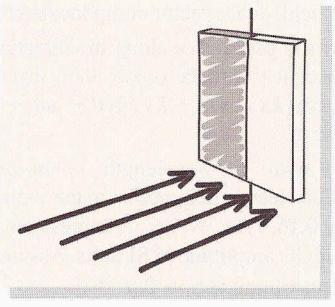


39. (II) Suppose that you want to use the radiation pressure from a beam of light to suspend a piece of paper in a horizontal position; the paper has an area of 50 cm^2 and a mass of 0.20 g (Fig. 34–23). Assume that there is no problem with balance, that the paper is dark and absorbs the beam fully, and that the entire beam can be used to hold the paper against the pull of gravity. How many watts must the light produce? Given your answer, what do you suppose would happen to the paper?

▲ FIGURE 34–23 Problem 39.

40. (II) Tiny flakes of mica are kept aloft by a beam of light projected vertically upward. If the mass of a typical flake is 5.4×10^{-9} kg, and if on the average the area presented to the beam by a flake is 0.06 mm^2, what is the intensity of the beam? Assume that all of the light is reflected.

41. (II) A light beam with a given Poynting vector falls on a flat, fully reflecting surface at an angle of incidence θ (with respect to the vertical) (Fig. 34–24). What is the momentum transferred to the surface per unit area?



▲ FIGURE 34–24 Problem 41.

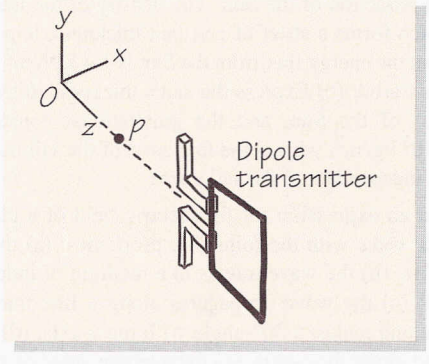
42. (II) A laser delivers 1.8×10^2 J of energy in a pulse that lasts 5×10^{-9} s. What are the peak electric and magnetic fields for a laser beam of diameter 0.5 mm?

43. (II) Consider an electromagnetic wave propagating in the negative x-direction with frequency of 6×10^9 Hz. The wave exerts a pressure of 10^{-4} N/m^2. Write down an expression for the electric and magnetic fields. You may choose your axes such that the electric field is polarized along one of the axes. Specify your choice.

44. (II) Consider a standing electromagnetic wave for which the electric field is $\vec{E} = \hat{j}E_0 \sin kx \cos \omega t$. (a) What is the wavelength of the electromagnetic wave? (b) What is the magnetic field? (c) What is the value of the Poynting vector?

45. (III) The short side of a thin, stiff rectangle 3.0 cm $\times$ 1.0 cm is attached to a vertical axis. Half of each side is painted black and is fully light absorbent; the other half is a shiny, reflecting metal (Fig. 34–25). The back of each half is different from the front. There is no friction at the axis. The apparatus is bathed in a well-collimated (nonspreading) beam of light whose Poynting vector has magnitude 0.5 kg/s^3 and travels perpendicular to the vertical axis. Is there a net torque on the rectangle's surface? If so, what is its average value due to the light over a full, uniform rotation of the rectangle about the axis?

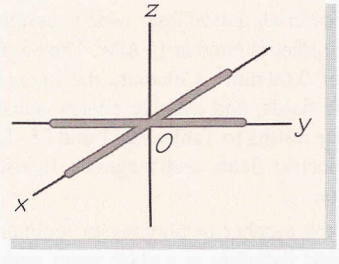
▲ FIGURE 34–25 Problem 45.



46. (III) The total power of a broadcasting dipole antenna is 20 MW. Calculate the intensity of its radiation at a distance of 1000 m, in the direction of the intensity maximum. Compare this to the intensity that would have been obtained if the intensity were distributed uniformly in every direction.

34–4 Dipole Radiation

47. (I) Suppose that a vertical tower 120 m tall acts as a dipole antenna, with currents running back and forth along the tower to generate electromagnetic waves in a dipole pattern. If the wavelength of each electromagnetic wave is the height of the tower, what is the period of the current oscillation in the tower?



48. (I) A charge moves harmonically along an 8-m length in the z-direction, emitting dipole radiation. Two observers detect this radiation. Observer A is at a position that is 10 km from the charge and at an angle of 25° with respect to the z-axis, while observer B is at a position that is also 10 km from the charge, but at an angle of 58° with respect to the z-axis. What is the ratio of the intensity detected by the two observers?

49. (II) A broadcasting dipole antenna is oriented along the y-axis. For the geometry shown in Fig. 34–26, give the following information for a point P far away along the z-axis: (a) the direction of the electric field; (b) the direction of the magnetic field; (c) the direction of the Poynting vector. (d) Repeat parts (a)–(c) for the electromagnetic wave one-half cycle later.

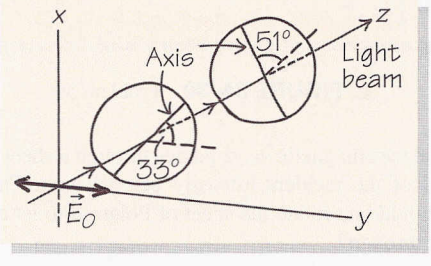
▲ **FIGURE 34–26** Problem 49.

50. (III) A cross-shaped antenna lies in the xy-plane, centered at the origin (Fig. 34–27). The charges oscillate with the same frequency within each arm of the cross. Find the Poynting vector along the z-axis as a function of z if charges moving in the $+x$-direction in the x-arm pass the origin at the same moment that (a) charges moving in the $+y$-direction in the y-arm pass the origin; (b) charges moving in the $-y$-direction in the y-arm pass the origin.

▲ **FIGURE 34–27** Problem 50.

34–5 Polarization

51. (I) At what angle should the axes of two ideal Polaroid sheets be placed to reduce the intensity of a given source of unpolarized light to (a) 7/10; (b) 3/10; (c) 3/20; (d) 1/20?

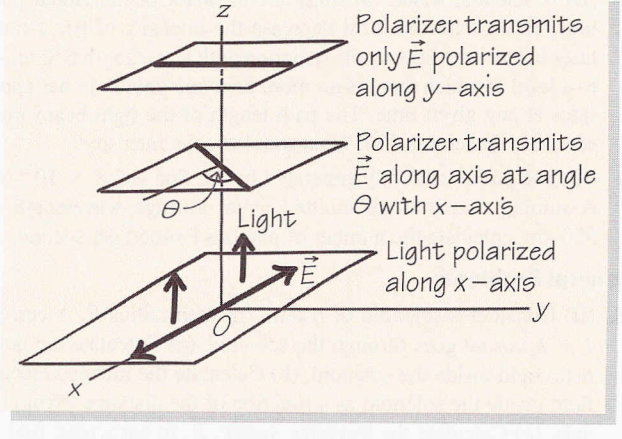


52. (I) The axes of four ideal Polaroid sheets are stacked, each at 28° with respect to the previous one. What fraction of initially unpolarized light passes through all four sheets?

53. (I) The Moon reflects light off a still pond at night. At what angle above the horizon is the polarization a maximum? The index of refraction of water is 1.33.

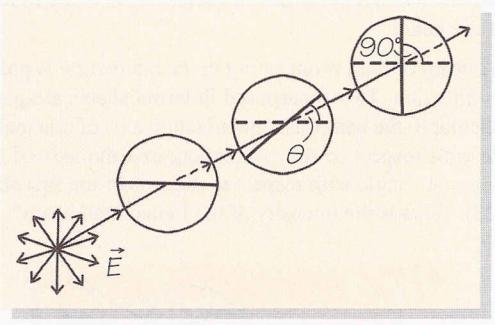
54. (I) Polarized light of intensity $1.0 \times 10^6\ \text{W/m}^2$ is incident on a Polaroid sheet placed perpendicular to the light beam with the polarizing axis of the sheet at an angle of 40° to the polarization vector of the light. What is the intensity of the beam after passing through the polarized sheet?

55. (I) The beam of Problem 54, after passing through the Polaroid sheet described in that problem, then passes through another Polaroid sheet, this one with its polarizing axis at an angle of 80° to the original polarization vector. What is the final intensity of the beam?



56. (II) A beam of light propagating in the z-direction is polarized in the y-direction. Two superposed Polaroid sheets are placed perpendicular to the beam. The polarization axis of one makes a 33° angle with respect to the y-direction, and the axis of the other makes a 51° angle with respect to the axis of the first sheet (Fig. 34–28). What is the intensity of the transmitted beam?

▲ **FIGURE 34–28** Problem 56.



57. (II) What fraction of initially unpolarized light passes through two Polaroid sheets placed at right angles to each other? What happens if a third sheet is placed between the two sheets, with its axis at an angle of 45° to the two?

58. (II) If light of intensity I_0 moving in the z-direction is polarized linearly in the x-direction, it will not pass through a piece of Polaroid that passes light polarized in the y-direction. Figure 34–29 shows a way in which this light can pass the y-direction analyzer if a second analyzer is used. If the lower analyzer makes an angle of θ with respect to the x-direction, what is the intensity of the light that passes the upper analyzer?

▲ **FIGURE 34–29** Problem 58.

59. (II) Unpolarized light of intensity I_0 passes through two pieces of Polaroid successively. (a) What is the intensity of the light after it passes through the first piece of Polaroid? (b) The second piece is rotated so that the intensity of the transmitted light goes to zero. What angle does the polarizing axis of the second piece make with that of the first piece? (c) A third piece of Polaroid is inserted between the two pieces in place. Calculate the intensity as a function of the angle θ that the axis of the third piece makes with the axis of the first piece (Fig. 34–30). (d) Show that the intensity of the transmitted light is no longer zero unless the axis of the third piece is parallel to that of either of the other pieces.

▲ **FIGURE 34–30** Problem 59.

60. (II) An electromagnetic wave passes through a sheet of Polaroid, and 3/4 of the incident intensity gets through. Through what angle should one rotate the sheet of Polaroid to let all the radiation get through?

61. (III) We have *circular polarization* when the electric field of a wave propagating in the z-direction takes the form of the superposition of a wave linearly polarized with the electric field along the x-direction and another wave linearly polarized with the electric field along the y-direction. The phases of these waves must differ by $\pi/2$, and this gives a net electric field of the form $\vec{E} = [E_0 \cos(kz - \omega t)]\hat{i} + [E_0 \sin(kz - \omega t)]\hat{j}$. Show that this electric field at any given z-value forms a vector that rotates uniformly in the xy-plane. Why is this superposition of solutions a physically acceptable wave?

*34–6 Electromagnetic Radiation as Particles

62. (II) Calculate the number of photons emitted by an FM radio station that broadcasts at a frequency of 4.5×10^8 Hz that are required to equal the energy contained in one photon of visible light at a wavelength of 450 nm.

63. (II) A scientist wishes to study the behavior of individual photons. To do that, she must decrease the intensity of her 1-mm^2 laser beam—the laser emits radiation with wavelength 630 nm—to a level at which there is no more than one photon in her apparatus at any given time. The path length of the light beam from source to detector is 2 m. What should be the intensity?

64. (II) The power currently generated by the Sun is 3.8×10^{26} W. Assuming that it is all emitted at an average wavelength of 550 nm, calculate the number of photons emitted per second.

General Problems

65. (II) Consider a solenoid of n turns/m with radius R. A current $I = I_0 \cos \omega t$ goes through the solenoid. (a) Calculate the magnetic field inside the solenoid. (b) Calculate the induced electric field inside the solenoid as a function of the distance r from the axis. (c) Calculate the Poynting vector, $\vec{S}$. In particular, find its direction at different times during one cycle.

66. (II) The electric and magnetic fields of an electromagnetic wave act on a charge q. With what speed must the charge move so that the magnetic force on the charge is, at most, 30 percent of the electric force? If the electromagnetic wave is traveling in the z-direction and the electric field has only an x-component, what is the direction (or directions) of motion of q so that the magnitude of the magnetic force is greatest?

67. (II) Consider the solar sail described in Question 9. A solar sail can be aligned with its area perpendicular to a radial line from the Sun so that the sail is pushed straight outward. Show that in this configuration the force on the sail always has the same sign and is proportional to $1/r^2$, where r is the distance from the sail to the Sun. (Assume that only the radiation pressure and the gravitational force due to the Sun act on the sail.) This economical method of propulsion has been proposed for travel to the far reaches of the solar system when transit time is not an important factor.

68. (II) A solar sail (see Question 9) is to be designed such that, when it is aligned perpendicular to the Sun's rays and is 1.5×10^{11} m from the Sun, the radiation pressure on it, P, just cancels the gravitational attraction of the Sun. The density of the material of the sail, which forms a sheet of constant thickness, is ρ. (a) Find P, given that the energy flux from the Sun is 1.4 kW/m^2 at the radius of Earth's orbit. (b) Express the sail's thickness in terms of ρ, P, the mass of the Sun, and the gravitational constant. If ρ is 2.0×10^3 kg/m^3, what is the thickness of the sail material? Your result is independent of the sail's area.

69. (II) Find an expression for the electric field of a plane electromagnetic wave with the following properties: (a) the frequency is 10^{14} Hz; (b) the wave travels in a medium of index of refraction 1.4; (c) the wave propagates along a line that lies in the xy-plane and makes a 30°-angle with the x-axis; (d) the wave is polarized along the z-axis; (e) the average value of the Poynting vector is 500 W/m^2.

70. (II) A swimming pool has underwater lights. What is Brewster's angle for reflection off the upper surface of water? The index of refraction of water is 1.33.

71. (II) The amount of solar energy reaching your body when you sunbathe on an ocean beach in summer is about 800 W/m^2. Assume that your body absorbs 40 percent of this incident radiation and that your exposed body area is 0.5 m^2. How much solar energy do you absorb in 1 h? Estimate how much perspiration must evaporate to dissipate this energy (see Chapter 17).

72. (II) A high-powered, pulsed laser used to confine plasma for nuclear fusion studies is rated at 15 MW. The laser beam is focused on an area of 0.60 mm^2. Calculate the intensity, peak electric and magnetic fields, and average energy density in this beam. Compare your results to Tables 22–1 and 28–1, which list some values for electric fields and magnetic fields, respectively, in other contexts.

73. (II) What is the number of photons/m^3 contained in a beam of electromagnetic radiation in a plane wave with a wavelength of 2 cm and an electric field amplitude 10 V/m?

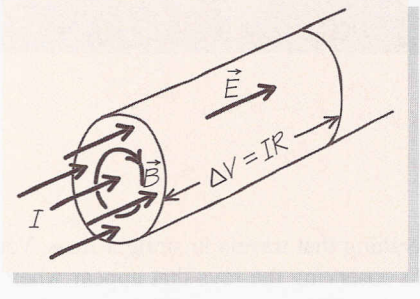
74. (II) The solar energy flux at a distance $R_0 = 1.5 \times 10^{11}$ m from the Sun (the radius of Earth's orbit) is 1400 W/m^2. (a) What is the total energy flow from the Sun in watts? (b) Use your result to calculate the rate at which photons are emitted. Assume an average wavelength of 600 nm. (c) Using the result of part (b), find the number of photons/s that strike a 1 mm × 1 mm surface at a distance R_0. The surface is oriented perpendicular to the Sun.

75. (II) A laser emits N photons of frequency f. The beam strikes a mirror that is moving with speed v in the direction of propagation of the laser beam. Assuming that the kinetic energy of the mirror is much larger than that of the beam, use energy conservation and momentum conservation to find the frequency of the reflected beam. Treat the photon as a particle of energy hf and momentum hf/c.

76. (II) A wire is bent into a loop. The two ends are attached to the terminals of a battery and a current flows through the wire. Sketch the direction of the Poynting vector field near the wire.

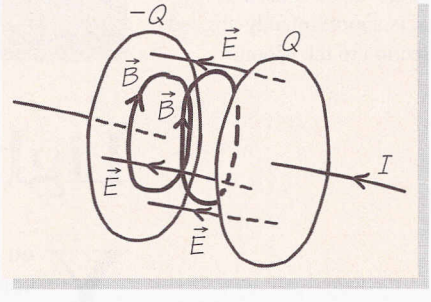
77. (III) Many people believe solar sails are a useful source of propagation in space. What acceleration would a 150-kg space probe have if it had a 100 m^2 sail perpendicular to the line to the Sun and starts at Jupiter's orbit? The intensity of sunlight at Earth is 1400 W/m^2; use this fact to find the corresponding quantity at the radius of Jupiter's orbit, all the way to Saturn's orbit. How long would it take this probe to reach the orbit of Saturn?

78. (III) Consider a current I that flows through a cylindrical wire of length L, radius b, and resistance R (Fig. 34–31). The current flows uniformly across the cross section of the wire. Calculate the electric fields inside and on the surface of the wire. The current in the wire gives rise to a magnetic field, which you can calculate. Use these fields to find the direction and magnitude of the Poynting vector on the surface of the wire. Show that the rate of energy flow into the wire through its surface is IR^2, the power dissipated in ohmic heating.



79. (III) Consider Eq. (34–3), in which the current I passes through the surface dA, so that $I = \int_{\text{surface}} \vec{J} \cdot d\vec{A}$. If the wave propagates in a medium in which there is some conductivity, we may write the right hand side of Eq. (34–3) as

$$\mu_0\varepsilon_0 \frac{d}{dt}\int \vec{E}\cdot d\vec{A} + \frac{\mu_0}{\rho}\int \vec{E}\cdot d\vec{A}.$$



This means that in Eq. (34–5) we should make the replacement $\frac{\partial}{\partial t}E_x \rightarrow \frac{\partial}{\partial t}E_x + \frac{1}{\varepsilon_0\rho}E_x$. How does this affect the wave equation for E_x?

80. (III) Consider a plane electromagnetic wave of frequency f that propagates in the z-direction in a cubic box whose sides are length L, with L much larger than the wavelength. The electric field of the radiation has the form $\vec{E} = E_0 \sin(kz - \omega t)\,\hat{i}$. Alternatively, we can say that the radiation consists of N photons, each propagating in the z-direction with energy hf, where h is Planck's constant. Use two alternative expressions for the energy of the radiation to express E_0 in terms of h, f, N, and L.

81. (III) Consider a capacitor that consists of two circular metal plates of radius R a distance d apart (Fig. 34–32). R is so much larger than d that all fringe fields can be neglected. If the charge on the plates, Q, changes with time, then according to Ampère's law a magnetic field will be induced in the region between the plates. (a) What is the induced magnetic field? (b) Using the induced magnetic field and a calculation of the electric field between the plates, find the Poynting vector. (c) Show that with this Poynting vector, the net energy flow into the capacitor is the rate of change of the capacitor energy $Q^2/2C$.

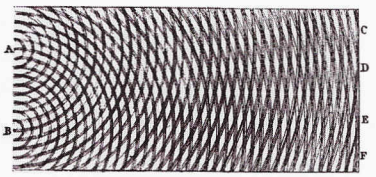
Chapter 35

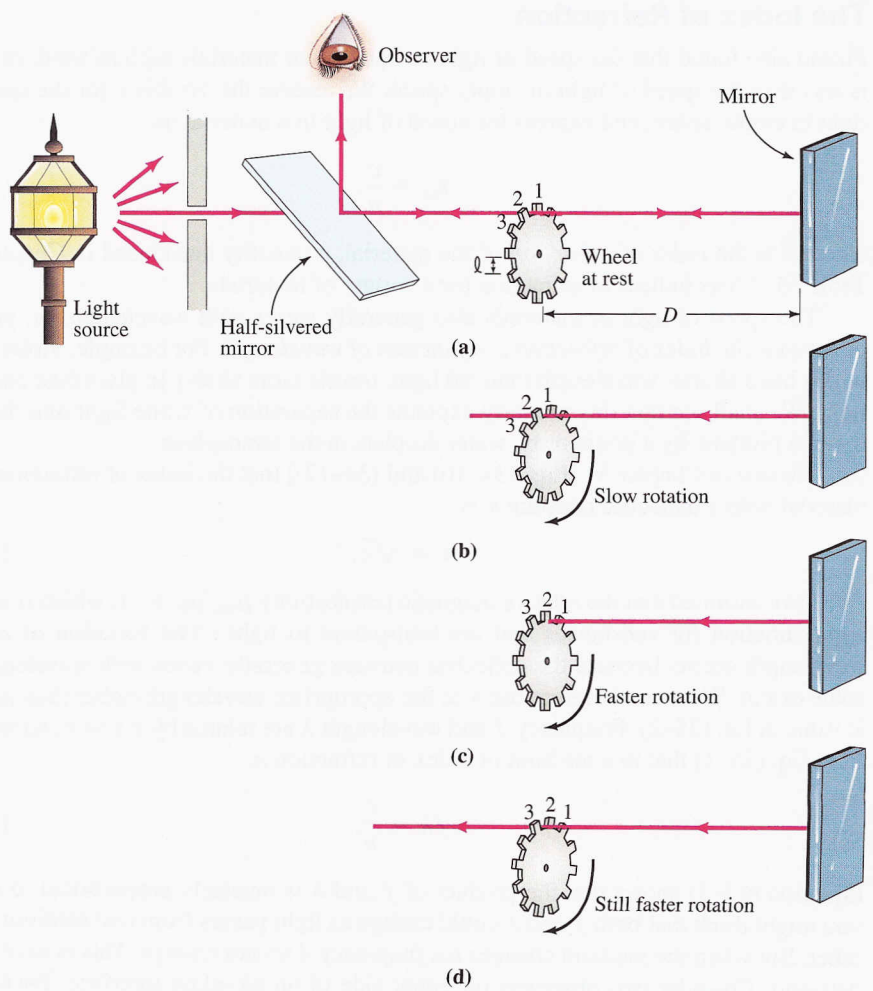


▶ This spectacular shuttle launch produced a very special and memorable effect. The launch took place just after sunset, and the lower part of the plume was in shadow while the upper part still received the rays of the Sun. The launch also took place very close to a full Moon, so that the Sun, Moon and Earth were nearly aligned. The upper part of the plume cast a shadow, visible in the form of an "anticrepuscular ray," a shadow that is approximately aligned along the direction to the Moon.

Light

You may think of light as something that travels in straight lines. You may have come to this conclusion from observing the rays that appear when light penetrates a forest on an early morning. This property of light strongly suggests that light is composed of particles emitted by a source, and Isaac Newton, whose earliest work was on optics, supported that view. The phenomena he considered in coming to a conclusion include many with which we have some everyday experience: the reflection of light from mirrors, refraction as light passes through glass lenses or water, and observations of rainbows and the prismatic separation of colors. The particle model provided such a good explanation of these observations that it is surprising that the idea that light consists of waves could have taken root in Newton's day. Yet Robert Hooke's idea that light is some type of oscillatory activity in an unidentified medium led Christian Huygens to propose a wave theory of light in 1687. In this chapter, we shall show that the wave theory of light can explain almost everything that the particle theory can, as well as the interference and diffraction phenomena that cannot be explained by a particle picture.

By the early nineteenth century, it had become apparent that certain observations could not be explained by the particle theory; an explanation of these observations demanded that light behave like a wave. For example, when we look very closely, light does not cast *sharp* shadows, and so to some extent light bends around corners. (Newton did not have the equipment to make this observation, and, in fact, he argued against the wave theory on the basis that light does *not* appear to bend around corners!) Under controlled conditions, we can also see that beams of light interfere with each other in just the same way as the waves discussed in Chapter 15 interfere. Definitive experiments by



Thomas Young in 1801 on the wave aspects of light eventually established the preeminence of the wave theory (Fig. 35–1). The phenomena associated with the wave aspects of light are the subject of Chapters 37 and 38. The prediction from Maxwell's equations that light is an electromagnetic wave would seem to have settled the question of whether light is a particle or a wave once and for all. In the twentieth century, however, we had to revise our view once more, as new experimental evidence suggested that some aspects of light can be explained only if light sometimes behaves as particles. Today we are not forced to choose between a particle picture and a wave picture of light; a quantum mechanical explanation encompasses them both.

▲ **FIGURE 35–1** Young's view of the wave nature of light. In this sketch published in 1807 from his lectures, points A and B represent pinholes; points where the waves reinforce each other on the screen are marked.

35–1 The Speed of Light

Light travels so rapidly that it requires a good deal of ingenuity to show that its transmission is not instantaneous. Although Galileo had thought that the speed of light might be finite, he failed to find a time delay in the passage of light from one mountaintop to another. Ole Roemer observed the eclipses of the moons of Jupiter in 1675 and found that the timing of these phenomena could be explained if light traveled with a large, but finite, speed. The solar system data available to Roemer at the time gave a value of 2×10^8 m/s for the speed of light—certainly a result of the correct order of magnitude. The first terrestrial measurements were made in 1849 by Hippolyte Fizeau, who used the device shown in Fig. 35–2. A light source is placed behind a toothed wheel that can be rotated at high speeds. The light passes through an inclined glass plate and then between two teeth of the rotating wheel. It then travels to a mirror and is reflected straight back. If the speed of light were infinite, light would be reflected back through the gap before the wheel had moved at all (Fig. 35–2b). Light traveling at a finite speed would also pass

◀ **FIGURE 35–2** Fizeau's method for measuring the speed of light: (a) a sketch of the apparatus he used. (b) Incident and reflected light pass through the same gap when the wheel rotates slowly. (c) As the rotation of the wheel increases, it will become fast enough so that the reflected light fails to pass through the original gap, and instead strikes the cog between. (d) When the rotation speed is still higher, the reflected light passes through the next gap by traveling the distance $2D$ in the time the wheel rotates to the next gap.

through the same gap if the rotational speed of the wheel were small. But if the wheel is rotating fast enough and the speed of light has a finite value c, then, at a certain value of angular velocity, the wheel moves enough during the time the light travels to the mirror and is reflected back that the light will strike cog 2 (Fig. 35–2c), and no light reaches the observer in this case. As the wheel rotates even faster, light once again reaches the observer, but this time it passes through the *next* gap in the wheel, the one between cogs 2 and 3 (Fig. 35–2d). If the edge of the wheel is moving at speed v when Fig. 35–2d first applies, then we can equate the time $2D/c$ for light to make a round trip from the wheel to the mirror (D is the distance from wheel to mirror) and back to the time ℓ/v (ℓ is the cog spacing) for the wheel to move a distance of one gap:

$$\frac{\ell}{v} = \frac{2D}{c}.$$

If D is much larger than ℓ, then a value of v much smaller than c would suffice to measure c accurately. In Fizeau's 1849 experiment, the light traveled almost 20 km, while a wheel with more than 700 cogs rotated tens of times per second. Fizeau reported a result of about 3.1×10^8 m/s, a few percent different from the correct value.

Better measurements improved the value of c. Ultimately, because a measurement of c is the ratio of a distance to a time, the best measurement of c would be limited by our ability to measure time (today, to one part in 10^{13}) and distance (today, to four parts in 10^9). Because distance is harder to measure accurately than time, today we pass this difficulty by *defining* the speed of light in a vacuum to be $c = 299{,}792{,}458$ m/s and use time along with the definition of c to measure distances. In this way of doing things, the meter is no longer defined but is rather measured: One meter is 1/299,792,458 times the distance traveled by light in 1 s (see Section 1–2). For practical purposes, you can use $c = 3.00 \times 10^8$ m/s.

The Index of Refraction

Fizeau also found that the speed of light in transparent materials such as water or glass is *less* than the speed of light in empty space. We reserve the symbol c for the speed of light in empty space, and express the speed of light in a material as

$$v_m = \frac{c}{n}, \tag{35–1}$$

where n is the *index of refraction* of the material, a quantity introduced in Chapter 34. Table 35–1 lists indices of refraction for a variety of materials.

TABLE 35–1 • Indices of Refraction for Various Substances (λ = 600 nm)

Material	Index of Refraction, n
Air (1 atm, 0°C)	1.00029
Carbon dioxide (1 atm, 0°C)	1.00045
Ice	1.31
Water (20°C)	1.33
Ethyl alcohol	1.36
Castor oil	1.48
Benzene	1.50
Fused quartz	1.46
Glass (crown)	1.52
Glass (flint)	1.66
Diamond	2.42

The speed of light in materials also generally varies with wavelength, or, put another way, *the index of refraction is a function of wavelength*. For example, violet light, which has a shorter wavelength than red light, travels more slowly in glass than does red light. We shall see that this property explains the separation of white light into the colors of a rainbow by a prism or by water droplets in the atmosphere.

We saw in Chapter 34 [Eqs. (34–16) and (34–17)] that the index of refraction for a material with a dielectric constant κ is

$$n = \sqrt{\kappa}. \tag{35–2}$$

(We have assumed that the relative magnetic permeability $\mu_m/\mu_0 \cong 1$, which is a good approximation for substances that are transparent to light.) The variation of n with wavelength occurs because the dielectric constant generally varies with wavelength to some extent. We must therefore use κ at the appropriate wavelength rather than its static value in Eq. (35–2). Frequency f and wavelength λ are related by $f\lambda = v$, so we find from Eq. (35–1) that in a medium of index of refraction n,

$$f\lambda = \frac{c}{n}. \tag{35–3}$$

Equation (35–3) shows that the product of f and λ is inversely proportional to n, and you might think that both f and λ could change as light passes from one medium to another. But when the medium changes *the frequency does not change*. This is easy to understand: Consider two observers on either side of an air–glass interface. Each wave front that passes one observer must pass the other—otherwise wave fronts would pile

up or disappear, neither of which happens. As a consequence, *it is the wavelength of light that changes with the index of refraction* in such a way that $c/f = n\lambda$ is constant [see Eq. (35–3)]. Thus, when light passes between media 1 and 2,

$$n_1\lambda_1 = n_2\lambda_2. \tag{35–4}$$

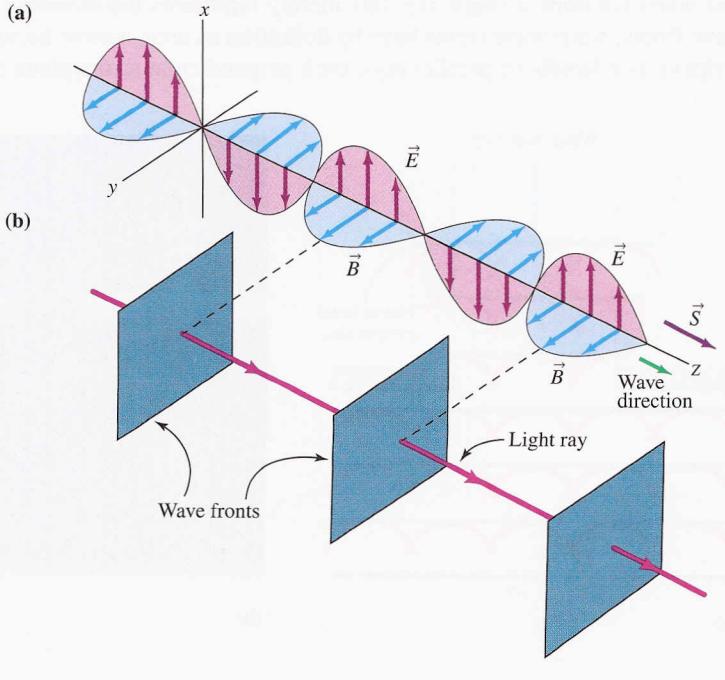
35–2 When Can Light Waves Be Treated as Rays?

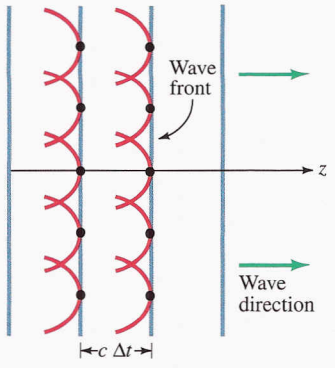
A particle model of light accounts for many of the apparent features of light propagation, including the facts that light seems to travel in a straight line and casts a sharp shadow. But a wave model can also explain these features, as well as how they break down when we take a closer look. These issues are of some importance because one of the goals of this chapter is to establish the validity of a wave picture of light.

In Chapter 34, we discussed electromagnetic waves that propagate along the $+z$-axis. It will be helpful to review the properties of those waves here. The space dependence and time dependence of the electric or magnetic fields are described by a function such as $\cos(kz - \omega t)$. This function has a series of crests and troughs, with, for example, crests occurring at $kz - \omega t = 0$, or

$$z = \frac{\omega t}{k} = ct.$$

Thus the crest propagates at speed c. We referred to this as a plane wave because all points in the xy-plane defined by a fixed value of z have the same fields, whatever the x- or y-value (Fig. 35–3a). This allows us to make the idea of the wave fronts in electromagnetic waves more explicit: The planes for which the argument $kz - \omega t$ is constant represent the fronts. Figure 35–3b shows a sequence of wave fronts transverse to the direction of the electromagnetic (light) wave. It is useful to think of these fronts as representing a particular set of field values along the wave. For example, the wave fronts could represent the planes on which the electric field is a maximum or the points where the field is zero. (Figure 35–3b arbitrarily sets the wave fronts at the points where the electric field is maximal; since the magnetic and electric fields are in phase, these are also the points where the magnetic field is maximal.) In empty space the sequence of wave fronts moves at speed c along the original direction of propagation. Light is observed to move in a straight line, and the description above is in fact in accord with the observation. Christian Huygens, who was one of the earliest proponents of the wave theory of light, was able to strengthen this agreement between the wave picture and observation with a special approach to the process.





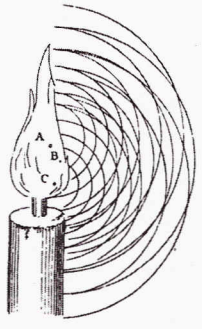


FIGURE 35–3 (a) The electric and magnetic fields of an electromagnetic wave propagating in the direction of the Poynting vector $\vec{S}$ (see Chapter 34). (b) Wave fronts are chosen arbitrarily at points where the electric and magnetic fields are maximal; the fronts could be chosen at the fields' zero points instead.

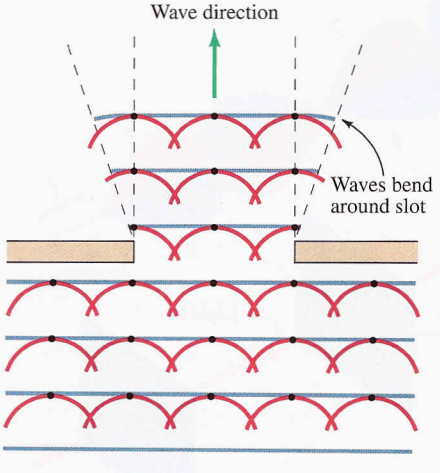
(a)

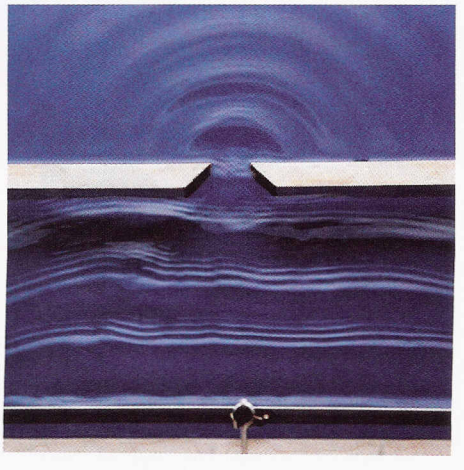
(b)

▲ **FIGURE 35–4** (a) Huygens' construction of wave fronts. Wavelets emitted at each point along the wave front add to a new wave front and produce plane waves. (b) Huygens' illustration of wavelets, here for a candle flame, from his book *Traité de la Lumière* (1885).



Huygens' Principle

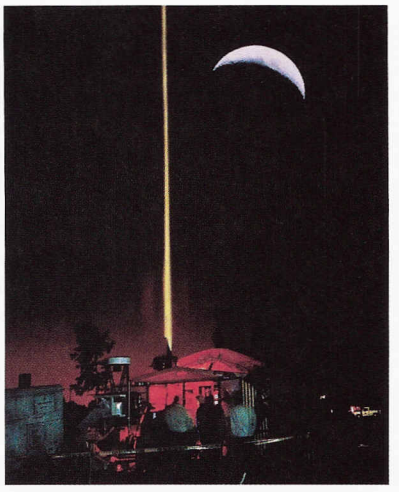
Consider, as Huygens did in a publication dating from 1690, a wave front perpendicular to the $+z$-direction (Fig. 35–4a). Huygens located the wave front after a time interval Δt by viewing *every* point on the original wave front as a source of light emitting a spherical pulse (or *wavelet*) of radiation (Fig. 35–4b). The radius of the wavelet sphere in empty space is $c\,\Delta t$, the distance the light travels in time Δt. (In a medium in which the speed of light is c/n, the radius of the sphere is reduced by a factor of n to $(c/n)\,\Delta t$.) In the limit that the separation between all the emission points is small, the envelope of all these tiny spheres, taken in the direction of propagation of the initial wave front, is the new wave front. As long as no matter boundaries are encountered, the wave fronts generated in this way remain planes parallel to the xy-plane, and the straight-line propagation of wave fronts is assured. This treatment of waves, in which each point on an advancing wave front emits wavelets, and the wavelets add to the future configuration of the entire wave, is called **Huygens' principle**. Huygens' principle can be justified from a detailed study of the behavior of waves in Maxwell's equations, although we shall not do so here.



We know from our study of mechanical waves in Chapter 15 that when a wave front such as that formed by water waves approaches a slot, or opening, in a barrier, the wave spreads as it passes the edge of the opening, a phenomenon known as *diffraction*. Huygens' principle can be applied to this situation (Fig. 35–5). When the wave front arrives at the wall, only the part of the wave at the opening can continue to propagate beyond the wall. This part of the wave front generates waves that travel past the slot, with the additional feature that the spherical wavelets emitted near the edges of the slot have no neighboring wavelets to maintain a parallel wave front, and *a wave that spreads away from the slot edges is generated past the slot*. In effect, the light bends around the corner of the opening. Huygens' principle suggests that the spreading is significant (in terms of the fraction of energy in the bent waves) only if the wavelength is about the same as, or larger than, the size of the slot. If the slot width is much larger than the wavelength, only a small fraction of the energy goes into the bent waves, and it is adequate to view the entire slot as a source of a plane wave front. Light has wavelengths around 5×10^{-7} m; therefore the slot must not be too much larger than this size for the effect to be significant. Diffraction had in fact been observed in Newton's day, and it presented a difficulty, although for some reason not a mortal one, for the particle picture. We'll study this phenomenon as it applies to light in Chapter 38.

If the slot is large compared with the wavelength of light, then diffraction can be ignored. The wall casts a shadow, but to a good approximation that is its only effect. We have a *beam* of light, and we can talk about **rays** of light. It is important to remember that when we draw a single ray, this merely represents the *direction* of the motion of wave fronts; since wave fronts have by definition an area, a more accurate graphical description is a *bundle* of parallel rays, each perpendicular to the plane of the wave front.

▶ **FIGURE 35–5** (a) Huygens' construction of wave fronts that approach and pass through an open slot in a wall. Past the slot, the wave fronts bend around the slot edges. (b) A concrete realization of the effect, in a ripple tank, with an opening small enough to act as a single point source.



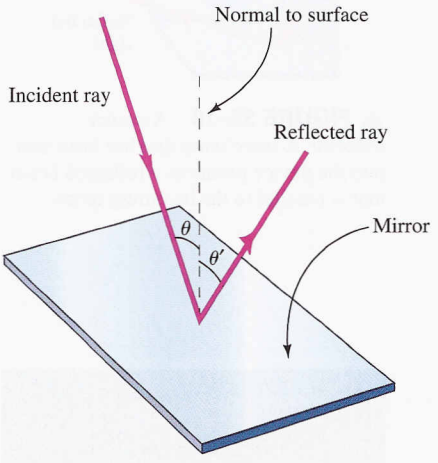
(a)

(b)

Light entering a darkened room through a pinhole or the beam of a searchlight or laser provides vivid images of the propagation of light in the form of rays. We normally do not *see* rays, but they can be made visible by, for example, putting dust particles in the path of the ray (Fig. 35–6). A small part of the light is scattered to the side and is visible from there. The description of light based on the straight-line propagation of rays is called **geometric optics**. This description is perhaps more intuitively referred to as particle-like, because straight-line propagation in free space is a particle characteristic.

In the next section we introduce the two principal laws that allow a complete treatment of geometric optics, laws that describe the reflection and refraction of light rays. In Section 35–4 we describe how both of these laws can be derived directly from Huygens' principle. Even though Huygens' principle is based firmly on the idea that light is a wave phenomenon, to the extent that it explains the behavior of geometric optics, it describes something that more clearly resembles a particle phenomenon. And, as we have seen in our discussion of the passage of light through slots, Huygens' principle will also account for the characteristically wavelike features of light. As we proceed, keep in mind that our treatment of wave phenomena is reserved for Chapters 37 and 38. Here we concentrate on geometric optics.

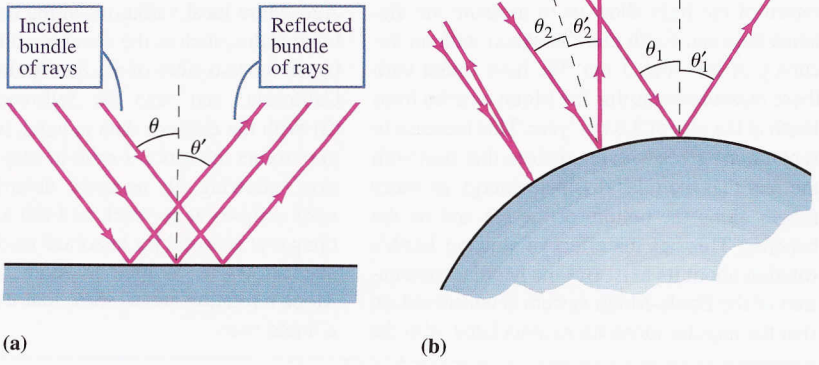
▲ **FIGURE 35–6** A beam of light generated by a laser. The beam is visible because particles in the air have scattered the light. Lasers have many uses—this beam is used to make a reference for astronomical instruments that can adjust for atmospheric turbulence. It supplies a view of the instantaneous turbulence, which can then be corrected for.



35–3 Reflection and Refraction

Reflection

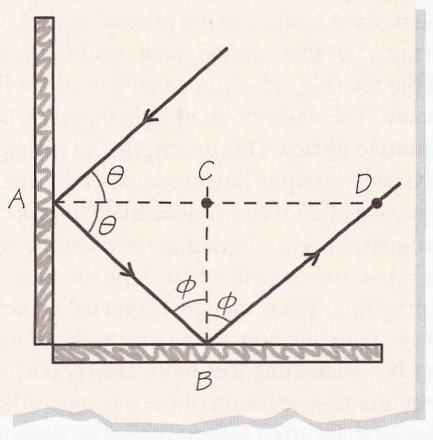
A light ray **reflects**—it "bounces back"—when it strikes a smooth surface such as that formed by a mirror. (This, of course, oversimplifies much of what happens to reflected light. Virtually everything we see comes from light that has reflected from objects. But these reflections are for the most part quite complicated, because of both the nature of the material that is doing the reflecting and the surface structure of that material. Here you should be thinking of a mirror, something whose surface is essentially invisible but that reflects light rays in the ways we'll describe now.) The *incident ray* makes an angle θ with a line normal to the surface at the point of reflection (Fig. 35–7). The *reflected ray* lies in the plane formed by the incident ray and the normal. The angle θ' that the reflected ray makes with the normal obeys the equation known as the **law of reflection**:



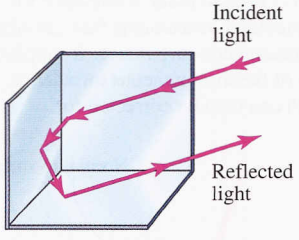
$$\theta' = \theta. \qquad (35\text{–}5)$$

LAW OF REFLECTION

▲ **FIGURE 35–7** The angle of incidence θ equals the angle of reflection θ'.



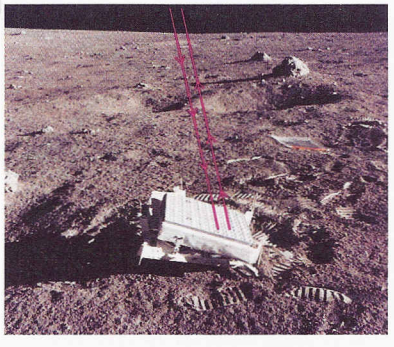
The consequences of this law are shown in Fig. 35–8a for the reflection of a set of parallel incident rays (a *bundle* of rays) from a flat mirror and in Fig. 35–8b for that from a smooth, curved surface. For the curved surface, the angles of incidence and reflection are indeed equal, but the direction of the normal to the surface varies from point to point, and the reflected rays radiate in various directions.



◀ **FIGURE 35–8** Reflection of rays from (a) flat and (b) curved surfaces.

CONCEPTUAL EXAMPLE 35–1 Show that two flat mirrors placed at 90° with respect to each other form a perfect reflector if the incident ray is in the plane perpendicular to the two mirrors. By a perfect reflector we mean that after two successive reflections the outgoing ray will travel back parallel to the line of incidence for an incoming ray at any incident angle.

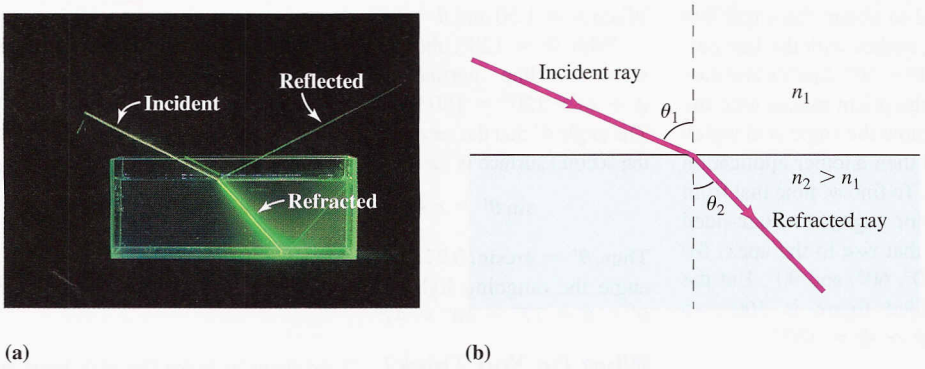
Answer By drawing the two mirrors perpendicular to the page, as in the sketch of Fig. 35–9, the incident ray is in the plane of the page. Then we need only note that angle *ACB*—the angle between two normals to surfaces perpendicular to each other—is 90°. We can then establish that the sum of the remaining two interior angles of triangle *ACB* add to 180° − 90° = 90°, that is, $\theta + \phi = 90°$. That means the angle of the outgoing ray with respect to the incoming ray, which the diagram shows is $2\theta + 2\phi$, is 180°. The incoming and outgoing rays are parallel.



▲ **FIGURE 35–9** The incoming ray that strikes point *A* eventually emerges along *BD*, parallel to the incoming ray.

▲ **FIGURE 35–10** A corner reflector. A laser beam that has been sent into the device produces a reflected beam that is parallel to the incoming beam.

Corner Reflectors: Example 35–1 illustrates the principle behind the construction of *corner reflectors* (Fig. 35–10). In a corner reflector, *three* mirrors are placed together at mutual 90° angles, like the walls of an interior corner of a room, or an array of such corners is placed adjacent to one another. Geometry of the kind used in Example 35–1 shows that a ray incident at *any* angle reflects out from a corner reflector along a ray parallel to the incident ray. Corner reflectors are used on some highway signs so that the reflection of light from a vehicle's headlight automatically heads back to the vehicle, making the presence of the reflector very evident to the driver. Other applications stem from the fact that it is possible to measure time delays with great accuracy; a pulse from a laser directed at a corner reflector comes back, and the time delay gives a measurement of distance. In this way, for example, slight movements across fault lines on Earth's surface can be accurately surveyed.



▲ **FIGURE 35–11** This array of corner reflectors was left on the Moon by the *Apollo 14* astronauts. By shining a laser beam from Earth at the reflector and looking for the return light on Earth, the distance to the Moon can be accurately measured. The red lines indicate the directions of the incoming and outgoing laser beams.

THINK ABOUT THIS. . .

WHAT HAVE WE LEARNED FROM CORNER REFLECTORS ON THE MOON?

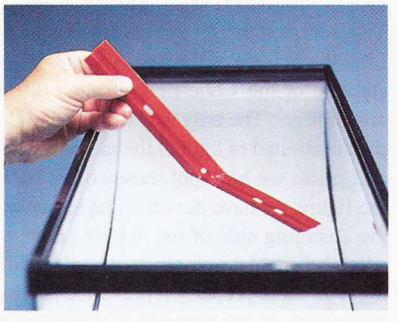
Starting with the *Apollo 11* lunar landing in 1969, several corner reflectors have been placed on the Moon (Fig. 35–11). Flashing laser beams sent through terrestrial telescopes and aimed at the reflectors allow us to capture a fraction (actually only one in about 50 of the very brief flashes ever sends back as much as a single photon—the minimum possible amount—to the detectors on Earth) of the sent beam and measure the time elapsed between departure and arrival. Precision atomic clocks that time the return of the light allow us to measure the distance between Earth and the Moon with an accuracy of less than 1 cm! We have found with these measurements that the Moon recedes from Earth at the rate of 3.8 cm/year. This increase in separation agrees with predictions that start with the fact that the tides dissipate energy as water moves along the bottom of the sea and on the beaches. This has the effect of slowing Earth's rotation about its axis. But the angular momentum of the Earth–Moon system is conserved, so that the angular momentum associated with the Moon's orbiting the Earth must increase to compensate, and for this to happen, the radius of the Moon's orbit increases—in other words, the Earth–Moon separation increases. The measurement of the rate gives us confidence that we understand the process. We have learned other things from the Earth-Moon distance measurements: (1) There is a constant change in Earth's shape, resulting from the fact that land masses are slowly recovering from the compression caused by the weight of glaciers in the last Ice Age. More local variations in the height of tectonic plates, such as the changing difference between the two sides of the San Andreas Fault in California, can also be followed in time. (2) With the distance data in hand, it is possible to retrodict the Moon's orbit to very high precision, allowing an accurate determination of solar eclipses as far back as 1400 B.C.E., something that is useful for historical studies. (3) The data allows us to look in more detail at the Moon's rotation and to show that the Moon has a liquid core.

◀ **FIGURE 35–12** (a) A beam of light is refracted as it enters a tank of water. (b) Refraction from a medium with index of refraction n_1 into a medium with index of refraction n_2. In this case $n_2 > n_1$, and the refracted ray is bent toward the normal to the boundary surface. If n_2 had been less than n_1, the refracted ray would have bent away from the normal.

Refraction

We are all aware of the fact that some media are transparent and that light can pass from one transparent medium into another; air and water form one familiar pair, as do air and glass. We have referred to this process as *transmission*. When the light forming a ray undergoes transmission, the incident ray does not continue along a single straight line but instead changes direction at the boundary between the media. The ray is said to undergo **refraction** (Fig. 35–12a).

Let the index of refraction of the medium with the incident ray be n_1 and that of the medium with the *refracted ray* be n_2. The angles that the incident and refracted rays make with the line normal to the boundary between the media are θ_1 and θ_2, respectively (Fig. 35–12b). Then one finds that

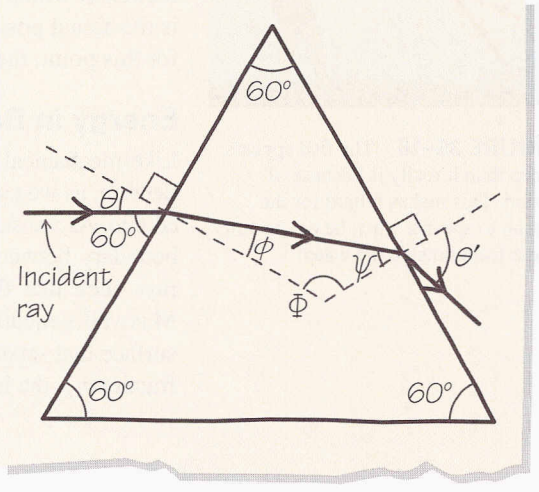


$$n_1 \sin\theta_1 = n_2 \sin\theta_2. \qquad (35\text{–}6)$$

SNELL'S LAW

This is **Snell's law**, discovered by Willebrord Snell in 1621. The index of refraction of air is very close to unity, so the angle of the refracted ray θ_2 at the interface for light that passes from air into a medium with index of refraction n is given by

$$\sin\theta_1 = n \sin\theta_2. \qquad (35\text{–}7)$$



Because n is generally larger than one, it follows that $\theta_2 < \theta_1$; that is, *the light is bent toward the normal to the boundary surface*. Equation (35–6) also shows that when light enters a medium with a lower index of refraction, such as when a ray of light travels from water to air, the ray is bent farther away from the line normal to the boundary. This makes a ray coming from an underwater object move closer to the horizontal upon reaching the air, so that an eye receiving this ray and mentally tracing it back will "place" the object at a shallower position (Fig. 35–13).

▲ **FIGURE 35–13** Water has a higher index of refraction than air, so the immersed part of this ruler appears in a position that is shallower than its actual position.

EXAMPLE 35–2 Consider a horizontal ray of light approaching a prism, a piece of glass shaped as a rod whose cross section makes a triangle. In this example, the triangle is an equilateral triangle, and the ray is perpendicular to the axis of the rod. The ray is refracted once as it enters the glass and then a second time as it exits to the air. What is the total deflection of the ray, given that the index of refraction of the prism glass is 1.50?

Setting It Up The essential part of this problem is the sketch (Fig. 35–14), because the tools necessary for this problem are those of simple geometry. The sketch defines a series of angles that must be calculated to find the angle of the final ray.

▶ **FIGURE 35–14** Geometric construction of the path followed by a ray incident on a prism.

(continues on next page)

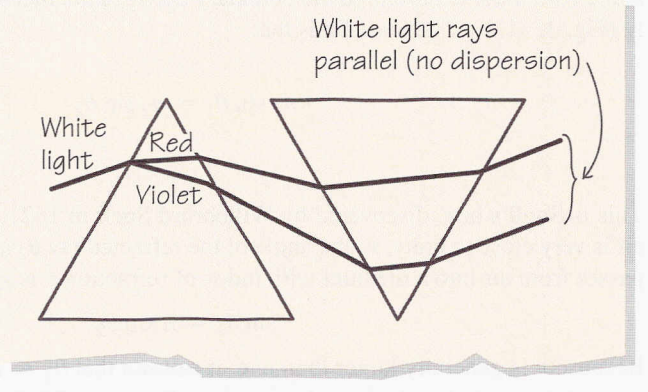
Strategy Simple geometry can be used to obtain the angle that the incident ray, drawn parallel to the base, makes with the line perpendicular to the face of the prism, namely $\theta = 30°$. Snell's law then gives us the angle ϕ that the beam inside the prism makes with the perpendicular to the first face. We need to know the angle ψ at which the interior ray meets the second face, and then another application of Snell's law will give us the final angle θ'. To find ψ, note that from the figure, the interior angle Φ is an interior angle of a four-sided figure (the two dashed lines and the lines that rise to the apex) for which the other three interior angles are 90°, 60°, and 90°. But the sum of the interior angles of a four-sided figure is 360°, so $\Phi = 120°$. Then we find ψ by using $\phi + \psi + \Phi = 180°$.

Working It Out To find ϕ, we use Eq. (35–7):

$$\sin\theta = n \sin\phi.$$

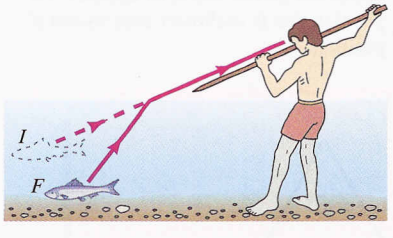
When $n = 1.50$ and $\theta = 30°$, this expression gives $\phi = 19.5°$.

With $\Phi = 120°$, the angle ψ that our once-refracted ray makes with the line normal to the second surface is given by $\phi + \psi + 120° = 180°$, or $\psi = 60° - \phi = 60° - 19.5° = 40.5°$. The angle θ' that the second refracted ray makes with the line normal to the second surface is then given by a second application of Snell's law,



$$\sin\theta' = n \sin\psi = 1.50 \sin(40.5°) = 0.97.$$

Thus, $\theta' = \arcsin(0.97) = 77°$, and we see from Fig. 35–14 that the angle the outgoing light ray makes with the base of the prism is $\theta' - \theta = 77° - 30° = 47°$.



What Do You Think? If we want to make the exit angle θ' smaller, how do we change the angle θ? *Answers to **What Do You Think?** questions are given in the back of the book.*

CONCEPTUAL EXAMPLE 35–3 The study of refraction originated with the discovery by Isaac Newton that white light falling on a prism is split into the colors of the rainbow, and his interpretation of this as white light being composed of all the colors at once. Some people argued that another interpretation was possible: that sunlight, falling on the prism, generated the emission of a variety of colors. Can you propose one or two experiments, using a second, identical prism, to argue that it is indeed white light that is composed of the rainbow colors?

Answer (a) Put the second prism upside down so that the face of the first prism from which the spread of colors emerges is parallel to the face of the second prism that the colored rays will enter (Fig. 35–15). This reverses the refraction process of the first prism. What emerges from the far side of the two prisms is white light, illustrating the reconstitution of the white light through direct combination of its colorful components. The only way this is possible is that the white light is simply constituted of light of the rainbow colors, and that in adding the second prism we have put those colors back together again. Note that in the figure we have drawn a single ray entering the prism, whereas on the emerging side of the double prism we have parallel rays. But we noted before that rays represent only a direction, with the actual incoming light more properly represented as a bundle of rays. The correct representation of our situation is that there is a bundle of incoming white light rays and a bundle of outgoing white light rays. (b) Again insert the second prism, but this time place a mask on the surface of the second prism so that only light of one color enters (say green). The result of this is that only green will emerge on the far side of the prism. This can be done with each of the colors. Again, the constituent colors of white light are nothing more than that—constituents—and the only role of the first prism is to separate them out.

▲ **FIGURE 35–15** Arrangement of two prisms that shows that the colors are the components of white light.

▲ **FIGURE 35–16** The fish appears less deep than it really is because of refraction. This makes it hard for the fisherman to spear it when he or she aims the spear from outside the water.

Refraction is responsible for some curious optical effects, as Fig 35–13 shows. You may be familiar with the problem of spearing a fish (Fig. 35–16). The source of the light ray from the fish is seen to originate from a point that lies on a straight line along the direction at which the ray enters the observer's eye. Thus the observer thinks the image I is the actual position of the fish, and if the observer is a spear fisherman who is aiming for this point, the fish will not be touched.

Energy in Reflection and Refraction

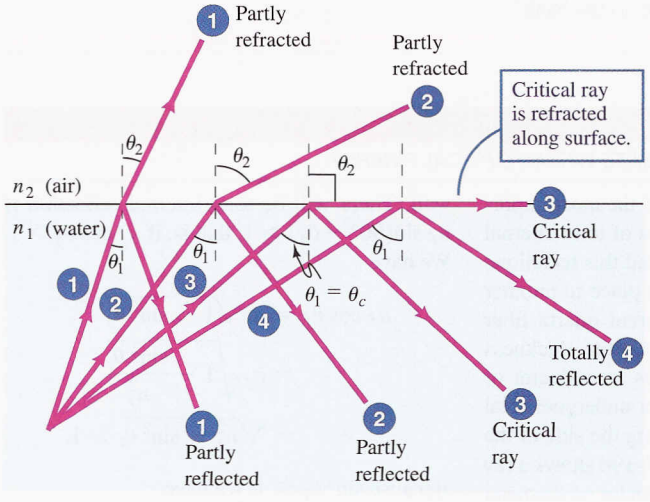
Like mechanical waves, transmission (with refraction) is generally accompanied by reflection, as we can see in Fig. 35–12a where a reflected ray is visible as well as a refracted one. As we saw in Chapter 34, the incident ray carries electromagnetic energy. At the boundary between media, this energy is apportioned among the reflected and refracted rays such that the total energy is conserved. Here we quote a result without proof: Maxwell's equations can be used to show that when light is perpendicularly incident on a surface that separates a medium of index of refraction n_1 from a medium of index of refraction n_2, the intensity of the reflected light, I_r, is related to the incident intensity, I_0, by

$$\frac{I_r}{I_0} = \frac{(n_2 - n_1)^2}{(n_2 + n_1)^2}. \qquad (35–8)$$

For light perpendicularly incident—the angle of incidence is zero—from air ($n = 1.0$) into glass ($n = 1.5$), only 4 percent of the incident light is reflected. Note the squares in this equation. The ratio is the same for light coming from air and moving into glass as it is for light coming from glass and passing into air. More generally the intensity of the reflected (and refracted) light varies with the angle of incidence, with the intensity of the reflected ray a minimum at perpendicular incidence.

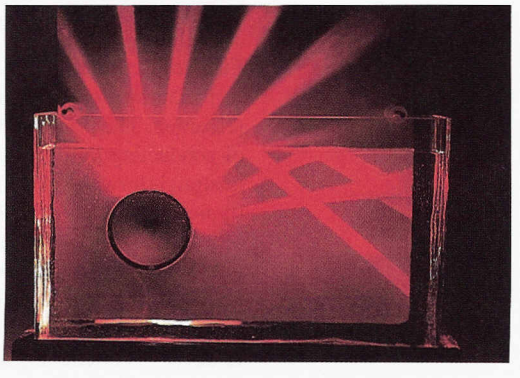
CONCEPTUAL EXAMPLE 35–4 What is the intensity of the transmitted light that falls in a perpendicular direction on a thin sheet of glass ($n = 1.5$) and then passes out of the far side of the sheet?

Answer The index of refraction of air is approximately unity, so from Eq. (35–8) the fraction of energy reflected at the first surface is $f_r = (1.5 - 1.0)^2/(1.5 + 1.0)^2 = 0.04$. By energy conservation, the fraction that penetrates is $1 - 0.04 = 0.96$. This intensity of light falls on the second interface, and here again 4 percent is reflected, and therefore the total fraction of light transmitted is $(0.96)^2 = 0.92$. Some of the light reflected at the second interface will be re-reflected at the first interface and head back out the far side, but there we are dealing with fractions like 4 percent of 4 percent, which we can neglect. We should add that when monochromatic light is involved, wavelike phenomena can make the fraction reflected vary dramatically with wavelength or glass thickness (see Chapters 37 and 38).



Total Internal Reflection

For some incident angles, *all* the incident energy is contained in the reflected ray. This situation, known as **total internal reflection**, can occur only when light travels from a medium with a larger index of refraction toward a medium with a smaller index of refraction, such as when light passes from water toward air. Simple geometry explains this phenomenon.



Let's consider a light-ray incident from a medium with an index of refraction n_1 to a medium with an index of refraction n_2; this time $n_1 > n_2$. Snell's law, Eq. (35–6), may be written in the form $\sin\theta_2 = (n_1/n_2)\sin\theta_1$. As θ_1 increases, θ_2 reaches 90° before θ_1 does, because the factor n_1/n_2 is larger than unity. Figure 35–17 shows the reflected and refracted rays for various values of θ_1. When $\theta_2 = 90°$, the ray in medium 2 skims along the interface of the two media. This occurs when θ_1 reaches a critical angle θ_c such that $(n_1/n_2)\sin\theta_c = \sin 90° = 1$, or

$$\sin\theta_c = \frac{n_2}{n_1}. \qquad (35\text{–}9)$$

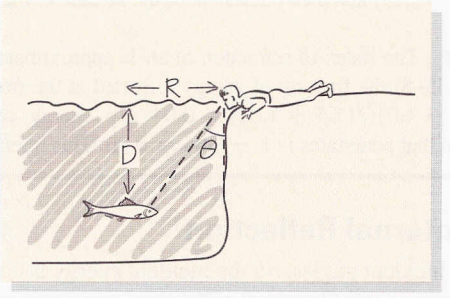
When θ_1 exceeds θ_c, there is no angle θ_2 that can satisfy Snell's law. The electromagnetic energy carried by the incident ray must go somewhere, and the ray is reflected. There is no diminution of the intensity of the reflected ray, and the reflection is total.

(a)

(b)

▲ **FIGURE 35–17** (a) Various rays traveling from a medium with a larger index of refraction (water) to a medium with a smaller index of refraction (air). When the incident angle is θ_c, there is total internal reflection. (b) Refraction and total internal reflection off the air–water interface in a water tank.

CONCEPTUAL EXAMPLE 35–5 Suppose a ray of white light originates inside the tank in Fig. 35–17 and that the ray is at an angle larger than the critical angle for all the colors in white light. The ray is then rotated so that the incident angle decreases. What color light emerges first into the air?



Answer The observation of the decomposition of white light by a glass prism shows that the index of refraction for blue light is larger than that for red light: $n(\mathrm{B}) > n(\mathrm{R})$. Taking the index of refraction of air as unity, Eq. (35–9) reads $\sin\theta_c = 1/n$ and thus $\theta_c(\mathrm{B}) < \theta_c(\mathrm{R})$. This means that *red* light emerges first as the white-light source rotates upward to make a smaller and smaller angle of incidence in Fig. 35–17.

EXAMPLE 35–6 A fisherman knows of a fishing spot whose horizontal distance from a river bank is a distance $R = 1.5$ m from the bank. Thinking to sneak up on a fish which might be at any water depth, he stealthily approaches the bank with his eyes at ground (and water) level. Describe what he might see.

Setting It Up We draw in Fig. 35–18 an illustration. We have drawn a particular ray, with angle of incidence θ, that meets the surface very close to where the eye is located.

Strategy and Working It Out If we model the fish as a point, then for a given depth D, there is only a single ray from the fish that reaches the fisherman's eyes. When D is large (the fish is deep) and the angle of incidence is smaller than the critical angle, then when the ray leaves the water it continues upward, although more parallel to the surface than the incident ray. The only such ray able to reach the eye at the edge must then strike the surface very close to the edge. The fisherman extrapolates this ray back and mentally places the fish closer to the surface, just as for the spear fisherman of Fig. 35–16.

We can now imagine that D decreases, until at a critical depth D_c the incident angle in the figure is the critical angle θ_c. The refracted ray comes off parallel to the surface, so the fisherman sees the fish right at the surface. The corresponding ray that comes from any fish closer to the surface than D_c does not make it out of the water, because the incident angle is greater than the critical angle. But a ray from that fish that is incident at the critical angle, and which intersects the surface at a point in between the edge and the horizontal location of the fish, will propagate in air parallel to the surface and ends at the eye. The fisherman sees *all* the fish from just below the surface to a depth of D_c at once, squashed into a flat pancake at the surface and hardly recognizable. Hanging in the region from $D = 0$ to $D = D_c$ is a good way for the fish to hide from this particular fisherman!

▲ FIGURE 35–18

What is D_c? We can easily find it from geometry. The figure shows that generally $\sin\theta = R/\sqrt{D^2 + R^2}$. With $\sin\theta_c = 1/n_{\text{water}}$, we then have

$$\frac{R}{\sqrt{D_c^2 + R^2}} = \frac{1}{n_{\text{water}}} \quad \text{or} \quad \frac{\sqrt{D_c^2 + R^2}}{R} = n_{\text{water}}.$$

We solve this for D_c:

$$D_c^2 = R^2(n_{\text{water}}^2 - 1) = (1.5\ \text{m})^2(1.33^2 - 1) = 1.7\ \text{m}^2;$$
$$D_c = 1.3\ \text{m}.$$

What Do You Think? Can a fish see the fisherman sneaking up to the bank?

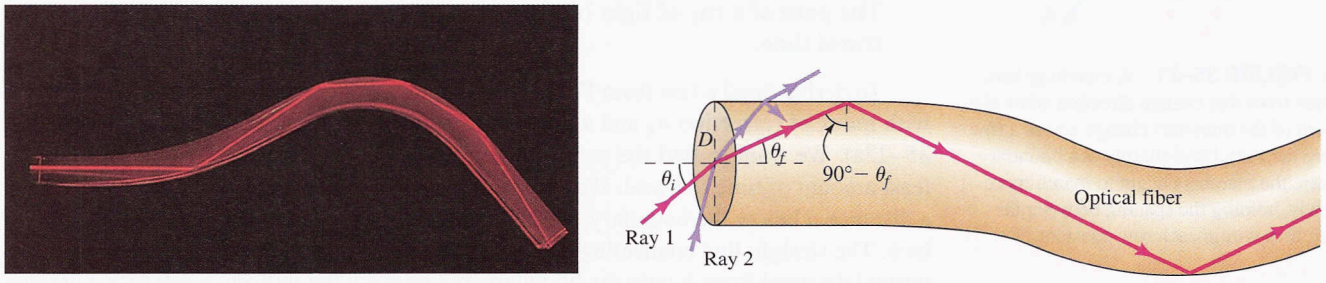
THINK ABOUT THIS. . .

HOW DOES LIGHT PROPAGATE WITHIN OPTICAL FIBERS?

Fiber optics represents one of the most important technological applications of total internal reflection. The principle behind this technique of conducting light from one place to another is straightforward: A transparent quartz fiber (typically of diameter 50 μm—the thickness of a human hair) will serve as a conductor of light if any ray inside the fiber undergoes total internal reflection upon striking the side of the fiber (Fig. 35–19a). Figure 35–19b shows a ray in air ($n = 1$) entering a cylinder of diameter D at an angle θ_i with the axis of the cylinder. If n_f is the index of refraction of the fiber, then the angle that the ray makes with the axis inside the fiber is θ_f, where $\sin\theta_f = \sin\theta_i/n_f$. This ray will strike the wall of the cylinder at an angle $(90° - \theta_f)$ with the normal to the wall. There will be total internal reflection if $n_f \sin(90° - \theta_f) > 1$; that is, if $n_f \cos\theta_f > 1$. We have

$$\begin{aligned} n_f \cos\theta_f &= n_f\sqrt{1 - \sin^2\theta_f} \\ &= n_f\sqrt{1 - \frac{\sin^2\theta_i}{n_f^2}} \\ &= \sqrt{n_f^2 - \sin^2\theta_i} > 1. \end{aligned}$$

Because $\sin^2\theta_i \le 1$, we have



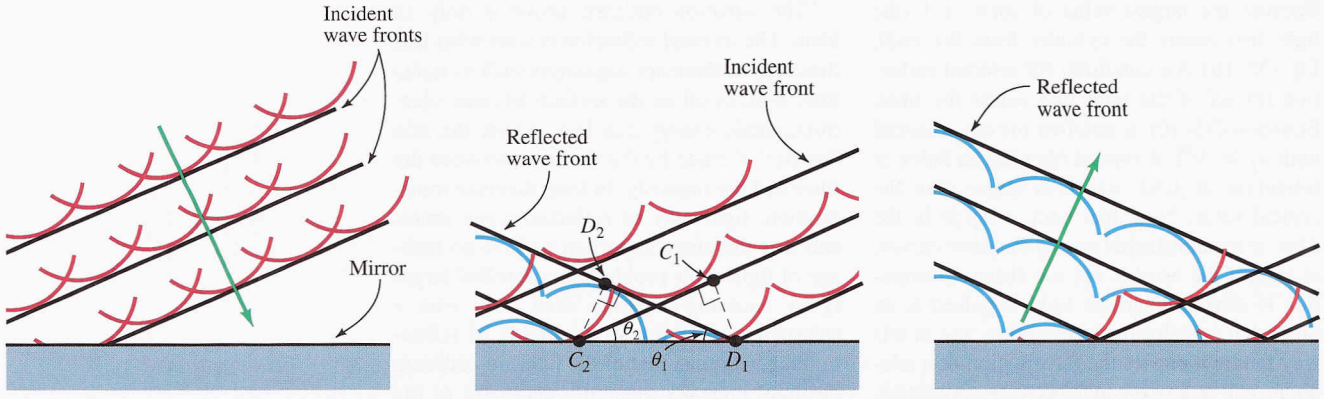
$$\sqrt{n_f^2 - \sin^2\theta_i} \ge \sqrt{n_f^2 - 1}.$$

Thus we automatically satisfy the condition for total internal reflection, $n_f \cos\theta_f > 1$, if

$$\sqrt{n_f^2 - 1} > 1. \qquad (35\text{–}10)$$

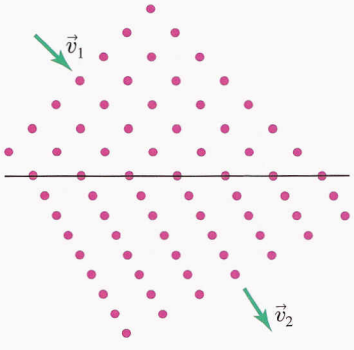
Because the largest value of $\sin\theta_i$ is 1 (the light first enters the cylinder from the end), Eq. (35–10) is a condition for internal reflection for *all* of the light that enters the fiber. Equation (35–10) is satisfied for any material with $n_f > \sqrt{2}$. A typical fiber has an index of refraction of 1.62, which is larger than the critical value. Note that once a ray is in the fiber, it remains inside *even if the fiber curves*, at least if the bend is not too sharp. Information is carried when the light is pulsed in an order that contains the information, and in this way the light carries the information of a telephone call or an exchange between computers. There is a considerable advantage to optical fibers: Compared to the density of information that can be carried in an old-fashioned coaxial cable, a fiber can carry a much greater density of information. That translates into a capacity to carry many telephone calls at once, or to carry the enormous amounts of information exchanged by modern computers. This is in addition to the fact that for the same weight or diameter of an ordinary cable, one can put together a great number of fibers to carry information in parallel.

The situation outlined above is only an ideal. The internal reflection is somewhat less than total if there are impurities such as moisture, dust, or oil on the surface, because electromagnetic energy can leak across the thin "barrier" formed by the air layer between the fiber and the impurity. In long-distance transmission, light may be reflected many times, and it is therefore important to have no leakage of light. This problem is controlled largely by *cladding*—coating each fiber with a transparent covering whose index of refraction is lower than that of the fiber. In addition, the light intensity generally decreases as the ray propagates in a medium because the medium is not perfectly transparent. This effect is reduced by making the fiber from fused quartz, a highly transparent material, and purifying it to remove all traces of water. For the trans-Atlantic cable TAT-8, which can carry 40,000 conversations over two pairs of glass fibers simultaneously, it is necessary to boost the signal only every 50 km with a repeater station. This is much less expensive than systems of metal wire, which require boosting every kilometer.



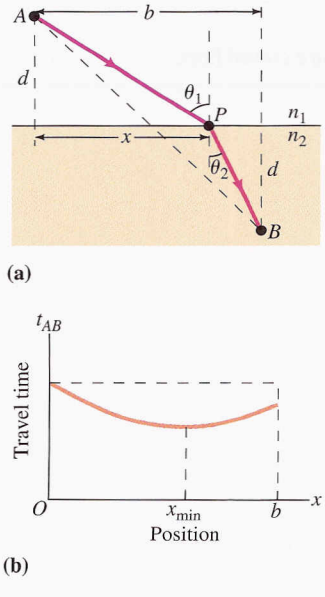
(a) (b)

▲ **FIGURE 35–19** (a) Total internal reflection in an optical fiber. (b) Detailed construction of ray angles in a curved fiber.



*35–4 Fermat's Principle

Fermat's principle provides us with an interesting way to understand reflection and refraction. In order to set the stage for Fermat's principle, let us first look at how Huygens' principle leads to the law of reflection [Eq. (35–5)]. Figure 35–20a shows a sequence of wave fronts as they approach a mirror. In Fig. 35–20b, point C_2 is the center of a reflected spherical wave, one of many along the mirror. An outgoing (reflected) wave front—here, the line tangential to point D_2 of the semicircle centered on point C_2—forms. The distance the wave travels in time Δt is the same for incoming and outgoing waves, so a simple geometrical argument yields the result described by Eq. (35–5); namely, that the angle of reflection equals the angle of incidence. Figure 35–20c shows a later part of the sequence.



Snell's law may also be obtained by an application of Huygens' principle. The bending of the wave front is associated with the slowing down of the light waves in the medium. The bending can be visualized by analogy with the direction change of a band whose members march at an angle toward a sidewalk. Each row is like a wave front. The band members are given orders that each one must walk more slowly, without changing the distance between marchers in each row, as soon as that marcher steps on the sidewalk.

▲ **FIGURE 35–20** (a) Incident wave fronts approaching a plane mirror. (b) The wave fronts reflect. (Note that for clarity, fewer wavelets are shown.) The reflected wave fronts are generated by Huygens' construction. The relation $C_2D_2 = C_1D_1$ leads by geometrical reasoning to equal angles of incidence and reflection. (c) Most of the wave fronts have been reflected.

▲ **FIGURE 35–21** A marching band forms rows that change direction when the speed of the marchers change across a row. Here the rows bend sharply at a boundary where the marchers begin to march more slowly, holding the spacing between the marchers within each row constant.

▲ **FIGURE 35–22** (a) Geometry for proving Snell's law by Fermat's principle. (b) The travel time t_{AB} for the ray as a function of x.

The result is that the front formed by the row of band members bends (Fig. 35–21). Rather than going through the derivation of Snell's law from the Huygens construction, which leads to a picture like that of the marching band, let's demonstrate it from the principle enunciated by Pierre de Fermat in 1657. **Fermat's principle** states that

> **The path of a ray of light between two points is the path that minimizes the travel time.**

To derive Snell's law from Fermat's principle, let's consider a point A in medium 1 with index of refraction n_1 and a point B in medium 2 with index of refraction n_2 (Fig. 35–22a). We want to find the path between points A and B that takes a ray of light the least amount of time to travel. We choose A to be a distance d above the boundary and B a distance d below the boundary; we choose the horizontal distance between A and B to be b. The straight line connecting A to B crosses the boundary at a distance $b/2$ from the normal dropped from A onto the boundary, but because the indices of refraction are different, this will not be the ray's path; instead the ray's path crosses the boundary at some point P that we want to find. Figure 35–22a shows that the distance from A to the intersection point P is $\sqrt{d^2 + x^2}$, and the distance from the intersection point P to B is $\sqrt{d^2 + (b - x)^2}$. The time for the ray to travel a distance D in a medium of index of refraction n is given by $t = D/v = D/(c/n) = nD/c$. Thus the total travel time is

$$t_{AB} = t_{AP} + t_{PB} = \frac{n_1\sqrt{d^2 + x^2} + n_2\sqrt{d^2 + (b - x)^2}}{c}. \qquad (35\text{–}11)$$

Figure 35–22b is a graph of t_{AB} as a function of x. The minimum travel time is obtained by finding the place at which the slope of t_{AB} as a function of x is flat; that is, the value of x at which

$$\frac{dt_{AB}}{dx} = 0.$$

This condition implies that

$$\frac{dt_{AB}}{dx} = \left(\frac{1}{c}\right)\left[\frac{n_1 x}{\sqrt{d^2 + x^2}} - \frac{n_2(b - x)}{\sqrt{d^2 + (b - x)^2}}\right] = 0. \qquad (35\text{–}12)$$

Now observe from Fig. 35–22a that

$$\frac{x}{\sqrt{d^2 + x^2}} = \sin\theta_1 \qquad (35\text{–}13a)$$

and that

$$\frac{b - x}{\sqrt{d^2 + (b - x)^2}} = \sin\theta_2, \tag{35–13b}$$

where θ_1 and θ_2 are the angles the two rays make with respect to the normals in their respective media. Thus Eq. (35–12) may be rewritten as

$$n_1 \sin\theta_1 = n_2 \sin\theta_2, \tag{35–14}$$

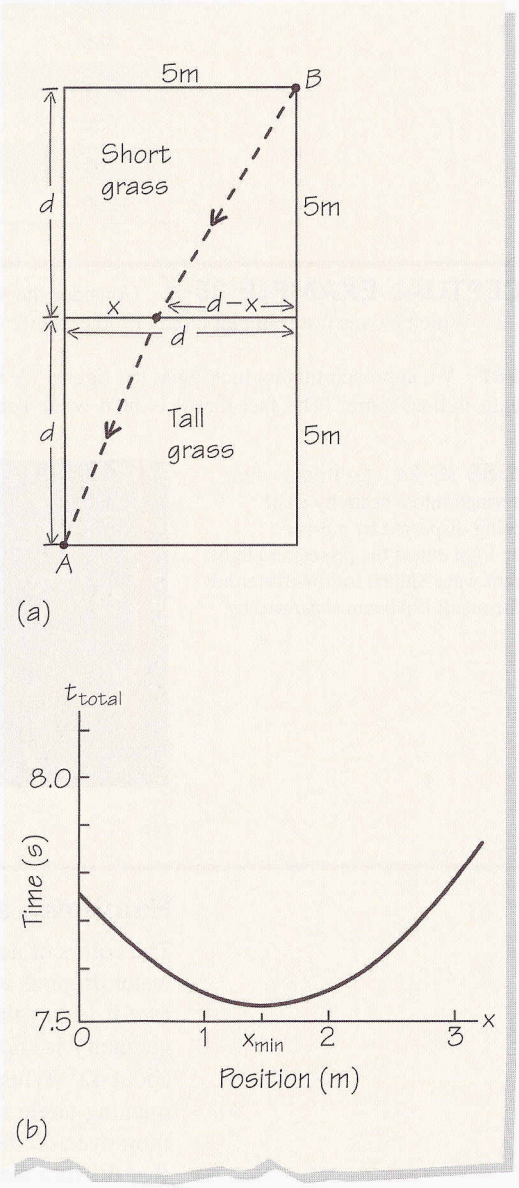
which is just Snell's law.

Both the straight-line propagation of light in a single medium and the law of reflection can also be derived from Fermat's principle. Fermat's principle in fact follows directly from Maxwell's equations, although we do not perform the derivation here. As Example 35–7 shows, principles such as Fermat's principle (more generally termed minimum principles) can apply in surprising circumstances.

EXAMPLE 35–7 A girl located at point B in Fig. 35–23a spots a ball at point A. Point A is in tall grass, where the girl can run at 1.1 m/s, and point B is in short grass, where the girl can run at 2.2 m/s. The whole area is flat. At what point should she cross the boundary between the grasses so that she retrieves the ball as quickly as possible?

Strategy Fig. 35–23a shows that the problem is conceptually identical to the problem of deriving Snell's law from Fermat's principle. We want an expression for the total travel time, consisting of the time in the short grass where the speed is 2.2 m/s and the time in the tall grass, where the speed is 1.1 m/s. The distances in the two regions can be calculated in terms of the unknown crossing point, whose position is at x.

For a given (to be found) value of x, the distance to be covered in the short grass is given by $L_{\text{short}} = \sqrt{d^2 + (d - x)^2}$. If the speed of travel in the short grass is v_{short}, then the time spent in the short grass is $t_{\text{short}} = \dfrac{\sqrt{d^2 + (d - x)^2}}{v_{\text{short}}}$. The distance traveled in the tall grass is $L_{\text{tall}} = \sqrt{d^2 + x^2}$, hence the time in the tall grass is $t_{\text{tall}} = \dfrac{\sqrt{d^2 + x^2}}{v_{\text{tall}}}$. Our task then is to consider the total time as a function of x and find the value of x for which this sum is a minimum.



Working It Out The expression for the total time involves $d = 5.0$ m, $v_{\text{short}} = 2.2$ m/s, and $v_{\text{tall}} = 1.1$ m/s. We thus want to minimize

$$t(x) = \frac{\sqrt{25 + x^2}}{1.1} + \frac{\sqrt{50 - 10x + x^2}}{2.2}.$$

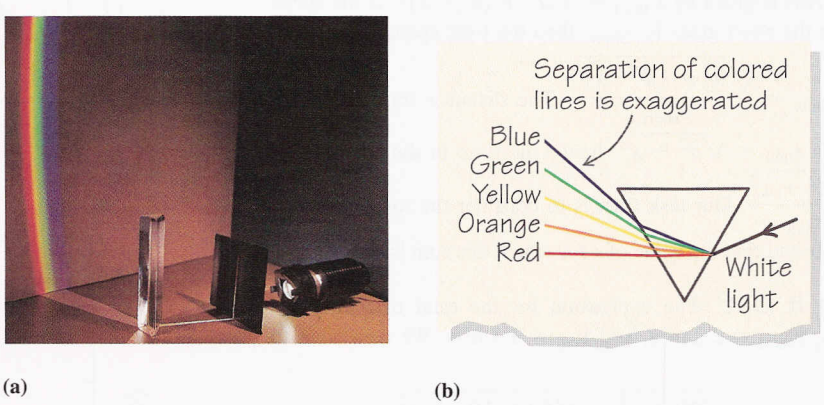
We plot $t(x)$ as a function of x in Fig. 35–23b. There is indeed a minimum, at about $x = 1.5$ m. Compare this to the 2.5-m value x would take if the child were to run in a straight line. It is best to run a little farther in the short grass.

Rather than plotting, we could also find the desired value of x by solving for x in the algebraic equation $\dfrac{dt(x)}{dx} = 0$. But this is a rather messy equation and needs more numerical work than the plot of Fig. 35–23b.

The path followed looks like the path a light ray would take in traveling from a medium with a larger value for the speed of light to a medium with a smaller value for the speed of light.

▲ **FIGURE 35–23** (a) Bird's-eye view of girl's path. (b) The travel time as a function of where the child crosses the border between the tall and short grass.

35–5 Dispersion



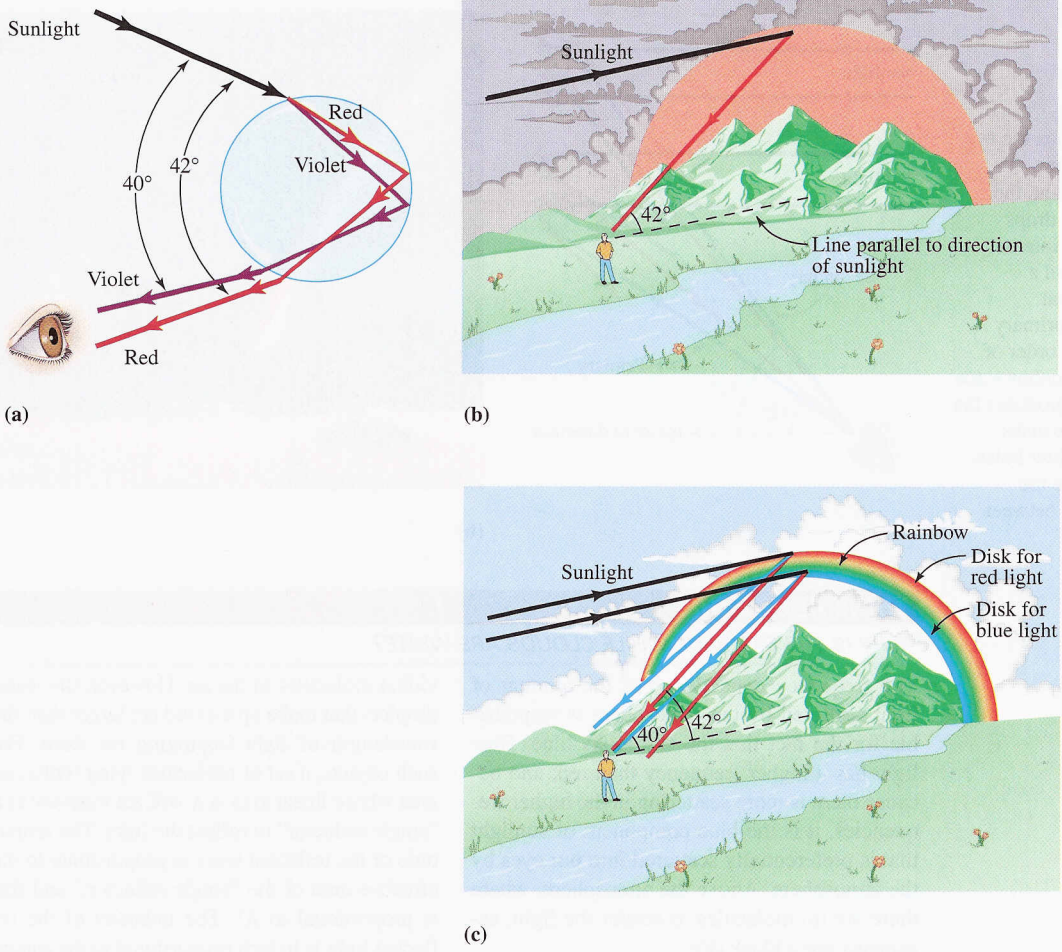
In this section, we explore another property of the index of refraction, a property with some truly spectacular consequences: In general, the index of refraction depends on the wavelength (or color) of the light being transmitted. Table 35–2 shows how n varies with wavelength for glass, for wavelengths near and including the wavelengths of visible light. Different wavelengths are refracted to different degrees. In this way, white light (a mixture of different wavelengths) can be separated into its constituent colors of the rainbow (Fig. 35–24). As we mentioned in Section 34–2, the dependence of refraction on the wavelength of light is called *dispersion*.

TABLE 35–2 • Index of Refraction of Glass as a Function of Wavelength

Wavelength in Air (nm)	$\omega = (2\pi c/\lambda)$ rad/s in units of 10^{15}	n	Color
361	5.22	1.539	Near ultraviolet
434	4.35	1.528	Blue
486	3.87	1.523	Blue-green
589	3.19	1.517	Yellow
656	2.86	1.514	Orange
768	2.45	1.511	Near infrared
1200	1.58	1.505	Infrared

CONCEPTUAL EXAMPLE 35–8 Consider the setup in Fig. 35–24. Which moves faster in glass, red or violet light?

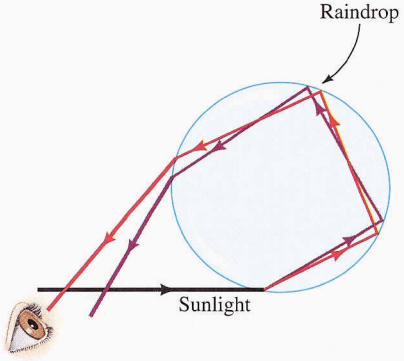
Answer We approach this by looking at the figure. We see that violet light is bent more. (The fact that it is bent twice because it passes through two surfaces does not change this conclusion.) By Snell's law this implies that n for violet light is larger than for red light, and since the speed of light is c/n, this implies violet light moves more slowly than red light. We confirm this by looking at Table 35–2, which shows that n is indeed larger for violet light.



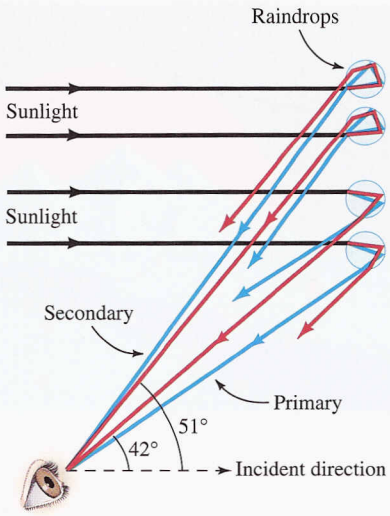
▶ **FIGURE 35–24** (a) Bright white light is formed into a beam by a slit before being dispersed by a prism. (b) White light enters the prism, and light of different wavelengths follows different paths. The result is a beam separated by color.

Rainbows and the Blue Sky

The colors of a rainbow result from dispersion in the reflection of light from individual water droplets in the air. When sunlight shines on a raindrop, light is reflected once before it leaves the drop. Many paths are possible; two are shown in Fig. 35–25a. The geometry is such that no ray can emerge after one reflection at an angle *steeper* than about 42°. When the Sun is behind the viewer, only drops that lie within a cone with an opening angle of about 42° reflect sunlight back to the observer's eye (Fig. 35–25b); moreover, *all* the drops in this cone reflect light to the observer. (We shall refer to a disk that fits into the cone because the depth of the cone is irrelevant.) One other feature of the disk is that light is reflected most strongly from raindrops at the edge, around 42°.



Dispersion has played no role in our discussion so far. The effect of dispersion is to make the angle of the outer radius of the disk slightly different for different colors. As Fig. 35–25c indicates, the disk for red light is larger than the disk for blue light. Because



▲ **FIGURE 35–25** (a) When sunlight enters a raindrop and exits after one reflection, no light exits at an angle steeper than about 42° from the incident ray. (b) As a result, light comes back to an observer with the Sun behind him from all the raindrops that lie within a cone with an angle of about 42°, as seen by the observer. (c) Sunlight is a variety of colors. Due to dispersion, the disks that fit into the cones are of slightly different sizes for different colors, with red forming the largest cone and violet the smallest. This figure exaggerates the effect.

the intensity of the light in the disk is strongest at the edges, we see a red ring outside a blue ring (with other colors placed accordingly). All the disks overlap inside the rainbow, giving white light. A *secondary rainbow* can be produced when there are two internal reflections within the raindrops (Fig. 35–26). The order of the colored disks produced by the raindrops will now be reversed, with red light at the bottom and blue light at the top of the secondary rainbow. Figure 35–27a illustrates how an observer sees rainbows and how the pattern of dispersion leads to the color inversion of a secondary rainbow compared with a primary rainbow. The light is brightest inside (below) the primary rainbow and outside (above) the secondary rainbow because the disks of each of the colors overlap in these regions; it is relatively darker between the two rainbows (Fig. 35–27b).

Dispersion in the more general sense of phenomena that depend on frequency (or wavelength) is quite common; for example, the scattering of light by matter has such dependence. In 1872 Lord Rayleigh showed that the fraction of incident light scattered by air molecules varies as f^4 for light in the visible range. This explains the color of the setting Sun. As the Sun sets, the rays of light pass through more and more atmosphere to reach our eyes, and an increasing number of the high-frequency (low-wavelength) components are scattered away, leaving the lower frequency in the direct rays from the Sun. The Sun's color changes from white to yellow to orange and finally to red, as it moves closer to the horizon, as the higher frequencies are scattered away from the observer.

▲ **FIGURE 35–26** The light that reaches the eye from a secondary rainbow has undergone two internal reflections in a set of raindrops. Light of shorter wavelengths (violet light) emerges at a steeper angle than light of longer wavelengths (red light) does, in contrast to the light that undergoes only one internal reflection, which forms the primary rainbow, and the colors of the secondary rainbow are inverted.

(a)

(b)

▶ **FIGURE 35–27** (a) When the eye sees a region of sky that contains raindrops illuminated by sunlight, the light reflected from individual drops forms a primary rainbow (one internal reflection within each drop) and a secondary rainbow (two internal reflections). (b) The brighter, primary rainbow is on the bottom. The order of colors is reversed in the two rainbows due to the extra reflection, which produces the fainter secondary rainbow. The disks overlap, so it is relatively brighter below the primary rainbow and above the secondary rainbow, but darker between them.

THINK ABOUT THIS. . .

WHY IS THE SKY BLUE WHILE CLOUDS ARE WHITE?

The frequency dependence of the amount of light scattered by the atmosphere is responsible for the fact that the sky looks blue. Blue light has a higher frequency than red, and because there is more scattering in the higher frequencies, it is the blue component of sunlight that is preferentially scattered into our eyes by the atmosphere. Above the atmosphere, where there are no molecules to scatter the light, astronauts see a black sky.

If the sky is blue, why are clouds white? The answer to this question has to do with the size of the objects doing the scattering. The f^4 law (equivalently what we could call the $1/\lambda^4$ law) applies only to the scattering of light by objects much smaller than the wavelength of the light. Thus it applies to the scattering of light by individual molecules in the air. However, the water droplets that make up a cloud are larger than the wavelength of light impinging on them. For such objects, a set of molecules lying within an area whose linear size is λ will act *together* as a "single reflector" to reflect the light. The amplitude of the reflected wave is proportional to the effective area of the "single reflector," and this is proportional to λ^2. The intensity of the reflected light is in turn proportional to the square of the amplitude, that is, to λ^4. This just cancels the $1/\lambda^4$ dependence of the individual contributions of the molecules, and consequently there is no preferential wavelength in scattering by droplets. All wavelengths are scattered equally, so that white light scattered by a cloud stays white, and that is how we see the cloud.

The Atomic Theory of Dispersion

Dispersion occurs because of the atomic structure of dielectric media. The atoms that make up the medium contain electrons bound to their respective nuclei (in opposition to conductors, in which some of the electrons are in effect free to roam). The size of the bound system has linear dimensions of about 0.1 nm. Let's think of each atom as a single electron (of mass m) that oscillates about a positive ion as though the electron were bound to that ion by a spring. If the spring constant is k, then the angular frequency of oscillation (the natural frequency) is ω_0, given by $\omega_0^2 = k/m$. If no other forces act, the motion of the electron along the z-axis is of the form

$$z = A \cos \omega_0 t, \tag{35–15}$$

where A is the amplitude of motion. While this may not immediately remind you of an atom, you can see that it is relevant if you recall that an object in a circular orbit has a motion whose projection along an axis in the orbit plane is simple harmonic motion (see Chapter 13).

Now suppose that a plane electromagnetic wave oscillating with angular frequency ω is incident on an atom, with the electric field oriented in the z-direction. The electric force

on an electron in the atom is then oscillatory with frequency ω. The situation is that of a driven harmonic oscillator. The motion of the electron is oscillatory with the driving frequency ω. The amplitude exhibits resonance, becoming large when $\omega_0 \cong \omega$. Thus, based on our knowledge of the driven harmonic oscillator, the motion is of the form

$$z \propto \frac{1}{\omega_0^2 - \omega^2} \cos \omega t. \tag{35–16}$$

We assumed here that ω_0 is not exactly at ω; in fact, for materials such as water and glass, ω_0 is on the order of 5 to 6 times larger than the characteristic angular frequencies of visible light. As you may recall from our work on the driven harmonic oscillator, there is no actual singularity when $\omega = \omega_0$, because there is an additional additive term in the denominator of Eq. (35–16) associated with damping. This term can be ignored unless ω_0 and ω are very close.

An accelerating charge (the electron) *radiates* electromagnetic energy, and the intensity of the radiation is proportional to the average of the acceleration squared. (While we are not going to show this in detail, it is implicit in our original discussion of electromagnetic waves in Chapter 34.) From Eq. (35–16), the average acceleration is proportional to

$$\frac{d^2z}{dt^2} \propto \frac{\omega^2}{\omega_0^2 - \omega^2} \cos \omega t \cong \frac{\omega^2}{\omega_0^2} \cos \omega t.$$

In the last step, we have used the fact that $\omega_0^2 \gg \omega^2$ for visible light in these materials. The intensity I of the radiation is proportional to the acceleration squared. Thus I varies as ω^4 or, equivalently, as f^4. (The average of $\cos^2 \omega t$ over many periods is just $1/2$.) The wavelength λ is related to ω by $\lambda = c/f = 2\pi c/\omega$, so *the intensity of the radiation emitted by a charge set in oscillation by an external electric field is proportional to* $1/\lambda^4$, *where* λ *is the wavelength of the oscillating field.* This fact, first obtained by Lord Rayleigh, explains the blue sky: blue light, which is a high-frequency component of visible light, is scattered preferentially from atmospheric molecules—they reradiate this light equally in all directions (see the "Think About This" box on p. 990).

This discussion shows how the original electric field is modified by the addition of a radiated field as a result of the electron's motion; in fact, it is such a modification that is described by a dielectric constant κ, and hence an index of refraction n given by Eq. (35–2), $\kappa = n^2$. We accordingly expect n to depend on the frequency; that is, to exhibit dispersion. A more advanced treatment of how the external field is modified in the presence of atomic electrons shows that

$$\frac{1}{n^2} = 1 - \frac{C}{\omega_0^2 - \omega^2}, \tag{35–17}$$

where C is a constant that is proportional to the density of atoms. This equation describes how the index of refraction varies with frequency. Because $\omega_0 \gg \omega$ for visible light, *the index of refraction increases as the frequency of the light increases*. This is certainly in accord with Table 35–2. In fact, atoms and molecules have many resonant frequencies, so a more accurate version of Eq. (35–17) must contain several terms of the form $C_k/(\omega_{0k}^2 - \omega^2)$ added together.

Summary

The wave theory of light allows us to understand almost all the classical properties of light, in particular straight-line propagation in open space, reflection, and refraction. Light waves propagate with speed $c = 3.00 \times 10^8$ m/s in a vacuum; in transparent media, the speed of propagation is c/n, where n is the index of refraction of the medium. In general, the index of refraction depends on the wavelength of the light.

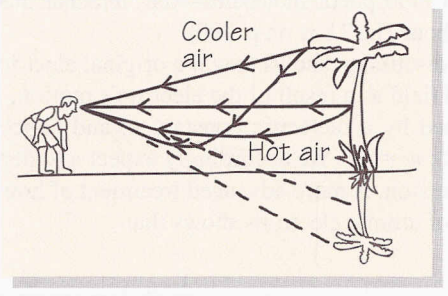
The propagation of light can be described either in terms of wave fronts, which form an envelope of spherical wavelets built upon earlier wavelets (Huygens' principle), or in terms of rays, which are lines perpendicular to the wave fronts. Light rays travel in straight lines unless they meet boundaries. Upon

reflection from a surface, the angle θ that the incident ray makes with the normal to the surface is equal to the angle θ' that the reflected ray makes with the surface (the law of reflection):

$$\theta' = \theta. \tag{35–5}$$

In the passage from a medium of index of refraction n_1 to a medium of index of refraction n_2, the incident angle θ_1 and the refracted angle θ_2 are related by Snell's law of refraction:

$$n_1 \sin\theta_1 = n_2 \sin\theta_2. \tag{35–6}$$



These results can be established using the geometry of wave fronts. They can also be derived with the help of Fermat's principle, which states that the path taken by a light ray between two points is the path that takes the shortest time. One consequence of Snell's law is that total internal reflection occurs when light moving in a medium with index of refraction n_1 strikes a boundary of a medium with index of refraction n_2, where $n_1 > n_2$. This holds true provided that the angle of incidence is larger than a critical angle θ_c, given by

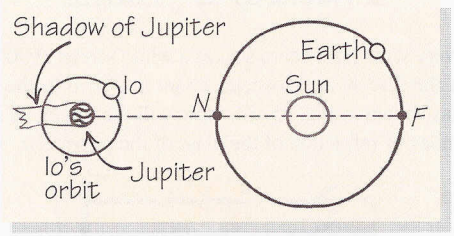
$$\sin\theta_c = \frac{n_2}{n_1}. \tag{35–9}$$

The dependence of the index of refraction on wavelength is called dispersion. Dispersion causes the different wavelengths in a beam of white light to refract through different angles. The colors of the rainbow and the blue sky are naturally occurring dispersion phenomena. Dispersion can be understood in terms of the atomic theory of matter.

Understanding the Concepts

1. If light travels only in straight lines, how does a light burning in one room give light in another room?
2. When light reflects from a surface, there is a change in (a) frequency, (b) wavelength, (c) speed of light, (d) all of these, (e) none of these.
3. How difficult would it be to reflect light back to Earth from the Moon by using two perpendicular plane mirrors? Why does it help if there are three mutually perpendicular mirrors?
4. If fish could think, they might realize that the relative indices of refraction of water and air allow them to outwit fishermen. Why?
5. A person swimming underwater sees a lifeguard who is standing in the shallow part of the pool; the water comes up to the lifeguard's waist. In what way does the swimmer see the lifeguard's upper body distorted?
6. If you lie at the bottom of a pool and look up, it appears that you are lying at the bottom of a conical hole. Why is that? Estimate the angle that apparent walls make with the vertical.
7. A fisherman standing up to his waist in a lake appears, to an observer outside the lake, to have shorter-than-normal legs. How will a fish in a horizontal position near the bottom of the lake appear to the observer?
8. A plane wave of radiation has an electric field of the form $\vec{E}_0 \cos(kz - \omega t)$ when it propagates in empty space. How do k and ω change when the plane wave enters a medium with index of refraction n?
9. When a beam of light of frequency f passes from air into glass (whose index of refraction is 1.5), which of the following happens: (a) f increases by 1.5; (b) f decreases by 1.5; (c) f becomes zero; (d) f is unchanged; (e) f decreases very slightly.
10. As the Sun sets, its color changes from white to yellow to orange and finally to red. As the lowest part of the Sun sinks below the horizon, the Sun appears squashed, more egg-shaped than circular. Why?
11. A coin lies at the bottom of a pool of water. Starting from a point immediately above the coin, you observe the coin from the level of the surface. You then move your head horizontally away from the coin across the surface of the water. Is there a horizontal distance at which the coin is no longer visible?
12. Light from the sky refracts near the surface of hot sand, giving the impression that there is a bright surface that could be interpreted as water: a mirage (Fig. 35–28). The air near the surface of hot sand is hotter than the surrounding air. Does light travel faster or slower in hot air than in cold air?

▲ **FIGURE 35–28** Question 12.



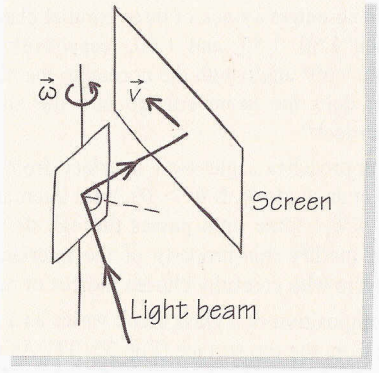
13. Mirages can occur when a layer of cold air lies closer to the surface. How would such an air layer affect the appearance of distant houses?
14. Consider Fizeau's experiment modified so that the light between the rotating wheel and the reflecting mirror goes through a pipe filled with water. Should the wheel be speeded up or slowed down in the repetition of the experiment described in the text? What would the result be if light traveled faster in water than in air?
15. Why does the sky look black rather than blue, as it does from Earth, to astronauts in orbit?
16. What is the index of refraction of a vacuum?
17. For a moment, you are lying in the middle of a circular swimming pool—at the bottom of the pool—which is filled to a depth of 1 m with water and is surrounded by trees. A 2-m-tall lifeguard is standing in the water about 3 m from you. What do things look like as you scan in all directions?

18. Laser light directed into the end of a glass rod comes out the other end with almost the original intensity. If another glass rod touches the side of the first rod, making a 30° angle with the lengthwise direction of the first rod, nothing happens. But if the point of contact is lubricated with glycerin, some of the original light beam is "stolen" by the second rod. Explain what happens.
19. White light is incident onto a pane of glass. Is there a dispersion of colors in the reflected light?
20. Stick a pin into the underside of a cylinder of cork, then float the cork in water. Even if you do not stick the pin in very far, you may not be able to see it from outside the water. Why not?
21. Why isn't the Moon red when it sets?

Problems

35–1 The Speed of Light

1. (I) What are the speeds of light in ice, ethyl alcohol, benzene, and diamond?
2. (I) The nearest star to our solar system (aside from the Sun) is Alpha Centauri, some 4.2 ly from Earth. How far is this in meters?
3. (I) A light wave of red light ($\lambda = 650$ nm) passes from air into water, where the index of refraction is 1.32. What are the wavelength and frequency of the light in water?
4. (I) Light of frequency 5.6×10^{14} Hz impinges on glass, $n = 1.45$. What are the wavelengths of this light in a vacuum and in glass? What is the index of refraction of a material within which the wavelength of yellow light is one-half its value in a vacuum?
5. (II) Suppose that you have a version of Fizeau's apparatus in which the round-trip distance for the light beam is $2D = 1{,}000$ m. The width of the opening between the teeth on the cogged wheel is 0.70 mm, and the center-to-center distance between these gaps is 1.5 mm. The wheel has a radius of 15.0 cm. What would the minimum rotational speed be, in revolutions per minute, so that light entering through the center of one gap would come out through the center of the next gap? Is such an apparatus realizable?
6. (II) Figure 35–29 shows an exaggerated view of the eclipsing of Io, the innermost moon of Jupiter, as seen from two different points on Earth's orbit around the Sun. If Earth were stationary at a point nearest Jupiter, N, a particular eclipse would begin at a precise time. When Earth is at point F, the eclipse starts somewhat later than expected because the light has to travel the additional distance of a diameter of the Earth–Sun orbit. The mean distance from Earth to the Sun is 1.50×10^{11} m. How much later will the eclipse be seen at point F compared with point N?



▲ FIGURE 35–29 Problem 6.

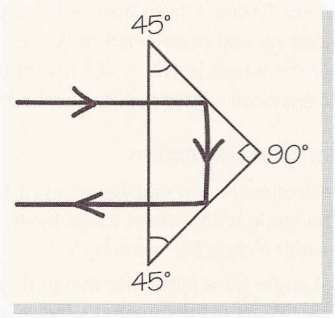
7. (II) Personal computers can perform as many as 5×10^7 steps every second. This means that some leads connecting different parts of the computer may carry this many pulses per second. If you assume that the pulses travel at the speed of light, what is the distance between pulses? Does this result have implications for the design of these machines?
8. (II) Telephone connections between Europe and North America can be carried by cable or by the use of a geosynchronous communication satellite. Estimate the time it takes for a signal to travel 10,000 km via cable, assuming the speed is close to the speed of light. How does this compare to the time required for the same signal to travel via satellite, 40,600 km from the center of Earth?
9. (II) The speed of light in a vacuum is defined to be 299,792,458 m/s. A lunar-ranging experiment measures the time for a light pulse to reach the Moon and reflect back to Earth. Such experiments allow us to determine the distance between the Moon and Earth, which is approximately 3.84×10^8 m, to an accuracy of 15 cm. What is the smallest time interval that can be measured by the clock used to determine the time it takes for light to go to the lunar reflector and back?
10. (II) Galileo attempted to measure the speed of light with the help of lights and a clock on two adjacent mountains. In essence, a shutter over a light was opened on the first mountain, an observer on the second mountain saw that signal and returned a second signal, and the experimenter on the first mountain looked for a delay between the time the shutter was opened and the time the signal was returned. Use your knowledge of human reaction time to estimate the time measured by the first experimenter for the total round trip. How long would it actually take for light to travel back and forth between two mountaintops separated by 4 km? Your answers explain why Galileo's attempt did not work.
11. (II) Imagine an experiment similar to Fizeau's, with a cogged wheel of diameter 20 cm. A laser beam shines through one opening, travels 1,500 m, and is reflected back. Given that the fastest rotation rate of the wheel is 1.2×10^5 rev/min, what should be the separation between adjacent cogs on the rim of the wheel?

35–3 Reflection and Refraction

12. (I) A fixed projector emits a narrow beam of light onto a plane mirror. At what angle with respect to the beam should you place the mirror in order to turn the beam by 75°?
13. (I) The critical angle for a particular material (used in air) is observed to be 38°. What is the material's index of refraction?
14. (I) A horizontal beam of light is reflected from a plane mirror that revolves about a vertical axis at a rate of 30 rev/min. The reflected beam sweeps across a screen that, at the point nearest the mirror, is 20 m away (Fig. 35–30). With what speed does the spot of light move across the screen at the point nearest the mirror?

▲ FIGURE 35–30 Problem 14.

15. (I) An intense light beam is incident at 45° to the surface of a clear lake. If the lake is 500 m deep and has a flat bottom, how far does the light beam travel before it hits bottom?



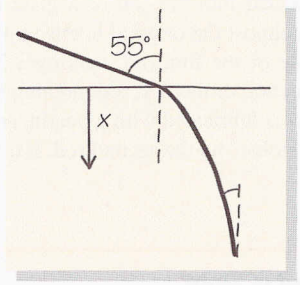
16. (I) A beam of light is sent from medium 1, index of refraction n_1, into a medium 2, index of refraction n_2; here, $n_2 > n_1$. We know that a refracted ray is bent toward the perpendicular to the boundary. Are there any incident angles for which the angle of the refracted ray is 90°? If not, what is the largest possible angle of refraction? Give a numerical value to your answer in the case of water-to-glass, $n_1 = 1.33$ and $n_2 = 1.50$.

17. (I) A burglar stands in front of a department store window and directs his flashlight into the store. What fraction of the light is reflected at the window's surface, assuming that the index of refraction of the glass is 1.43? Ignore all reflections except for that at the outside interface between the glass and air.

18. (I) A swimmer is at the bottom of a large, shallow swimming pool. Through what angle must she move her eyes so that her direct gaze swings across the whole sky? Water's index of refraction is 1.33.

19. (I) The index of refraction of air is $1 + (2.93 \times 10^{-4})$. Assume that the atmosphere may be treated as a uniform medium of thickness 8.3 km, which covers Earth's surface; further, suppose a ray of light hits the top of the atmosphere parallel to the top of the atmosphere—grazing incidence. What is the angle that the refracted ray makes with the *horizontal*?

20. (II) What is the critical angle for total internal reflection in a glass (used in air) for which $n = 1.46$? Is it possible to use a 45° – 45° – 90° triangular prism of crown glass (see Table 35–1) to make a perfect reflector of light (Fig. 35–31)?

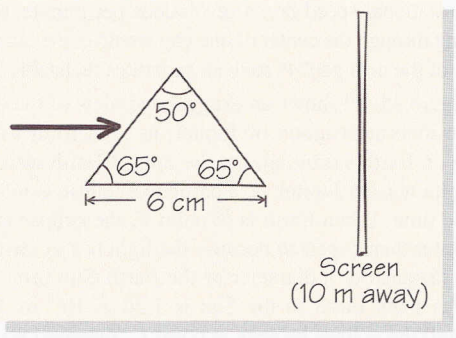


▲ **FIGURE 35–31** Problem 20.

21. (II) A thick glass plate ($n = 1.53$) lies on the bottom of a tank of water ($n = 1.33$). A light ray enters the water from air, making an angle of 72° with the normal to the surface. What angle does the ray make with the normal when the ray is in the water? What angle does it make with the normal when it is in the glass?

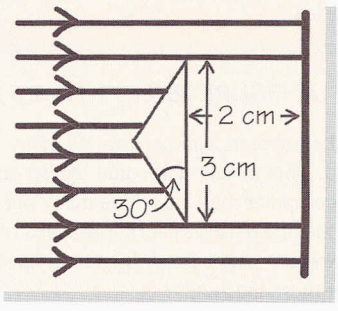
22. (II) Light in air enters a stack of three parallel plates with indices of refraction 1.50, 1.55, and 1.60, respectively. The incident beam makes a 60° angle with the normal to the plate surface. At what angle does the beam emerge into the air after passing through the stack?

23. (II) Light approaches a glass–air interface from the glass side ($n = 1.6$) at an angle θ_i. If $\theta_i > \theta_c$, total internal reflection occurs; if $\theta_i < \theta_c$, some light passes through the interface. Is it possible to modify this property of the interface by adding a stack of layers with carefully chosen indices of refraction?



24. (II) The composition of a glass block varies as a function of the distance x from the top surface (Fig. 35–32). As a consequence, the index of refraction increases as a function of x according to $n(x) = 1.54 - (0.18\ \text{cm}^2)/(x + 1\ \text{cm})^2$, with x in centimeters. A beam of light strikes the surface at an angle of incidence of 55° from the vertical. What will be the direction of the beam deep inside the block?

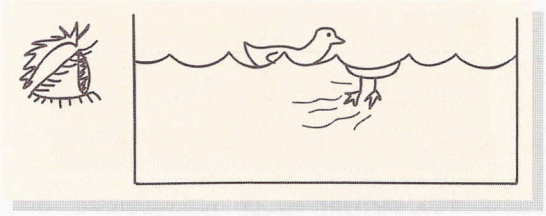
▲ **FIGURE 35–32** Problem 24.



25. (II) A glass sphere ($n = 1.6$) is centered at the origin of a coordinate system, with its equatorial plane defining the xy-plane. A beam of light enters the glass sphere at a latitude of 40°, parallel to the x-axis in the xz-plane. Make a careful drawing to determine the angle at which the beam will strike the back of the sphere. Will there be total internal reflection?

26. (II) White light is refracted by the triangular prism shown in Fig. 35–33. A beam of light enters the prism along a path parallel to the prism base. The light is observed on a screen that is located 10 m from the prism and is perpendicular to the emerging rays. How far apart on the screen are the spots of blue light ($n = 1.528$) and red light ($n = 1.514$)?

▲ **FIGURE 35–33** Problem 26.

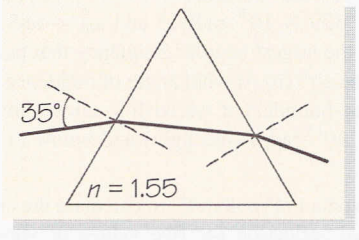


27. (II) A very wide light beam strikes a white screen at 90° to the surface of the screen. An isosceles prism is placed in the way of the beam, as shown in Fig. 35–34. How will the screen be illuminated if the index of refraction of the glass of the prism is $n = 1.5$?

▲ **FIGURE 35–34** Problem 27.

28. (II) A lifeguard whose eyes are 1.78 m from his feet stands in water 90 cm deep. From a vantage point at the bottom of the pool, a swimmer sees the lifeguard's head to be along a line at a 46° angle to the vertical. How far is the swimmer's eye from the lifeguard's feet? (For water, $n = 1.33$.)

29. (II) Suppose that you look at an aquarium with your eyes at the level of the water surface (Fig. 35–35). A duck swims on the surface of the water. When you look at the duck from the front, everything seems normal. However, when you look at the duck at an angle to the glass surface, the duck seems to be split in half, with the feet paddling ahead of the upper body. Explain this phenomenon. Suppose that both the duck and your eyes are at a distance of 1 m from the glass, and the line connecting them forms a 30° angle with the glass. Calculate the difference between the directions of the line of sight of the upper and lower halves of the duck.

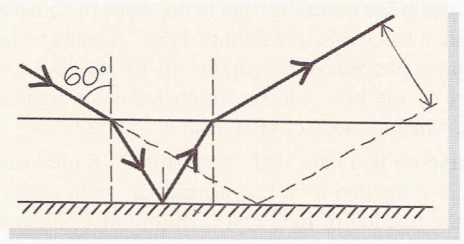


▲ **FIGURE 35–35** Problem 29.

30. (II) A transparent tank of water, of index of refraction n_1 and thickness t_1, is placed on top of a slab of glass of index of refraction n_2 and thickness t_2. A laser beam strikes the upper surface of the tank at an angle θ. At what horizontal distance from the point of entry will the beam emerge from the bottom surface of the glass? What is the answer if the tank and the slab of glass are interchanged?

31. (II) A beam of light from a flashlight is reflected by a mirror which is placed under a sheet of glass (index of refraction 1.6) that is 5 cm thick. The beam makes an angle of 60° with the vertical. If the light source is 15 cm above the surface of the glass, how far below the surface of the glass will you see a source of light matching the original? You are locating the *image* of the light source. [*Hint*: In this exercise in trigonometry, use $\tan\theta = \sin\theta/\cos\theta$; $\cos\theta = \sqrt{1 - \sin^2\theta}$.]

32. (II) A narrow beam of light is incident at a 30° angle from the normal onto a glass pane 6 mm thick. Describe the position of the exit beam of light. What is its direction? Is it displaced from the incident beam? If so, by how much? (For the glass, $n = 1.60$.)

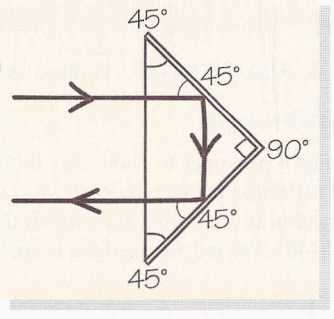


33. (II) Light is incident on an equilateral triangular prism ($n = 1.55$) at a 35° angle from the normal to one of the faces (Fig. 35–36). What is the exit angle?

▲ **FIGURE 35–36** Problem 33.

34. (II) Consider a solid glass rod of length 75 cm and diameter 1.5 cm, with index of refraction 1.46. The ends of the rod are perpendicular to the lengthwise direction. (a) Light enters the center of the end of the rod from air. What is the maximum angle of incidence for which the light is totally reflected inside the rod? (b) Repeat part (a) for a similar rod totally immersed in water ($n = 1.33$).

35. (II) A ray of light impinges at a 60° angle of incidence on a glass pane of thickness 5 mm and index of refraction 1.54. The light is reflected by a mirror that touches the back of the pane (Fig. 35–37). By how much is the beam displaced compared with the return path it would have if the pane were absent?



▲ **FIGURE 35–37** Problem 35.

36. (II) When a light beam is reflected by a conventional mirror, part of the light is reflected by the front surface of the glass pane, and part by the silvered back surface. What is the distance between the two reflected beams if the mirror is 2.0 mm thick, if it is made of glass with $n = 1.45$, and if the angle of incidence is 70°? (To avoid this double reflection, many optical instruments use mirrors with their front surfaces silvered.)

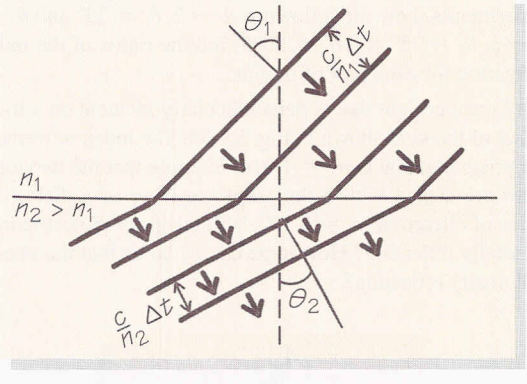
37. (II) At noon, a 2.0-m-long vertical stick casts a shadow 1.0 m long. If the same stick is placed in a flat-bottomed pool of water half the height of the stick (still at noon), how long is the shadow on the floor of the pool? (For water, $n = 1.33$.)

38. (II) You have three transparent liquids labeled 1, 2, and 3 that do not mix. When light is sent from liquid i to liquid j, there is an angle of incidence θ_i and an angle of refraction θ_j. Two separate experiments show the following: $1 \rightarrow 2$, $\theta_i = 22°$ and $\theta_j = 29°$; $2 \rightarrow 3$, $\theta_i = 35°$ and $\theta_j = 53°$. Find the ratios of the indices of refraction for each pair of liquids.

39. (II) Consider light that is perpendicularly incident on a triangular prism of the kind shown in Fig. 35–38. The index of refraction of the prism material is $n_1 = 1.814$. Suppose that the two reflecting sides are coated with a thin, uniform layer of a dielectric with index of refraction $n_2 = 1.380$. Will the glass–dielectric interface be totally reflecting? How large can n_2 be so that the interface is still totally reflecting?

▲ **FIGURE 35–38** Problem 39.

40. (II) A sodium lamp emitting light with $\lambda = 589$ nm is placed at the bottom of a pool 4 m deep. (a) Seen from the edge of the pool, where will the light appear? (b) The lamp is taken out of the pool and the light now shines into the pool. What will be the frequency, wavelength, and speed of the light as it appears to a swimmer under the surface of the pool? ($n_{\text{water}} = 1.33$)

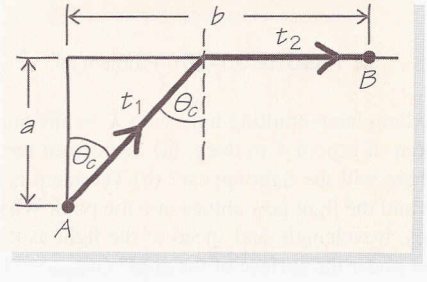


41. (II) A prism made of glass with index of refraction n and whose cross section is an equilateral triangle deflects light of wavelength 550 nm. As the beam is moved to make different angles with respect to the prism, the minimum angle through which the beam is deflected is 35°. What is the value of n?

42. (II) A prism has a cross section in the shape of an isosceles triangle with a base-to-height ratio of 1/2.5. A beam of light is incident upon the left side, parallel to the base. At what angle relative to the base will the beam leave the right side of the prism, which is made of glass with $n = 1.58$?

43. (II) Suppose you have eight perfectly clean microscope slides, index of refraction $n = 1.5$, stacked on top of each other. Estimate the fraction of light that is transmitted. There are tiny air gaps between the slides; ignore multiple reflections.

44. (II) Zeno and his friends are discussing light incident perpendicularly on a glass pane in air. The pane has two surfaces at which reflection can take place—we'll call them A and B, with A being the first surface encountered by the light. The discussion centers around the fact that some light reflects back from A directly, but more light comes back to the A side of the pane after having undergone reflection at surface B, then from double reflection at surface B, having bounced once from A, and so on. They reason that since each bounce contributes something to the A side, an infinite amount will end up there! But of course this is just Zeno's paradox, and you know that this is really a matter of a limit. What is the total intensity of the light reflected back to the A side, including an arbitrary number of bounces at the boundaries? Assume an incident intensity I_0. Take the index of refraction of air to be 1, that of the glass n, and assume that there is no absorption within the glass.

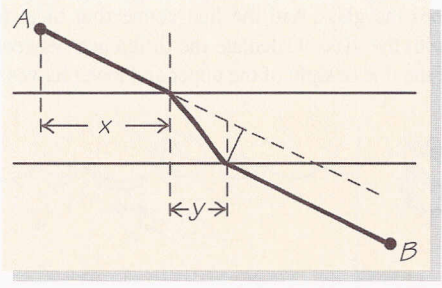


45. (III) Use Huygens' construction to prove Snell's law by working out the geometrical details in Fig. 35–39.

▲ **FIGURE 35–39** Problem 45.

*35–4 Fermat's Principle

46. (II) Use Fermat's principle to show that the critical angle for total internal reflection is given by $\sin\theta_c = 1/n$, where n is the index of refraction of the medium in which the light ray originates (Fig. 35–40). The outside medium is air.



▲ **FIGURE 35–40** Problem 46.

47. (II) Show that the law of reflection follows from Fermat's principle.

48. (II) By using Fermat's principle, show that if two media have exactly the same index of refraction, then a beam of light travels in a straight line when it crosses the boundary between them.

49. (II) Use Fermat's principle to show that a beam of light that enters a plate of glass of uniform thickness emerges parallel to its initial direction (Fig. 35–41).

▲ **FIGURE 35–41** Problem 49.

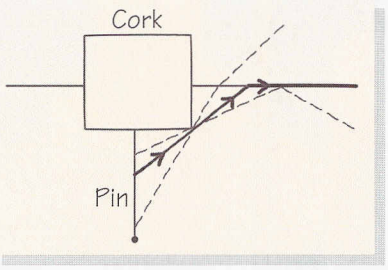
50. (III) Calculate the parallel displacement of a beam of light that strikes a vertical slab of glass, with index of refraction n and thickness D, at an angle ϕ with the horizontal (use Fermat's principle). (In Problem 49, we showed that a ray of light that passes through a slab of glass emerges parallel to its initial direction. The ray is, however, displaced from its original line, and that displacement is what we want here.)

35–5 Dispersion

51. (I) At 0°C, the index of refraction in water of light of wavelength 397 nm (violet) is 1.3444, whereas it is 1.3319 for a wavelength of 656 nm (red). What is the difference in angles of refraction for rays refracting from water near the freezing point into air for these two wavelengths? The angle of incidence is exactly 30° in each case. Take $n = 1$ for air and ignore dispersion in this medium.

52. (I) By what percent does the speed of red light in a type of glass ($\lambda = 656$ nm, $n = 1.522$) exceed that of blue light in the same glass ($\lambda = 486$ nm, $n = 1.545$)?

53. (II) A beam of white light, whose frequencies are mixed with equal intensity, passes within a piece of glass and impinges on a boundary to the air at an angle of incidence θ. The index of refraction of the glass increases with increasing angular frequency according to the formula $n^2 = 1 + [C/(\omega_0^2 - \omega^2 - C)]$, where $C = 529 \times 10^{30}\ \text{rad}^2/\text{s}^2$ and $\omega_0^2 = 685 \times 10^{30}\ \text{rad}^2/\text{s}^2$. (a) What is the largest angular frequency that passes through the glass into the air? (b) At what angle of incidence should the light approach the boundary if we wish to allow only frequencies of $\omega = 3.2 \times 10^{15}$ rad/s (red light) and below to pass through to the air?



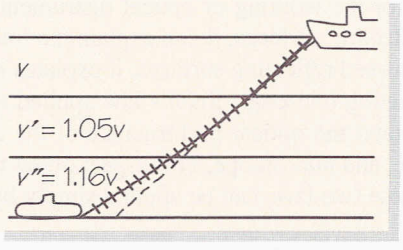
54. (II) Use the data in Problem 53 to calculate the critical angles for total internal reflection for five values of wavelengths in the range 430 nm to 770 nm. Plot your results.

55. (III) We wish to select a glass to construct a prism that can separate the yellow ($\lambda = 590$ nm) component of light from the blue-green ($\lambda = 490$ nm) component. The prism is to be a bar with the cross section of an equilateral triangle. If a ray of white light arrives parallel to the base of the prism, it must leave the prism with the two colors separated by at least 2°. What must the difference in indices of refraction be for the two colors? [*Hint*: Because the difference of angles is small, so is the difference of indices of refraction. Keep only leading terms in differences of angle and of index of refraction.]

General Problems

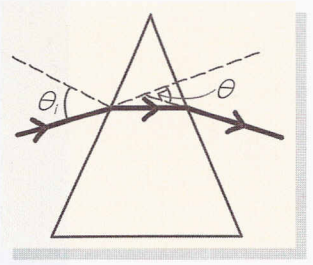
56. (I) Light of wavelength 450 nm enters a piece of glass with index of refraction 1.50. What are the wavelength, frequency, and speed of that light in the glass?

57. (II) A pin is partly inserted perpendicularly into the flat surface of a cork with a 1.5-cm radius (Fig. 35–42). The cork, with the pin on the underside, is set afloat in a pool. A length of 1.2 cm of cork is under the water surface. Because of the effects of refraction, much of the pin is hidden from view from above the surface. What length of pin can be hidden in this way?



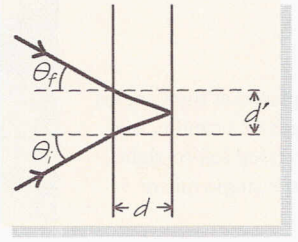
▲ **FIGURE 35–42** Problem 57.

58. (II) A beam of light is incident at an angle of 30° to the vertical on a horizontal glass plate of thickness 2.0 cm. The index of refraction of the glass is $n = 1.52$. The beam emerges on the other side. What is the perpendicular distance between the straight-line extrapolation of the incident ray and the ray refracted by the glass plate?



59. (III) Show that if an incident ray of white light that is parallel to the base of a prism in the shape of an isosceles triangle (apex angle 2ϕ) is separated into two components that exit the prism with an angular separation $\Delta\theta \ll 1$, then the difference in the indices of refraction for the two colors is proportional to $\Delta\theta$. Find the equation that expresses the relation between the differences in the indices of refraction and in $\Delta\theta$. [*Hint*: Consider the angle of emergence for a given n, and then find Δn as a function of $\Delta\theta$.]

60. (III) Sound can refract like light. Suppose that a submarine lies flat 180 m below the water surface, and that there are three thermal layers of water (each 60 m deep) of different temperatures (Fig. 35–43). The speed of sound in water depends on temperature. In the bottom layer, the speed is 1.16 times that in the top layer; in the middle layer, the speed is 1.05 times that in the top layer. A detection device at surface level determines that sound from the submarine arrives at the surface at a 36° angle with the horizontal. What is the horizontal distance between the detector and the submarine?



▲ **FIGURE 35–43** Problem 60.

61. (III) A ray of light is incident at an angle of incidence θ_i on one surface of a prism whose cross section is an isosceles triangle (apex angle 2ϕ). The light exits the prism at a total deflection angle θ (Fig. 35–44). The prism has index of refraction n and is in a vacuum, which has an index of refraction of exactly 1. For what angle θ_i is the angle of deflection θ a minimum?

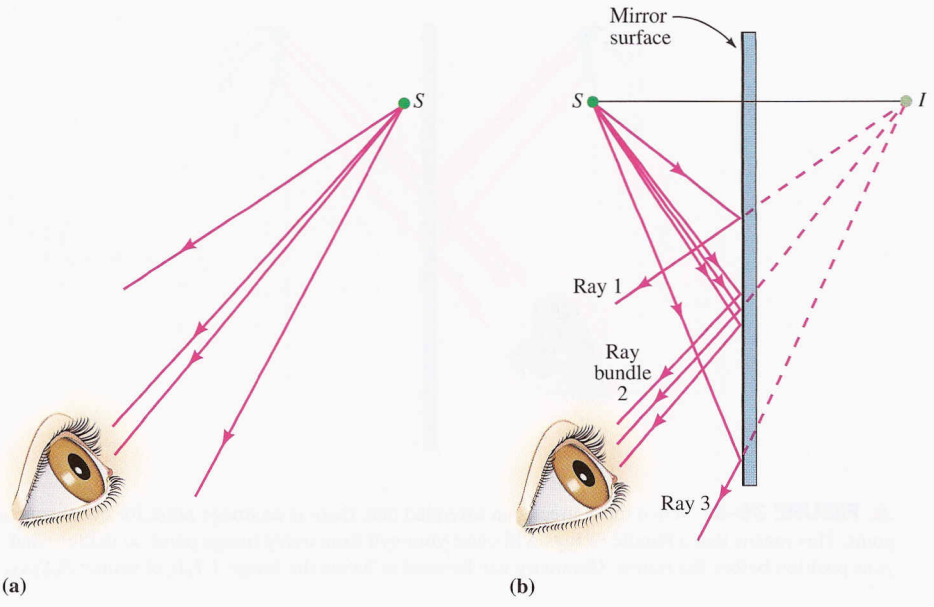
▲ **FIGURE 35–44** Problem 61.

62. (III) A ray of light incident from air onto a glass pane is partly reflected and partly refracted at the two surfaces of the pane (Fig. 35–45). The glass has an index of refraction n and a thickness d. Express in terms of n, d, and θ_i the displacement d' of the ray drawn, which enters the glass, reflects off the back surface, and exits.

▲ **FIGURE 35–45** Problem 62.

63. (III) The first successful measurement of the speed of light, made by Ole Roemer in 1675, was based on the following method. The mean orbital period of Io, a moon of Jupiter, is 42.5 h; however, that period is measured to be about 15 s less than this value when Earth in its orbit is approaching Jupiter, and about 15 s more when Earth is receding from Jupiter. (a) Given that Earth's orbital speed around the Sun is about 30 km/s, and that Earth is on a part of its orbit when it is moving toward Jupiter, how much closer will Earth have moved toward Jupiter during one orbit of Io? (b) Use the information given to estimate the speed of light.

Chapter 36



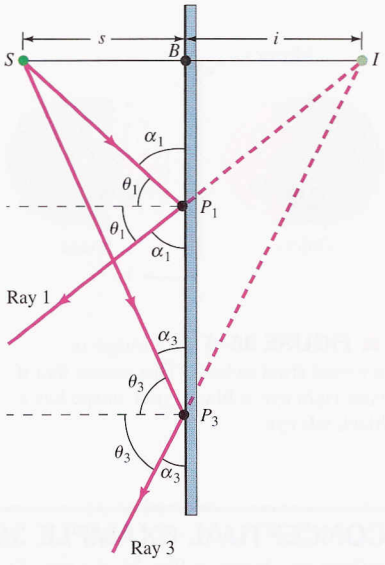
▶ Two mirrors placed at right angles gives us three images of a candle. Are all three images reversed left-to-right, as a single image in a single mirror would be?

Mirrors and Lenses and Their Uses

Instruments that can explore previously inaccessible domains often open new doors to understanding nature. For example, astronomy owes its progress to the invention of the telescope, and modern biology could not have been created without the microscope. In this chapter, we shall discuss the ideas that govern the construction of optical instruments such as these. The law of reflection and Snell's law, both introduced in Chapter 35, provide the foundation for the working of optical instruments. When the law of reflection is applied to flat reflecting surfaces, it can explain the images that we see in mirrors, and when applied to curved reflecting surfaces, it explains the functioning of rearview mirrors and the reflecting telescope. Snell's law applied to curved refracting surfaces can help us understand the optical performance of the eye, camera, magnifying glass, refracting telescope, and microscope. This aspect of the study of light is called geometric optics because these two laws can be applied simply by tracing the geometrical paths of light rays.

36–1 Images and Mirrors

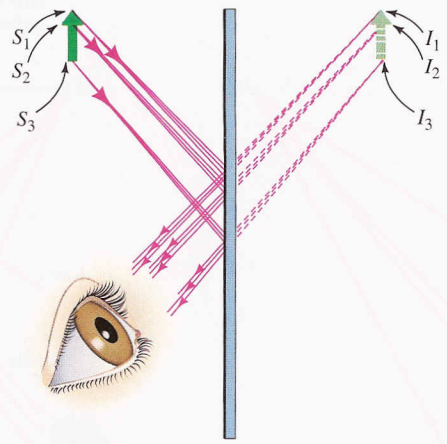
The simplest reflecting surface is a flat (or plane) mirror. When you look into a mirror, you see an image of yourself. What is an image, and how is it formed? Let's begin with rays going directly from a point source *S*—think of a small lightbulb—to a person's eye



▲ **FIGURE 36–1** Rays leaving source point S (a) go to an eye and (b) reflect from a plane mirror before going to the eye. A bundle of such rays enters the eye, apparently from point I.

(Fig. 36–1a), together with the light from the source reflecting from a plane mirror according to the law that the angles of incidence and reflection are equal (Fig. 36–1b). The rays we draw follow the direction of motion of the wave front that emanates from the light source, and we could, in fact, draw an infinite number of such rays as close to one another as we like. As we described in Chapter 35, rays that are near one another form *bundles*, visible in Fig. 36–1b.

When we look toward the mirror, we see an *image* of the light source. What exactly do we mean by this? The simple geometry in Fig. 36–1b allows us to see that *all the reflected rays from S trace back to the same point I*. To see this, look at rays 1 and 3 in Fig. 36–2, which shows in more detail the situation in Fig. 36–1. We have indicated the equal angles of incidence and reflection θ_1 and θ_3 for these rays, respectively, as well as the angles α_1 and α_3. The angle formed by BP_1I is then equal to α_1. If point B is formed by dropping a perpendicular line to the mirror from point S and if point I lies along the continuation of this line, triangles BIP_1 and BSP_1 are similar triangles. By the same method, so are triangles BIP_3 and BSP_3. Because both rays 1 and 3 emanate from the same point S, the distance BS forms the base of both triangles to the left of the mirror (the *object side*), and the distance BI forms the base of both triangles to the right of the mirror (the *image side*). The (imaginary) continuations of rays 1 and 3 to the image side meet at point I, as would the continuation of *any* reflected ray.

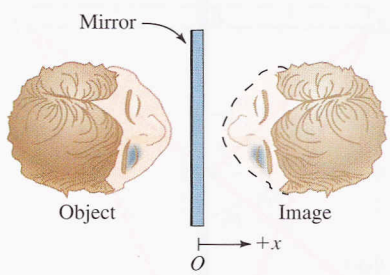


We have calculated the location of point I. Because BIP_1 and BSP_1 are similar triangles, the distances BS and BI are equal. How does the eye/brain "know" where to put I? Two eyes (or one eye that moves a little) sense a bundle of rays rather than a single ray. The eye/brain can measure their degree of divergence and is capable of extrapolating this diverging bundle back to point I.

▲ **FIGURE 36–2** All the reflected rays from point S trace back to point I. The geometry implies that the perpendicular distance s from the mirror to point S equals the distance i from the mirror to point I.

The Image of an Extended Object

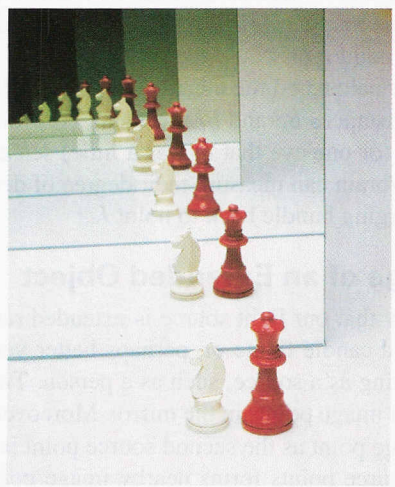
Suppose now that our light source is extended rather than being a point source—think this time of a candle flame or, perhaps better yet, think of an object that is reflecting light and acting as a source, such as a person. Two different points on the source form two different image points in the mirror. Moreover, the second image point is as close to the first image point as the second source point is to the first source point. Indeed, a set of nearby source points forms nearby image points (Fig. 36–3). The entire **object**, or *source* (we use the terms interchangeably), forms a set of matching image points, which together constitute an **image**. *An image is a set of contiguous points to which reflected rays lead when the rays are extrapolated back in straight lines*. Figure 36–3 illustrates



▲ **FIGURE 36–3** When the source is an extended one, there is an image point for every source point. This means that a bundle of rays will enter your eye from every image point no matter what your position before the mirror. Geometry can be used to locate the image $I_1I_2I_3$ of source $S_1S_2S_3$.

that the source and the image formed by a plane mirror have the same size. The idea of the size of the image will be of some importance throughout this chapter. We can also see that the image is as far behind the mirror as the object is in front.

No light rays actually emanate from the image formed by a plane mirror; thus, we call it a **virtual** image. Light rays actually do pass through a **real** image on their way to your eye, and we shall see how this can occur when we discuss mirrors with curved surfaces. We could summarize the difference between real and virtual images by saying that if you were to place a screen at the location of a virtual image, no light would strike the screen, whereas a screen placed at the location of a real image would reveal the presence of the image.



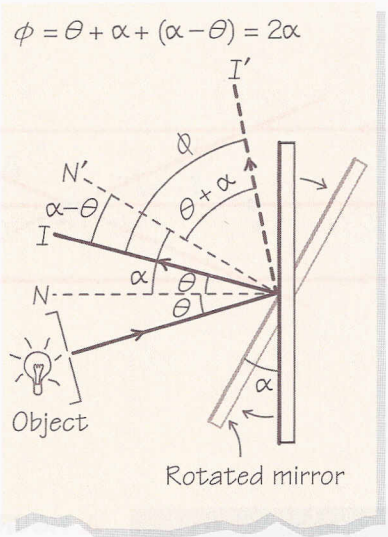
There is one striking peculiarity of plane mirrors. If your right eye is blackened, your image, viewed as if you were meeting yourself on the street, has a left eye that is blackened. From Fig. 36–4, however, we can see that the *actual* reversal is a front-to-back reversal (the nose of the object points in the $+x$ direction in the figure, whereas the nose of the image points in the $-x$ direction), and this is what lies behind the left-to-right reversal of the image.

▲ **FIGURE 36–4** An image is reversed front to back. This means that if your right eye is black, your image has a black left eye.

CONCEPTUAL EXAMPLE 36–1 How are the multiple reflections shown in Fig. 36–5 formed?

Answer The image of some source that is made by a mirror comes from the reflections of the rays emitted by the source. These reflected rays form a set of diverging rays, which result in the image. But the reflected rays can approach and reflect from a second mirror, and we have no way to tell whether the diverging set of rays incident on the second mirror come from an actual source or from the reflection from the first mirror of the source. In other words, *an image can act as a source for a second image*. It makes no difference whether an image is virtual or real—the only thing that matters is that the rays are diverging as they approach and then reflect from the second mirror. In the case of Fig. 36–5, the successive images must be due to a second mirror in front of the chess pieces, not visible in the photo. You might note that while the image produced by one reflecting surface is reversed left-to-right, the image of the original source produced by successive reflection from two (or more generally an even number of) mirrors is not.

▲ **FIGURE 36–5** Multiple reflections can be obtained with two plane mirrors. Where is the second mirror in this case?



EXAMPLE 36–2 A horizontal ray of light is incident at angle θ on a vertically suspended plane mirror. If the mirror is rotated about a vertical axis through an angle α, by what angle ϕ is the reflected ray rotated?

Setting It Up Figure 36–6 is an overhead view of the situation, including the initial and final normals to the mirror, N and N', respectively, as well as the reflected ray, labeled I.

Strategy A rotation of the mirror through an angle α means that the new angle of incidence is $\theta + \alpha$, which is also the new angle of reflection from N'. It is then a matter of geometry to find the required angle ϕ.

Working It Out From the figure, the angle between the incident ray and the new reflected ray I' increases from 2θ to $2(\theta + \alpha)$. Because the incident ray has not moved, the reflected ray is rotated by $\phi = 2\alpha$.

What Do You Think? Suppose you want to measure by how much an object has rotated and that the rotation angle is very small. How might you go about it? *Answers to **What Do You Think?** questions are given in the back of the book.*

▲ **FIGURE 36–6** Overhead view of a horizontal ray of light incident on a mirror that rotates about a vertical axis.

36–2 Spherical Mirrors

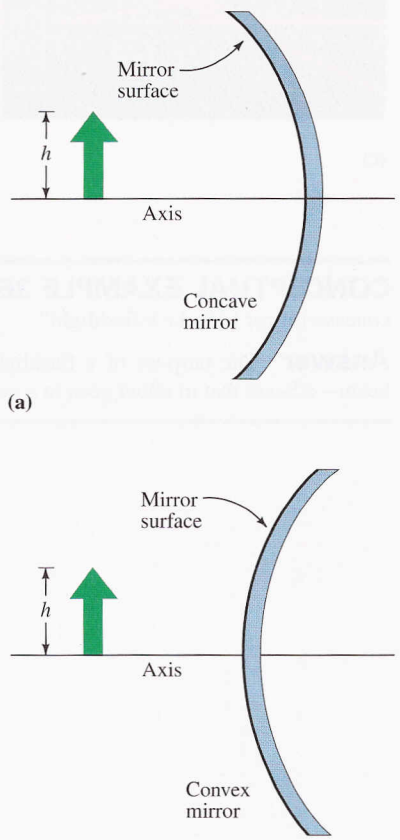


Figure 36–3 shows that plane mirrors produce images that are the same size as the object. We can construct mirrors that produce images of altered sizes by using curved surfaces. In this section, we shall study mirrors whose surfaces form a segment of a sphere. We look at both *concave* (Fig. 36–7a) and *convex* (Fig. 36–7b) mirrors: For concave mirrors the source (object) is on the same side of the surface as the sphere's center, while for convex mirrors the source is on the other side. There are some particularly simple and significant rays to follow in these situations, and the ray-tracing techniques of Section 36–1 will be useful here. We simplify things by studying only objects on or near the *axis*, the line perpendicular to the center point of the mirror, as shown in the figure. The tips of the arrows shown in Fig. 36–7 are a distance h from the axis, and if h is small compared to the radii of curvature of the mirrors, we say that the object is *near the axis*. We consider only rays that are so close to being parallel to the axis that we can use small-angle approximations in studying their reflections. Such rays are said to be **paraxial**.

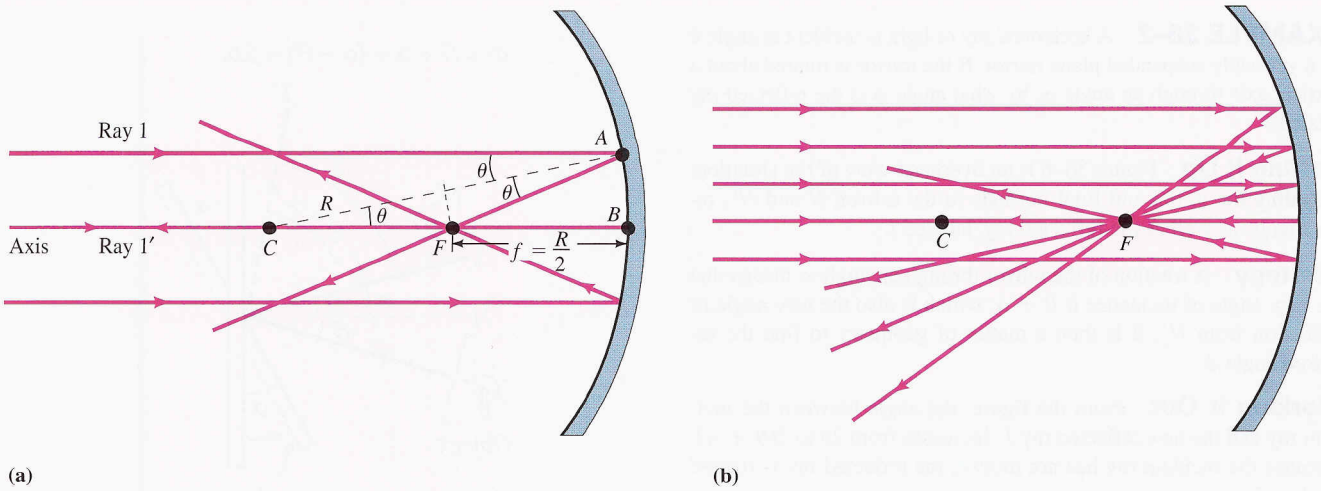
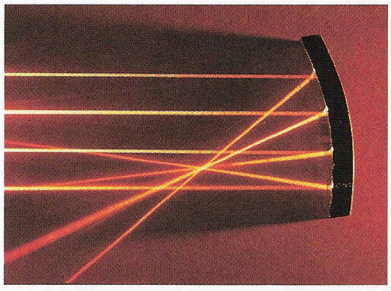
The Concave Mirror



We will first consider rays from a very distant point source (to the left of the figure) on the axis CB of the concave mirror in Fig. 36–8a. When a source is so far away that *all the rays from it arrive practically parallel to each other*, we say that the source is *at infinity*. Point C indicates the position of the center of the sphere (of radius R) of which the mirror is a segment. The position of C (called the *center of curvature*) is therefore a distance R from the mirror surface, and all lines from point C to the mirror are perpendicular to the mirror.

Location of the Focal Point: Look at ray 1, which is reflected at point A in the direction AF in Fig. 36–8a. Angle θ is the angle of incidence and the angle of reflection (line CA is perpendicular to the mirror). Note that triangle ACF is isosceles with a base of length R. Thus, by dropping a perpendicular from point F to the base of the triangle AC, we see that the distance CF is $CF = (R/2)/\cos\theta$. For small θ, $\cos\theta \cong 1$; hence $CF = R/2$, or $BF = R - CF = R/2$, *independent* of θ.† *All* the parallel rays near the axis reflect through point F, a distance $R/2$ from the mirror (Fig. 36–8b, c). This is the position at which we will see an image point of a very distant source point. Is the image we see at point F a real or virtual image? Unlike the image points produced by a plane mirror, point F is a real image point because rays actually cross there.



†This result is accurate to 1 percent for angles θ less than about 10°.

▲ **FIGURE 36–7** (a) Concave and (b) convex spherical mirrors. The object shown, an arrow, acts as an extended source.

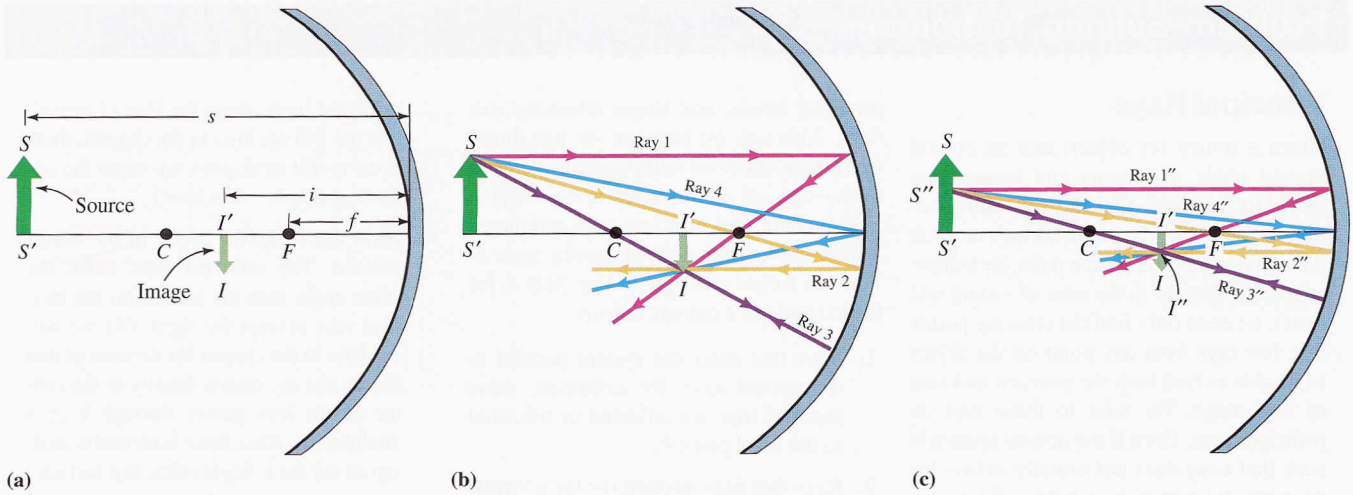
(a) (b)

(c)

▲ **FIGURE 36–8** (a) Rays emitted by an object at infinity are all parallel to the axis. Ray 1 is reflected by the concave mirror surface and passes through the focal point, F. (b) To a good approximation, F is independent of θ; that is, any incoming ray parallel to the axis is reflected through it. Thus all rays from infinity cross the axis at F, which is therefore an image point. (c) A demonstration of the construction of part (b).

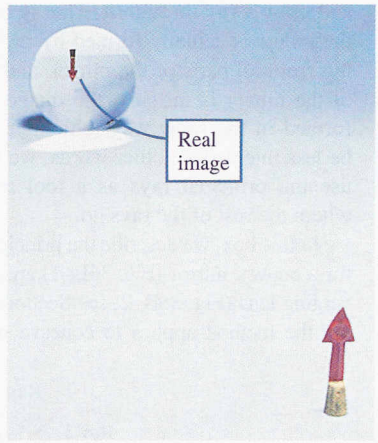
The paraxial rays from a source point at infinity are brought together to form an image at the point F; we say they are *focused* at point F, which is known as the **focal point**, or *focus*, and we say that its distance f from the mirror is the **focal length**. These terms can be applied to any optical system that produces images—including plane mirrors, whose focal length is infinite. We have shown that for concave mirrors

$$f = R/2. \tag{36–1}$$



CONCEPTUAL EXAMPLE 36–3 How could you use a concave mirror to make a flashlight?

Answer The purpose of a flashlight is to send out a parallel beam—a beam that in effect goes to a point far away. Since the path of any ray can be followed in reverse, this can be done by reversing the picture in Fig. 36–8a. We place a source of rays (a lightbulb) at the focal point, and the result will be a set of parallel rays leaving the mirror.

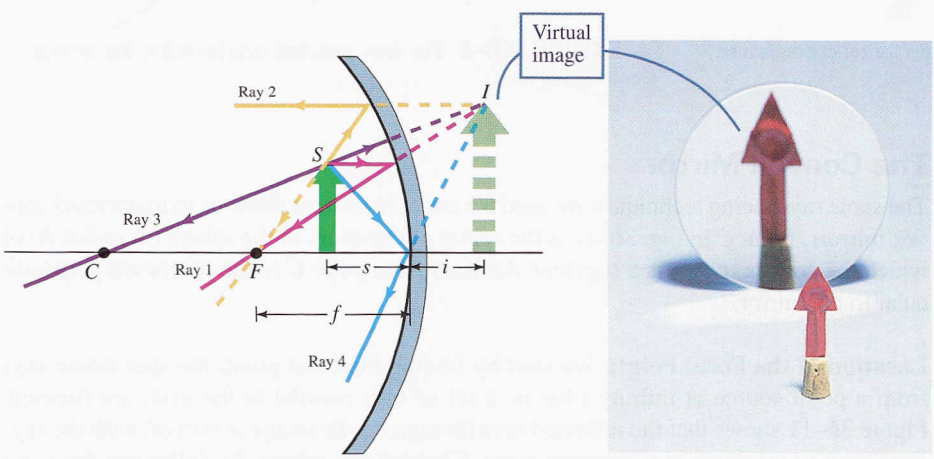


The Image of an Extended Object: Let's take an extended object—as, for example, the arrow in Fig. 36–7—that is small compared to the radius of curvature of the mirror and close enough to the axis so that the rays are paraxial. In Fig. 36–9a, we label two points on the object, which is *upright*, with the letters S and S'. If we follow bundles of light rays coming from a given spot on the object, we see that after reflection the rays pass through a corresponding spot in space, thus forming image points I and I' of the two points, and indeed an image of the entire object. We want to determine the position and size of the image. To do so, we use the principal-ray technique described in detail in the Problem-Solving Techniques, p.1004. In Fig. 36–9b, we draw the principal rays to find point I of the image that corresponds to point S of the source, and in Fig. 36–9c, we draw the principal rays to find the image point I'' that corresponds to source point S''. These sets of rays are

- ray 1, which approaches the mirror parallel to the axis and is reflected through the focus F;
- ray 2, which passes through the focus and reflects off the mirror parallel to the axis;
- ray 3, which passes through the center of curvature of the mirror and is reflected back in the direction from which it came;
- ray 4, which goes to the center of the mirror surface and whose reflection makes the same angle with the axis as the incident angle.

The rays leaving source point S do indeed cross at the image point I, and those from S'' cross at I''. All other points of the source have image points that can be constructed in

▲ **FIGURE 36–9** (a) An extended object a distance s from a mirror forms an image at a distance i from the mirror. The object is outside the focal length of the mirror. (b) Ray tracing for the concave mirror, with the principal rays for source point S. (c) Principal rays for source point S''. By repeating this exercise, we can build up the entire image. The principal rays are a guide; *any* ray from S that reflects will cross the image point I. (d) The object has produced an inverted and reduced image in a concave mirror.



(d)

the same way, and the image is thus constructed as in Figs. 36–9b and 36–9c. Note that both image point I' and source point S' lie along the optical axis. Our construction shows (and it is generally true) that a vertical source gives a vertical image, so that we can compute the location of just one image point rather than many. For example, the entire image can be constructed if we find only image point I of the top of the source (that is, of source point S), and, in fact, any two of the four principal rays are sufficient to determine point I. For example, rays 1 and 2 are sufficient for locating point I in Fig. 36–9b.

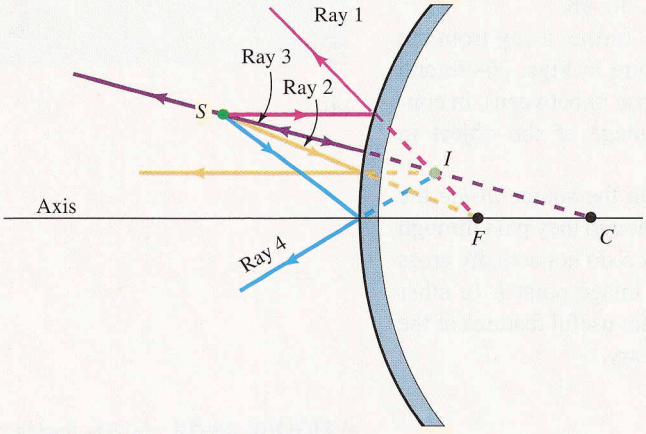
In this discussion, the source is *outside* the focal point, i.e., further away from the mirror than F. The image in Fig. 36–9a, located by the procedure in Figs. 36–9b and 36–9c, is *real* (real light rays pass through points I and I' and those in between), in contrast to the virtual image produced by plane mirrors. The image of the object in Fig. 36–9d is *inverted* (*upside down*) and *reduced in size*.

Let's now consider the situation depicted in Fig. 36–10, with the source *inside* the focal point of the mirror. In this case rays 2 and 3 only *behave* as though they pass through points F and C, respectively. The reflected rays from source point S do not actually cross but are aligned as though they come from behind the mirror at image point I. In other words, the image is virtual. It is also *upright* and enlarged. These are useful features of the concave mirrors used for shaving or applying makeup, or in dentistry.

◀ **FIGURE 36–10** (a) Ray tracing with the principal rays for a concave mirror, for a source closer to the mirror than that of Figure 36–9b. The image becomes virtual when the source moves inside focal point F. (b) An object is placed within the focal length of a concave mirror. This time the image it produces is upright and magnified.

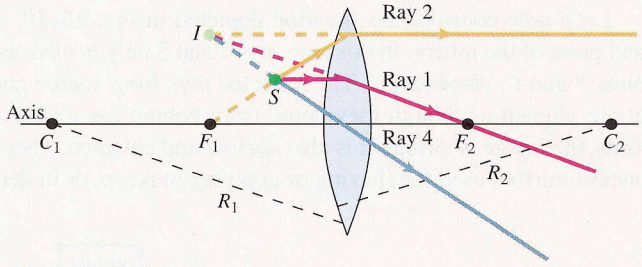
Problem-Solving Techniques

Principal Rays



Given a source (or object) and an optical system made of mirrors and lenses, one generally wants to find the size and location of the image. Because all rays cross at the image point of a source point (or behave as though they do in the case of virtual images), we need only find the crossing points of a few rays from any point on the object to be able to find both the position and size of the image. We refer to these rays as *principal rays*. Even if the optical system is such that a ray does not actually exist—for example, there may be a hole at the center of a mirror—we can pretend that it does and draw a ray through it. That is because the image is actually formed by rays coming from all parts of the mirror, and if part of the mirror is missing, the image is still formed in the same way (although it may be less intense). In other words, we simply use the principal rays as a tool to learn where the rest of the rays go.

In this box, we describe the principal rays for a convex mirror (Fig. 36B–1) and a converging lens (Fig. 36B–2; see Section 36–4), but the method applies to concave mirrors, diverging lenses, and single refracting surfaces. Although we have not yet introduced all of these cases, we will eventually come to them—they are all illustrated in this chapter.

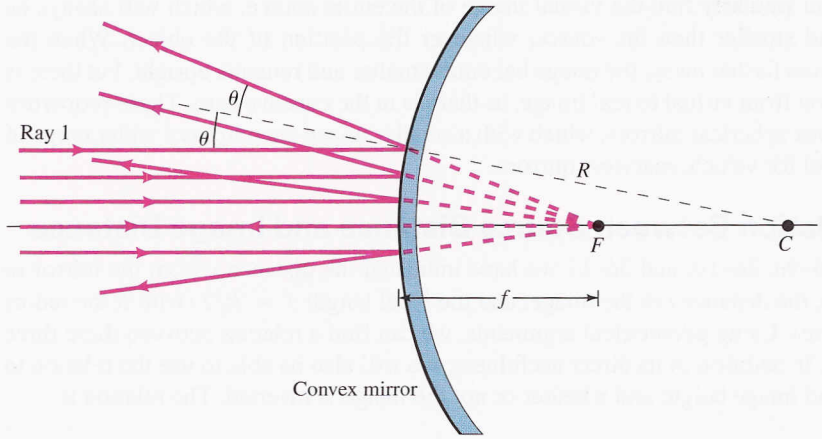


We count four principal rays, numbered 1 through 4, from a given source point S. You can follow each ray in Fig. 36B–1 for the example of a convex mirror:

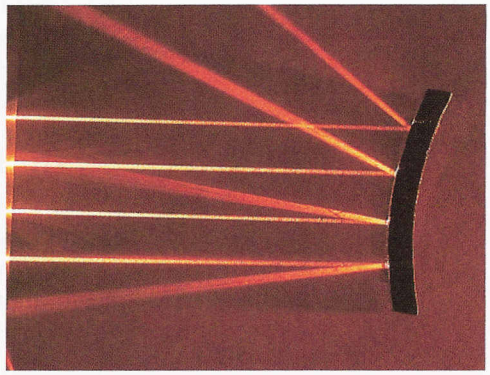
1. Rays that enter the system parallel to the optical axis. By definition, these paraxial rays are reflected or refracted to the focal point F.
2. Rays that pass through (or for a virtual image are aligned so that if they are extrapolated, they would pass through) the focal point as they enter the system. These rays are just reversed versions of type 1 rays and thus after reflection or refraction leave the system parallel to the axis.
3. Rays that pass through (or are aligned as though they pass through) the center of curvature C of the sphere from which a mirror or refracting surface is formed. These rays are perpendicularly incident on the surface and will be reflected or refracted back along the line of arrival. (As we will see later in the chapter, there is no useful analogous ray when the optical system is a thin lens.)
4. Rays that strike the center of the mirror surface. The reflected rays make the same angle with the axis as do the incident rays (except for sign). (As we will see later in the chapter for the case of thin lenses, the ray drawn directly to the center of the lens passes through it in a straight line. Also, there is no useful analogous ray for a single refracting surface.)

By drawing these principal rays from any given point S on a source, we find where the reflected or refracted rays cross (or for a virtual image appear to cross) and learn the location of the image point I of source point S. When an optical system has more than one reflecting or refracting surface (an "element"), we can apply the simple rule that the image formed by one element serves as a new object for the next element. In that case, *the principal rays must be redrawn for the new object* as they apply to the next optical element to locate the next image.

▲ **FIGURE 36B–1** The four principal rays for reflection from a convex mirror.



▲ **FIGURE 36B–2** The three principal rays for refraction through a converging lens.

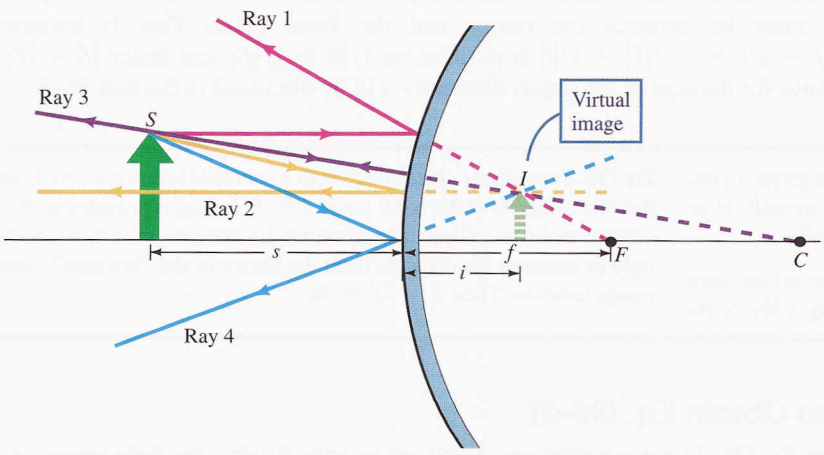


The Convex Mirror

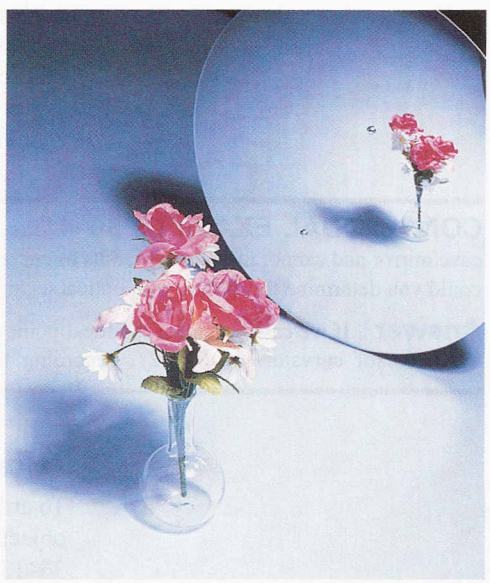
The same ray-tracing techniques we used for concave mirrors allow us to understand convex mirrors. Point C in Fig. 36–11 is the center of curvature of the sphere (of radius R) of which the convex mirror is a segment. All lines from point C to the mirror are perpendicular to the mirror.

Location of the Focal Point: We start by finding the focal point, the spot where rays from a point source at infinity (that is, a set of rays parallel to the axis) are focused. Figure 36–11 shows that the reflected rays diverge, so *the image is virtual*, with the rays appearing to originate at a common point F behind the mirror. By following the same trigonometric reasoning we used for the concave mirror and by using Fig. 36–11, we

(a)



(b)



▲ **FIGURE 36–11** (a) When a spherical mirror is convex, the focal point lies behind the mirror, as ray tracing shows. The reflected rays diverge, and their extensions all lead back to the focal point. (b) Parallel rays of light reflected by a convex mirror.

can see that the distance f is again given by Eq. (36–1), $f = R/2$ (see Problem 14). Note that the focal point of a convex mirror is on the side opposite the object, unlike the case of the concave mirror, for which the focal point is on the same side as the object.

The Image of an Extended Object: We trace the four principal rays from source point S of the extended object shown in Fig. 36–12: ray 1—parallel to the optical axis, and whose reflection extends back along the line from the mirror to point F; ray 2—drawn as though it would pass through F, and whose reflection is parallel to the axis; ray 3—drawn as though it would pass through C, and whose reflection returns along the line of incidence; and ray 4—striking the center of the mirror surface, and whose reflection makes the same angle with the axis as the incident angle. A careful drawing shows that the reflected rays diverge from each other, but all four (indeed, *all* rays from S) would originate at point I if they were traced back through the mirror. *Point I is the virtual image of point S.*

(a)

(b)

▲ **FIGURE 36–12** (a) Ray tracing describes the formation of a virtual image by a convex spherical mirror. (b) The image produced by a convex mirror is upright, reduced, and behind the mirror.

We can similarly find the virtual image of the entire source, which will always be upright and smaller than the source, whatever the position of the object. When the source moves farther away, the image becomes smaller and remains upright, but there is no transition from virtual to real image, as there is in the concave case. These properties make convex spherical mirrors, which with a smaller image encompass a wider range of view, useful for vehicle rearview mirrors.

The Relation Between Source Distance and Image Distance

In Figs. 36–9a, 36–10, and 36–12 we have indicated the distance s from the mirror to the source, the distance i to the image, and the focal length $f = R/2$ (with R the radius of curvature). Using geometrical arguments, we can find a relation between these three quantities. In addition to its direct usefulness, we will also be able to use the relation to help us find image height and whether or not the image is inverted. The relation is

$$\frac{1}{s} + \frac{1}{i} = \frac{1}{f}. \tag{36–2}$$

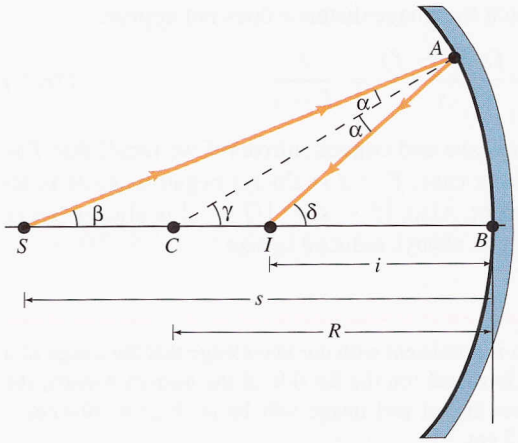
SOURCE–IMAGE–FOCAL-LENGTH RELATION

(The details of the argument for a concave spherical mirror are contained in the optional subsection that follows.) With an appropriate set of conventions about signs, *the same relation holds for the convex mirror*. Equation (36–2) is immediately understood in two limits. When the object is far away ($s \to \infty$), then $1/s \to 0$ and $i = f$ (which is the definition of f). When the object is at the focus, $s = f$, then $1/i = 0$: The image is very far away.

Equation (36–2) contains information on the sign of the image point i. We'll discuss this information here, but point out that later the information on the sign will be summarized in a table. To start, note that if the object is between the concave mirror and the focus, as in Fig. 36–10, then s is smaller than f, and Eq. (36–2) implies that *i must be negative*. We associate a negative i with the image on the far side of the mirror—that is, with a virtual image. Likewise, i is positive when the image is real. Equation (36–2) may be applied to a convex mirror if we follow the convention that *the focal length f is negative when the focus is on the "virtual image" side of the mirror*. This is equivalent to saying that if the mirror's center of curvature is on the back (nonreflecting) side of the mirror, f is negative. In the application of Eq. (36–2) to a convex mirror, s is always positive and f is always negative. If s is positive (as it is when our optical system consists only of the convex mirror), then i will be negative (the image is virtual). Furthermore, the image in this case must be between the mirror and the focal point. That is because $1/s = 1/f - 1/i = -1/|f| + 1/|i|$ is positive, so $1/|i| > 1/|f|$, and hence $|i| < |f|$.

The rules for the sign of the object distance s will be discussed in Section 36–3.

CONCEPTUAL EXAMPLE 36–4 You are given a concave mirror and cannot measure its radius of curvature directly. How could you determine this radius with optical techniques?



Answer If we can determine the focal point of the mirror, then its radius of curvature is $R = 2f$, according to Eq. (36–1). As Eq. (36–2) confirms, this is done with a source at infinity, $s \to \infty$, so that the image is at the focal point, $i = f$. Sunlight provides such a source, and if we allow it to shine on the concave mirror, we need only to measure the distance from the mirror to the "hot spot"—the image location. Then $R = 2f = 2i$.

*How to Obtain Eq. (36–2)

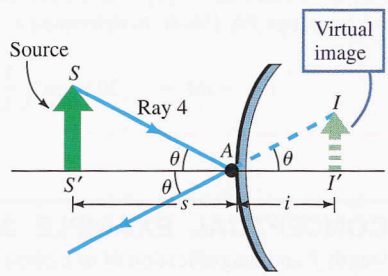
To arrive at Eq. (36–2), we consider two points on an optical axis—the light source (or object), S, and its image, I—and a concave spherical surface. We can see from Fig. 36–13 and from the fact that the sum of the internal angles (in radians) of a triangle is π, that the following relationships hold:

$$\gamma = \beta + \alpha; \tag{36–3}$$

$$\delta = \gamma + \alpha = \gamma + (\gamma - \beta) = 2\gamma - \beta. \tag{36–4}$$

◀ **FIGURE 36–13** Geometric construction for deriving Eq. (36–2) for a spherical mirror.

In arriving at Eq. (36–4), we have used Eq. (36–3) as an intermediate step to eliminate α. The distances of Fig. 36–13 are related to the angles by the exact relation $AB = R\gamma$ and by the *approximate* (small-angle) equations $AB = i\delta = s\beta$. These relations allow Eq. (36–4) to be rewritten as



$$\frac{AB}{i} = \frac{2AB}{R} - \frac{AB}{s}.$$

We divide out the common factor AB and use the focal length $f = R/2$ for a spherical surface. We immediately obtain Eq. (36–2).

Magnification

Our geometric constructions show that an image may not be the same size as its source. Consider the convex mirror in Fig. 36–14. Ray 4 to the center point A of the mirror is useful because all the angles marked θ are the same, so triangles $AS'S$ and $AI'I$ are similar triangles. Thus, the magnitude of the **magnification** M defined as the ratio of the heights of the source and image, is

$$|M| \equiv \frac{|II'|}{|SS'|} = \frac{|i|}{|s|}. \tag{36–5}$$

▲ **FIGURE 36–14** Geometry for the calculation of magnification.

We also specify whether the image is upright or inverted by writing

$$M = -\frac{i}{s}. \tag{36–6}$$

MAGNIFICATION

If M is negative, the image is inverted; if M is positive, the image is upright. We can verify that this form works in the following explicit cases:

1. When the mirror is concave and the source is outside the focal point, the image is real (i is positive). By Eq. (36–6), M is then negative and the image should be inverted, as it is in Fig. 36–9a.
2. When the mirror is concave and the source is inside the focal point, the image is virtual (i is negative). By Eq. (36–6), M is then positive and the image should be upright, as it is in Fig. 36–10.
3. When the mirror is convex, the image is virtual (i is negative). By Eq. (36–6), M is then positive and the image should be upright, as it is in Fig. 36–12.

Equation (36–2) can be rewritten as

$$\frac{1}{i} = \frac{1}{f} - \frac{1}{s} = \frac{s - f}{fs}.$$

We can thereby find M in a form in which the image distance does not appear:

$$M = -\frac{i}{s} = -\frac{fs/(s-f)}{s} = \frac{f}{f-s}. \tag{36–7}$$

This equation can be applied to both concave and convex mirrors if we recall that f is negative for convex mirrors. In the convex case, $f - s$ is always negative, so M is always positive; the image is always upright. Also, $|f - s| = |f| + |s|$ is always larger than $|f|$ for convex mirrors, so the image is always reduced in size.

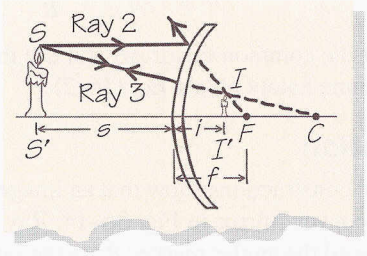
EXAMPLE 36–5 A convex spherical mirror of radius of curvature R of magnitude 20.0 cm produces an upright image precisely one-quarter the size of the candle that is the object. What is the separation distance between the object and its image?

Setting It Up We draw the mirror in Fig. 36–15, indicating the center of curvature C and the focal point F. We know the position of neither source nor image.

Strategy We find f from Eq. (36–1), $f = R/2$. We then rearrange Eq. (36–7) to find s in terms of the known quantities f and M. We can then use Eq. (36–6) to find i.

Working It Out First we have numerically $f = R/2 = -10.0$ cm. (The negative sign indicates that the mirror is convex.) The appropriately rearranged Eq. (36–7) is

$$s = f\left(1 - \frac{1}{M}\right) = (-10.0\text{ cm})\left(1 - \frac{1}{\frac{1}{4}}\right)$$
$$= (-10.0\text{ cm})(-3) = 30.0\text{ cm}.$$



(We have taken $M = \frac{1}{4}$, positive because the image is upright.) Next we rearrange Eq. (36–6) to determine i:

$$i = -sM = -(30.0\text{ cm})\left(\frac{1}{4}\right) = -7.50\text{ cm}.$$

The minus sign is consistent with our knowledge that the image of a convex mirror is virtual (on the far side of the mirror). Finally, the distance between object and image will be $|s| + |i| = 30.0$ cm + 7.50 cm = 37.5 cm.

Alternative Solution The ray-tracing construction in Fig. 36–15 confirms these conclusions qualitatively; to confirm the actual numbers, the ray-tracing technique requires a very accurate drawing.

What Do You Think? What happens to the image when the candle is slowly moved farther away from the mirror?

▲ **FIGURE 36–15** Ray tracing to find the image.

CONCEPTUAL EXAMPLE 36–6 What are the focal length f and magnification M of a plane mirror?

Answer A plane mirror is a special case of a concave or convex mirror in which $R \to \infty$. Since $f = R/2$, if $R \to \infty$, then $f \to \infty$ as well. We have seen that by using the relation between s, i, and f, we can determine the magnification in terms of any two of these. Here we use Eq. (36–7), which gives M in terms of f and s:

$$M = \frac{f}{f-s} \to \frac{f}{f} = 1.$$

We have used the fact that $f \gg s$, and the answer is no magnification (image size = object size) for any value of s. Note that M is positive, indicating an upright image—every morning, when you look in the bathroom mirror, you verify this!

THINK ABOUT THIS. . .

ARE RAY-TRACING TECHNIQUES REALLY USEFUL?

In this chapter our primary tools for analyzing optical systems are algebraic equations, not ray-tracing techniques. But ray tracing is the basis for the design of real optical systems, especially the most sophisticated. We may want an optical system to produce a very sharp image over a very limited range of source distances; for example, the lenses used in orbital satellites to image Earth's surface will never have to make an image of a very close source. Or, as in many cameras, we may want to sacrifice a sharp image in order for an optical system to operate in dim light. Real systems may have nonspherical mirrors, or thick, multielement lenses in which the elements move relative to one another, as in zoom lenses. To attain the desired optical properties, designers of such systems use computer programs capable of tracing large numbers of rays in a system design, which allows them to preview the quality and placement of the image and to test modifications in the design.

The relation between source distance, image distance, and focal length [Eq. (36–2)], the expression for magnification [Eq. (36–6)], and the ray-tracing techniques are applicable to lenses as well as to mirrors. For the lenses that we will study in this chapter, these three elements provide all the information we need.

We conclude this section with a comment on signs. Table 36–1 gives the signs of all the quantities necessary for mirrors, refracting surfaces, and lenses. However, in our opinion it is not necessary to keep track of the signs of the various quantities we have discussed. Develop your ray-tracing techniques, and you will be able to rederive the signs on your own. In this way a ray-tracing diagram is perhaps as useful as a free-body diagram.

TABLE 36–1 • Sign Conventions for Mirrors, Refracting Surfaces, and Lenses

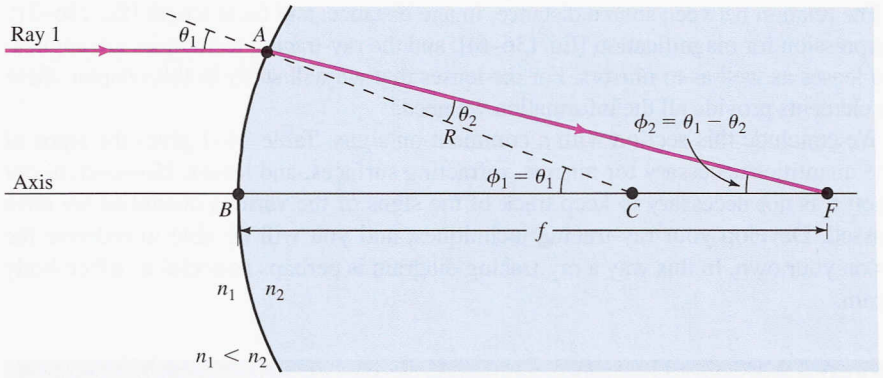
In applying the information in this table, we must distinguish two "sides" to a reflecting or refracting surface:

Side *A*, the side from which light originates, and

Side *B*, the side to which light passes.

For mirrors, side B is identical to side A; for refracting surfaces and lenses, the two sides are opposite. Only the sign of the source position is determined by side A. All other quantities are determined by reference to side B.

Determined by Side *A*	
Source distance s	Positive if object is on side A (real object)
	Negative if object is on side opposite to side A (virtual object)
Determined by Side *B*	
Image distance i	Positive if image is on side B (real image)
	Negative if image is on side opposite to side B (virtual image)
Curvature R	Positive if center of curvature is on side B
	Negative if center of curvature is on side opposite to side B
Focal point	Positive if on side B
	Negative if on side opposite to side B



36–3 Refraction at Spherical Surfaces

Mirrors change the direction of rays of light and create real or virtual images of objects. Lenses do the same, using pieces of transparent material to refract light. With Snell's law of refraction, we can use rays to determine the behavior of lenses in the same way that we handled mirrors using the law of reflection. The most basic type of lens typically has two curved refracting surfaces, and it is best to approach this case by first thinking about refraction through a single curved surface, which is the subject of this section. By repeatedly applying the rules we develop for a single boundary, we shall be able to understand the passage of light through lenses. We study, in particular, surfaces that are spherical sections without too much curvature, and we consider only paraxial rays. This simplifies the calculations and leads to the right qualitative conclusions.

Consider, then, light that crosses the boundary between one medium with index of refraction n_1 and another medium with index of refraction n_2 (Fig. 35–9). The angles of incidence and refraction satisfy Snell's law, Eq. (35–6):

$$n_1 \sin \theta_1 = n_2 \sin \theta_2.$$

Here we apply this law to a boundary that is not flat but rather forms a segment of a sphere of radius of curvature R. Let's take a convex surface, one whose center of curvature—point C in Fig. 36–16—is in the region to which light passes. Although we choose $n_1 < n_2$, so that the light that passes from medium 1 to medium 2 bends toward the perpendicular to the surface, the results will be more general.

▶ **FIGURE 36–16** Ray tracing of a ray that enters a medium whose index of refraction is different from than that of the medium from which the ray came requires us to use Snell's law of refraction. Here we see refraction at a convex spherical surface.

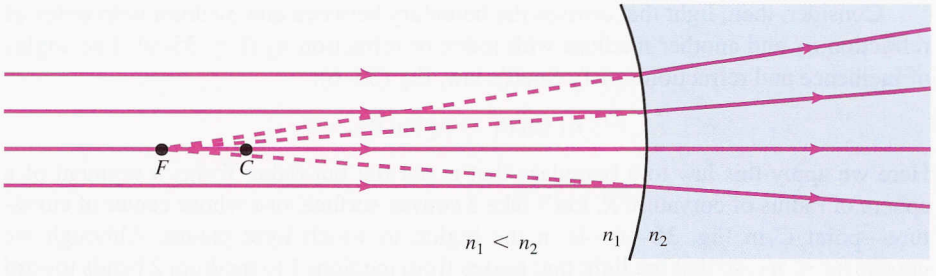
The Focal Point of a Single Refracting Surface

As for a spherical mirror, a single refracting surface has a focal point F that we find by tracing rays that come from a very distant source, parallel to the axis. For the convex surface in Fig. 36–16, ray 1 bends toward the axis and crosses it at a point F. This point will be a focal point if all the incident rays that are parallel to the axis cross at F. Here we show that this is the case for paraxial rays, where the angle of incidence θ_1 and that of refraction θ_2 are both small, so the relation $\sin\theta \cong \theta$ is a good approximation. In that case Snell's law becomes

$$n_1\theta_1 \cong n_2\theta_2. \tag{36–8}$$

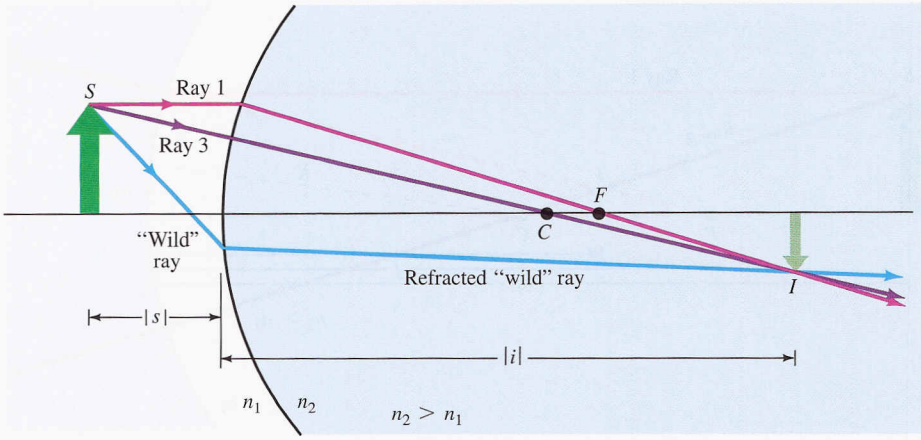
Simple geometry shows that in Fig. 36–16 $\phi_1 = \theta_1$, and therefore $\phi_2 = \theta_1 - \theta_2$. For small angles, the relation between BF and the arc length AB is given by

$$BF(\theta_1 - \theta_2) \cong AB.$$



Because $AB = R\theta_1$, this result, along with Eq. (36–8), implies that

$$BF \cong \frac{R\theta_1}{\theta_1 - \theta_2} \cong \frac{Rn_2}{n_2 - n_1}.$$



This distance is independent of θ_1 for small angles, so *all* parallel rays near the axis pass through point F, and F is the image of a point source at infinity. The focal length f is the distance BF:

$$f = \left(\frac{n_2}{n_2 - n_1}\right)R. \tag{36–9}$$

The focal point for a single refracting surface is farther from the surface than the center of curvature, as in Fig. 36–16 or by noting that in Eq. (36–9), $f > R$ if $n_2 > n_1$. Although we have derived Eq. (36–9) for a convex surface, we can derive it for a concave surface just as easily (Fig. 36–17). The center of curvature C of the concave surface is on the side from which the light is incident. We find exactly the same formula—except that the focal point is to the left of the surface, on the same side as C. We see in Fig. 36–17 that an image at the focal point F for such a surface is virtual.

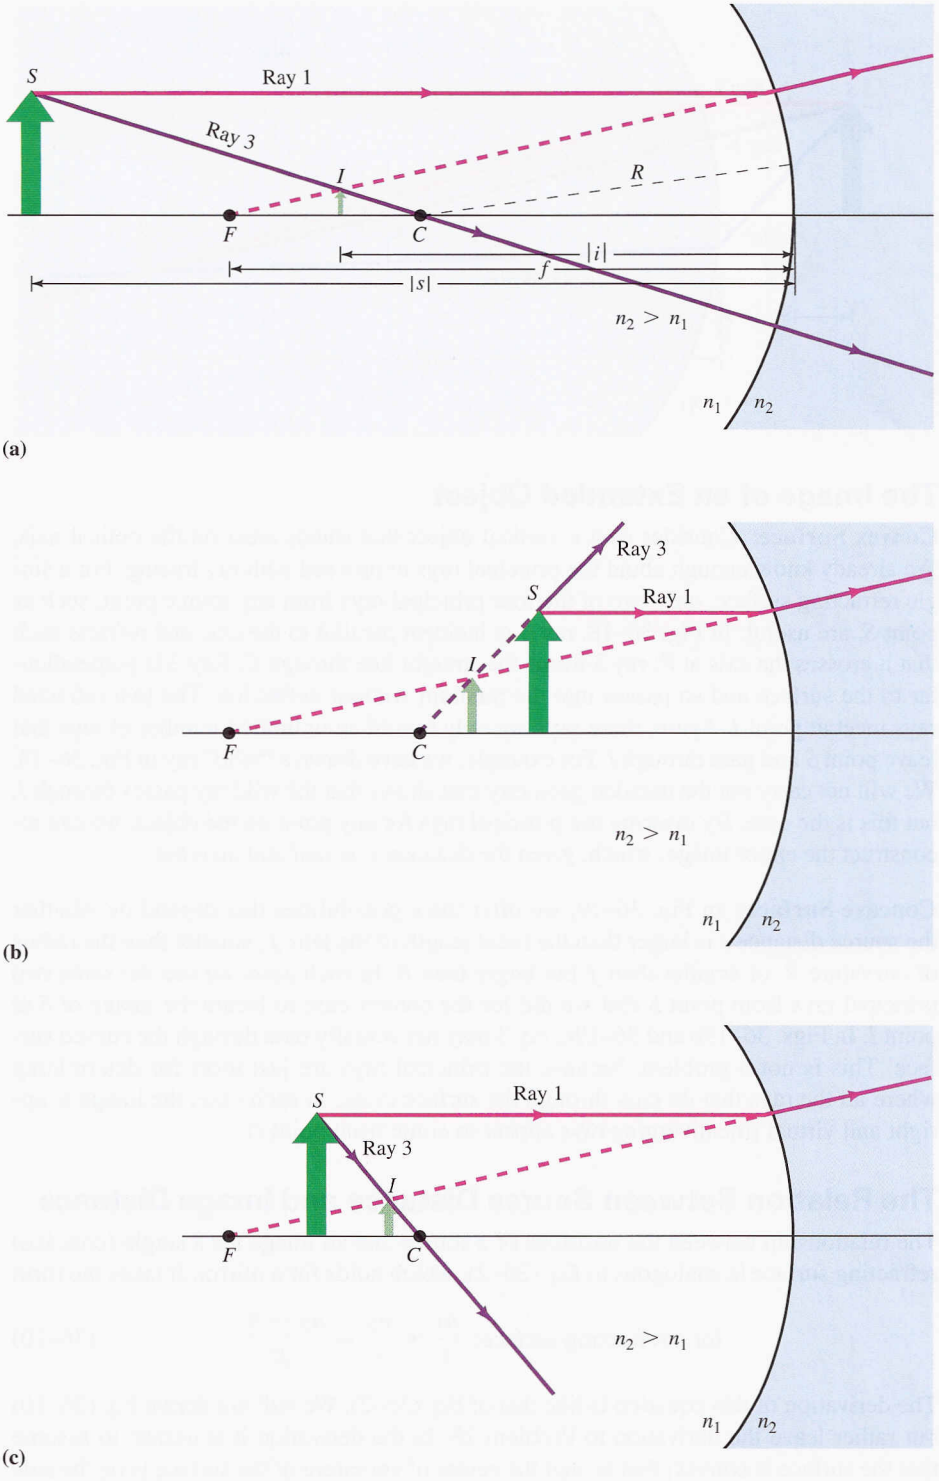
▲ **FIGURE 36–17** Refraction at a concave spherical surface.

◀ **FIGURE 36–18** Ray tracing shows how a real image is formed by a convex spherical refracting surface.

The Image of an Extended Object

Convex Surface: Consider next a vertical object that stands erect on the optical axis. We already know enough about the principal rays to proceed with ray tracing. For a single refracting surface, only two of the four principal rays from any source point, such as point S, are useful. In Fig. 36–18, ray 1 is incident parallel to the axis and refracts such that it crosses the axis at F; ray 3 forms the straight line through C. Ray 3 is perpendicular to the surface and so passes into the medium without deflection. The two refracted rays meet at point I. Again, these rays are only two of an unlimited number of rays that leave point S and pass through I. For example, we have drawn a "wild" ray in Fig. 36–18. We will not carry out the detailed geometry that shows that the wild ray passes through I, but this is the case. By drawing the principal rays for any point on the object, we can reconstruct the entire image, which, given the distance s, is *real* and *inverted*.

Concave Surface: In Fig. 36–19, we offer three possibilities that depend on whether the source distance s is larger than the focal length of the lens f, smaller than the radius of curvature R, or smaller than f but larger than R. In each case, we use the same two principal rays from point S that we did for the convex case to locate the image of S at point I. In Figs. 36–19b and 36–19c, ray 3 may not actually pass through the curved surface. This is not a problem, because the principal rays are just tools for determining where all the rays that do pass through the surface cross. In each case, the image is upright and virtual (the diverging rays appear to come from point I).



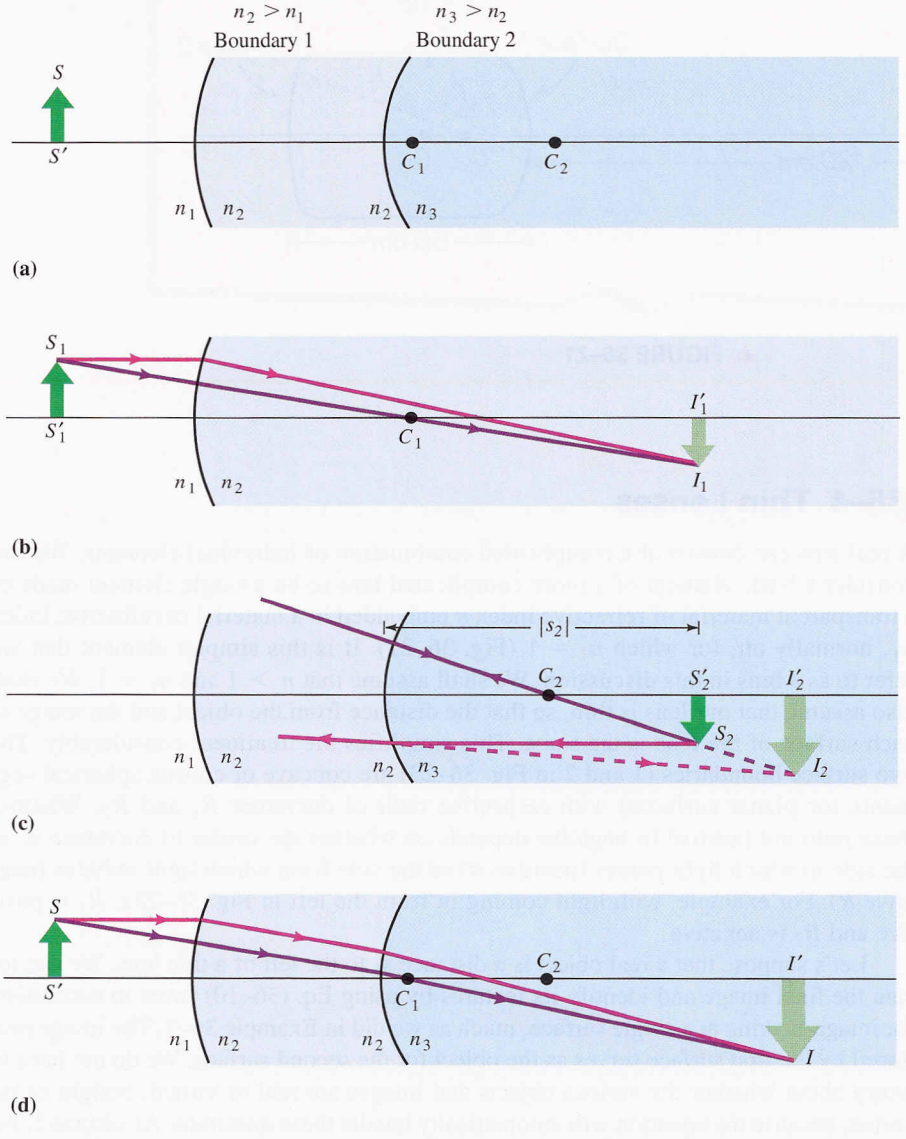
The Relation Between Source Distance and Image Distance

The relationship between the positions of a source and an image for a single (concave) refracting surface is analogous to Eq. (36–2), which holds for a mirror. It takes the form

$$\text{for a refracting surface: } \frac{n_1}{s} + \frac{n_2}{i} = \frac{n_2 - n_1}{R}. \qquad (36\text{–}10)$$

The derivation of this equation is like that of Eq. (36–2). We will not derive Eq. (36–10) but rather leave the derivation to Problem 28. In the derivation it is easiest to assume that the surface is convex; that is, that the center of curvature of the surface is on the side of the surface to which the light passes. Let's suppose that this corresponds to a positive value of R, as for the concave mirror. In addition, s is positive from the start. If we then find i from Eq. (36–10), it could be either positive or negative. When i is positive, it is on the side of the surface to which light passes and the image is real, meaning that light passes through it. When i is negative, it is on the side from which light is emitted and the image is virtual, meaning that light only *appears* to radiate from it when it is observed from medium 2. At the start of the discussion, we assumed that $n_2 > n_1$, but the result does not depend on this (see Problem 29), although a geometrical drawing does.

We can also repeat this exercise with a concave spherical surface between the two media (see Problem 30). In this case, the center of the spherical surface is on the side of the light source, and the important result is that *Eq. (36–10) continues to hold, but with a*



▶ **FIGURE 36–19** Ray tracing with principal rays for image formation for a concave spherical refracting surface: situations in which (a) $s > f$; (b) $R > s$; (c) $f > s > R$.

negative value of R. Summarizing, when the image is on the side to which light goes, i is positive and the image is real, while R is positive when it is on that side. When the image is on the side from which light radiates, i is negative and the image is virtual, while R is negative when it is on that side. Table 36–1 contains a summary of the various signs.

The Sign of the Object Distance

In order to be able to apply the results of this section to material with two surfaces—lenses—it will be necessary to understand one more aspect of signs. We have established that a negative image distance and radius of curvature have meaning. Is it possible for s

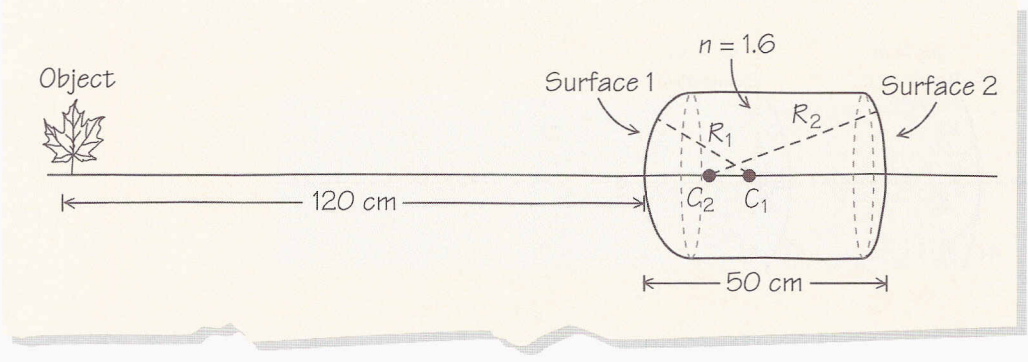
to take on a negative value? A positive s corresponds to a real object on the side from which the light radiates. For positive s, the light rays diverge from the object as they approach the boundary surface. Negative values of s correspond to the rays that *converge* as they approach the boundary, so their extrapolation would be on the side of the boundary to which the light passes. This cannot occur for a real object. But it is possible if the image produced by one surface—boundary 1, say—acts as the source object for a second surface: boundary 2 (Fig. 36–20a). We can break up the problem and find first the image point I_1 produced by boundary 1 (Fig. 36–20b). In actuality, the light never forms the image point I_1 because boundary 2 intervenes. However, the image I_1 becomes the virtual object S_2 for the light refracted at boundary 2 (Fig. 36–20c). According to our convention, the source distance s_2 is negative because the rays converge toward boundary 2. The light comes from the left side of boundary 2, but the virtual object is on the right side. Equation (36–10) holds for the refraction at boundary 2, with a negative object distance s_2. The actual paths of the light rays through both boundaries are shown in Fig. 36–20d.

▲ **FIGURE 36–20** (a) Image construction when two refracting surfaces are involved. To simplify, (b) we can split the problem up by first finding the image point I_1 from boundary 1. (c) The resulting image serves as a virtual object; we use virtual source point S_2 for the interaction with boundary 2 to find the final image, at image point I. (d) The actual ray path.

EXAMPLE 36–7 Consider a cylinder of glass 50 cm long, with $n = 1.6$, in air (Fig. 36–21). Surface 1 has a radius of curvature $R_1 = 0.20$ m; surface 2 has a radius of curvature $R_2 = 0.40$ m. Both surfaces "bulge out." A small object (a leaf) is placed perpendicular to the optical axis at a distance of 120 cm from surface 1. (a) Find the location of the object's image due to refraction at surface 1. (b) Let this image be the source object for surface 2, and find the location of *its* image as light passes through surface 2.

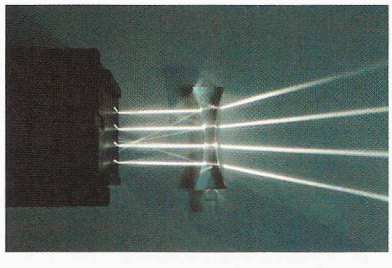
Strategy Equation (36–10) applied successively to the two surfaces leads to the location of the final images. We first find the image formed by surface 1, and this image then becomes the object for surface 2.

Working It Out (a) We calculate the distance i_1 of the image point I_1 from surface 1. We have $n_2 = 1.6$ and $n_1 = 1.0$ (air). The center of curvature is on the side to which light passes, so R_1 is positive. Finally, $s = +1.20$ m. We then have



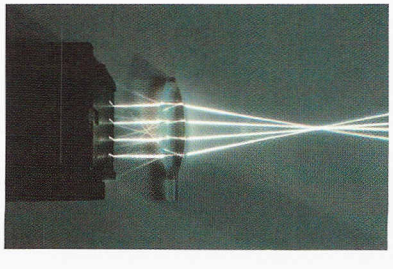
$$\frac{n_1}{s} + \frac{n_2}{i} = \frac{n_2 - n_1}{R}, \quad \text{or} \quad \frac{1.0}{1.20\text{ m}} + \frac{1.6}{i_1} = \frac{1.6 - 1.0}{0.20\text{ m}};$$
$$i_1 = +0.74\text{ m}.$$

The image is real and located (not shown) 74 cm to the right of surface 1.



(b) Because the surfaces are separated by 50 cm, this new object S_2 (which is the image I_1 for surface 1) is 24 cm to the right of surface 2. The object is on the side to which light passes, so its distance from surface 2 is negative: $s_2 = -0.24$ m. For this second step, $n_1 = 1.6$, $n_2 = 1.0$, and $R_2 = -0.4$ m (surface 2 is concave, so its center of curvature is on the side from which light comes). Thus Eq. (36–10) now gives

$$\frac{1.6}{-0.24\text{ m}} + \frac{1}{i_2} = \frac{1.0 - 1.6}{-0.4\text{ m}};$$
$$i_2 = +0.12\text{ m}.$$



This is positive, so the second image is real, or to the right of surface 2.

(a)

(b)

▲ FIGURE 36–22 (a) Light passing through a diverging lens and (b) light through a converging lens.

36–4 Thin Lenses

A real lens can consist of a complicated combination of individual elements. We can consider a basic element of a more complicated lens to be a single element made of a transparent material of refractive index n embedded in a material of refractive index n_1, normally air, for which $n_1 = 1$ (Fig. 36–22). It is this simpler element that we refer to as a **lens** in this discussion. We shall assume that $n > 1$ and $n_1 = 1$. We shall also assume that our lens is thin, so that the distance from the object and the image to each surface of the lens is the same. This simplifies the treatment considerably. The two surface boundaries (1 and 2 in Fig. 36–23) are concave or convex spherical segments (or planar surfaces) with respective radii of curvature R_1 and R_2. Whether these radii are positive or negative depends on whether the center of curvature is on the side to which light passes (positive R) or the side from which light radiates (negative R). For example, with light coming in from the left in Fig. 36–23a, R_1 is positive and R_2 is negative.

Let's suppose that a real object is a distance s_1 to the left of a thin lens. We can locate the final image and identify its features by using Eq. (36–10) twice in succession for image-making at a single surface, much as we did in Example 36–7. The image produced by the first surface serves as the object for the second surface. We do not have to worry about whether the various objects and images are real or virtual, upright or inverted, because the equation will automatically handle these questions. At surface 1, we have

$$\frac{1}{s_1} + \frac{n}{i_1} = \frac{n - 1}{R_1}, \tag{36–11a}$$

which we rewrite as

$$\frac{1}{i_1} = \frac{n-1}{nR_1} - \frac{1}{ns_1}. \tag{36–11b}$$

Now, the image point I_1 produced by surface 1 serves as an object point S_2 for surface 2, producing a final image point at I_2. What is the sign of i_1? If i_1 is positive, the image is on the right of surface 1 and hence on the right of surface 2. This corresponds to an object distance s_2 for surface 2 that is negative. Similarly, if i_1 is negative, the image is to the left of both surfaces, corresponding to a positive object distance s_2 for surface 2. We must then reverse the sign of i_1 when we use it as the source distance s_2 for surface 2. Finally, note that in applying Eq. (36–10) a second time, $n_1 = n$ and $n_2 = 1$. Thus

$$\frac{n}{s_2} + \frac{1}{i_2} = \frac{1-n}{R_2};$$
$$-\frac{n}{i_1} + \frac{1}{i_2} = \frac{1-n}{R_2}.$$

When we substitute Eq. (36–11b), we find that

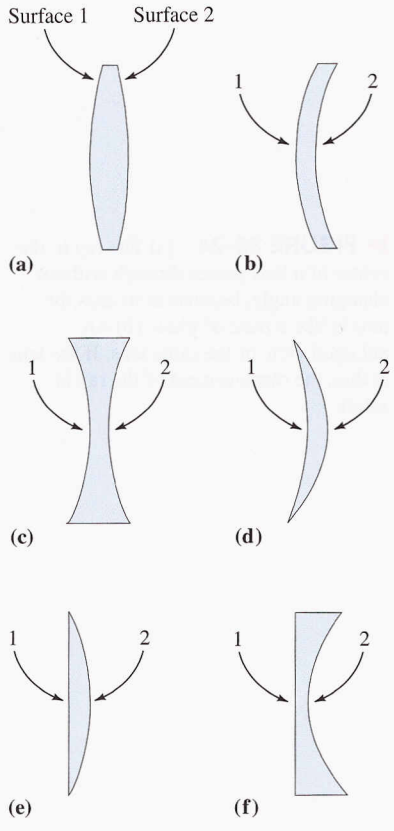
$$-n\left(\frac{n-1}{nR_1} - \frac{1}{ns_1}\right) + \frac{1}{i_2} = \frac{1-n}{R_2}.$$

If we now write $s_1 = s$ for the original object and $i_2 = i$ for the final image, we find (upon rearrangement)

$$\text{for a thin lens in air: } \frac{1}{s} + \frac{1}{i} = (n-1)\left(\frac{1}{R_1} - \frac{1}{R_2}\right). \tag{36–12}$$

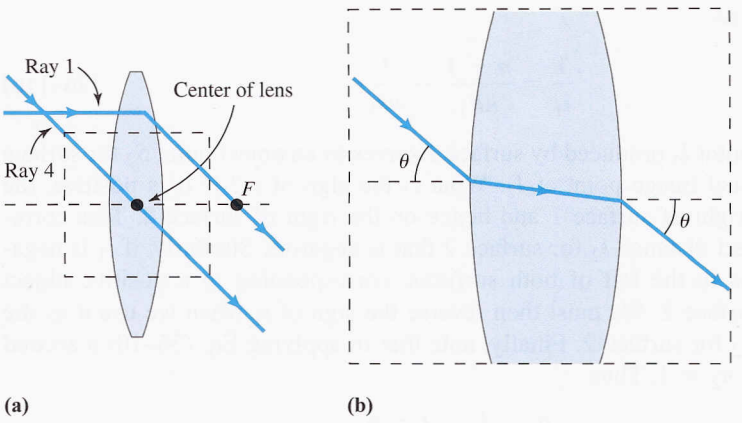
LENS-MAKER'S EQUATION

Equation (36–12), which applies *only* to thin lenses in air, is the *lens-maker's equation*. By Eq. (36–12), the image can be positive or negative; that is, real or virtual. The signs are summarized in Table 36–1, and ray tracing will alternatively allow you to understand the image—large or small, upright or inverted, real or virtual.



Equation (36–12) can be used to find the focal point of a lens. By definition, the image is at the focal point when $s \to \infty$. Therefore in this limit

$$\frac{1}{f} = (n-1)\left(\frac{1}{R_1} - \frac{1}{R_2}\right). \tag{36–13}$$



If we substitute this result into Eq. (36–12), we get Eq. (36–2), which we originally derived for mirrors—Eq. (36–2) is a general one that holds for most of the optical systems we study. The sign of f is determined by the signs of the radii of curvature, but we can say that f is positive if the image of a point source at infinity is on the side to which light passes (real image); f is negative if the image of the source at infinity is on the side from which light radiates (virtual image).

We now turn to some of the rays that help us understand the image. Ray 1, which comes in parallel to the optical axis of the lens, crosses (or behaves as though it crosses) the axis at f. This ray is drawn in Fig. 36–24a. Note that there is a symmetry in Eq. (36–12). When light arrives from the right of the lens rather than the left, R_1 and R_2 reverse their signs, and light from infinity coming from the right is focused the same distance from the lens as the first focal point, but on the opposite side. In turn, if light radiates (or behaves as though it does) from one of the two symmetric focal points of the lens (ray 2), the light emerges as a set of parallel rays.

Ray 4, which is drawn in Fig. 36–24a to the center of the lens and behaves as though it passes straight through, is a last useful ray. (Remember, principal ray 3 is not applicable to lenses.) This ray is shown in more detail at the enlarged section (Fig. 36–24b).

▲ **FIGURE 36–23** Six types of simple thin lenses with surfaces of different radii of curvature: (a) $R_1 > 0$, $R_2 < 0$; (b) $R_1 > 0$, $R_2 > 0$; (c) $R_1 < 0$, $R_2 > 0$; (d) $R_1 < 0$, $R_2 < 0$; (e) $R_1 = \infty$, $R_2 < 0$; (f) $R_1 = \infty$, $R_2 > 0$.

▶ **FIGURE 36–24** (a) The ray to the center of a lens passes through without changing angle, because at its axis the lens is like a pane of glass. (b) An enlarged view of the same lens. If the lens is thin, the displacement of the ray is small.

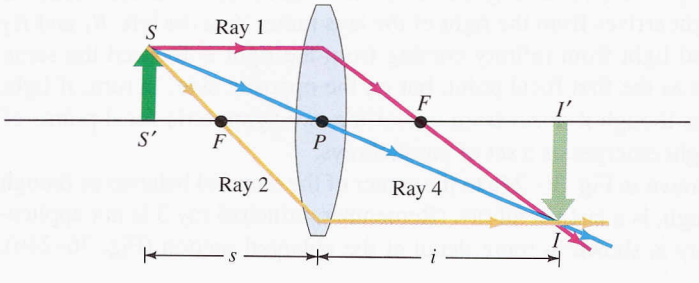
Since the two lens surfaces are in the middle of the lens, the ray behaves to a good approximation like a ray that passes through a thin pane of glass. There is a *small* displacement of the ray, but it drops to zero as the lens becomes thinner.

These three principal rays can be used to find an image. For example, Fig. 36–25 shows a lens that collects light from an object, and with the principal rays, we can easily find the image point I of object point S. The construction works for any point on the object. The image is real and inverted in this case. In general, if a lens causes rays that pass through it to come together, it is called a *converging lens*, and if it causes rays that pass through it to spread out, it is a *diverging lens*. Converging lenses have positive focal lengths, whereas diverging lenses have negative focal lengths. Some simple ray tracing will show that a lens like that of Fig. 36–23a is a converging lens, and one like that of Fig. 36–23c is a diverging lens.

Magnification

A thin lens produces a perfect image, to the extent that the small-angle approximation is valid. Thus we can find the magnification by direct use of similar triangles. In Fig. 36–25, the magnification of the image has magnitude

$$M = \frac{II'}{SS'}.$$



From the geometry of the similar triangles $SS'P$ and $II'P$, we see that the magnitude of the magnification is $|M| = |i|/|s|$. Just as for mirrors, a systematic look at signs shows that we can decide with a single sign whether the image is upright or inverted:

$$M = -\frac{i}{s}.$$

This is Eq. (36–6)—the same form we found for mirrors. If M is positive, the image is upright; if it is negative, the image is inverted. From Eq. (36–2), we have the alternate form

$$M = \frac{f}{f - s},$$

which is Eq. (36–7), also applicable to mirrors.

▶ **FIGURE 36–25** Ray tracing shows how a real image is formed with one type of thin lens. Point P marks the center of the lens.

EXAMPLE 36–8 A converging lens like that shown in Fig. 36–23a has surfaces with radii of curvature $R_1 = 80$ cm and $R_2 = 36$ cm. An emerald that is 2.0 cm tall is placed 15 cm to the left of the lens, for which $n = 1.63$. Where will the image be located, and what will its size be?

Setting It Up We have sketched Fig. 36–26 to include three rays. Such a diagram is useful if one wants to use ray tracing to verify results.

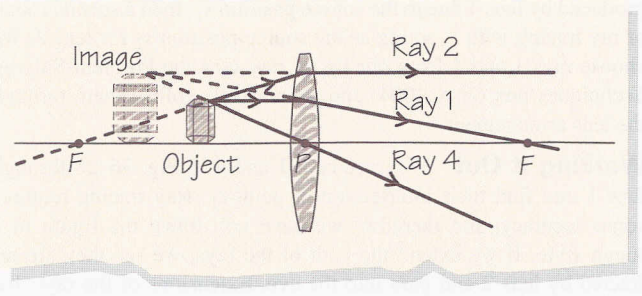
Strategy We first calculate the focal length from Eq. (36–13). Then we use Eq. (36–2) to determine the image distance i. At that point we will have both s and i and can find M.

Working It Out The radius of curvature of the first surface is positive, $R_1 = 80$ cm, whereas the second surface has negative curvature, $R_2 = -36$ cm. Thus Eq. (36–13) gives

$$\frac{1}{f} = (n-1)\left(\frac{1}{R_1} - \frac{1}{R_2}\right)$$
$$= (1.63-1)\left(\frac{1}{80\text{ cm}} - \frac{1}{-36\text{ cm}}\right) = 0.025\text{ cm}^{-1}.$$

The object distance is positive, $s = 15$ cm, so Eq. (36–2) gives

$$\frac{1}{i} = \frac{1}{f} - \frac{1}{s} = 0.025\text{ cm}^{-1} - \frac{1}{15\text{ cm}} = -0.041\text{ cm}^{-1}.$$

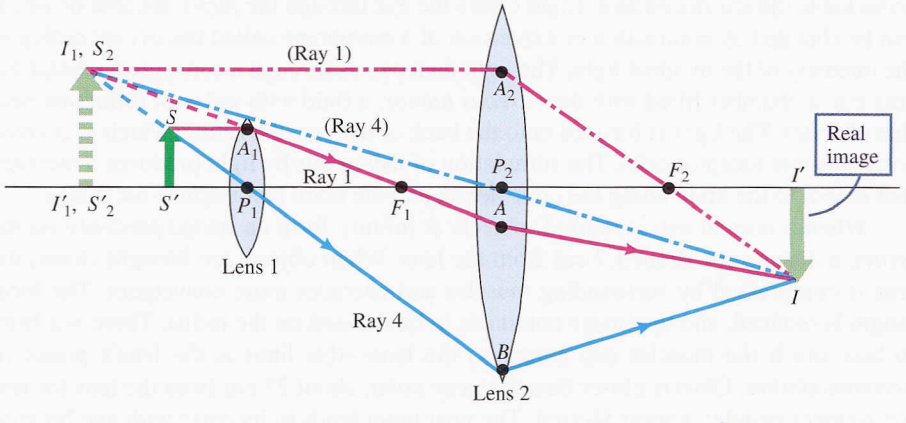


Thus $i = -24$ cm. The minus sign indicates that the image is virtual and on the same side as the light source. The magnification is given by

$$M = -\frac{i}{s} = -\frac{-24\text{ cm}}{15\text{ cm}} = 1.6.$$

The positive value indicates that the image is upright.

The rays in Fig. 36–26 confirm the qualitative aspects of our results.

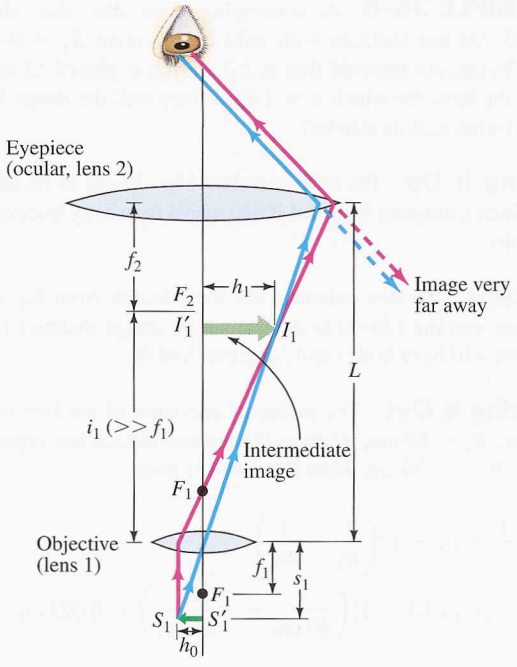


What Do You Think? Suppose the lens were replaced by one with a smaller value of n. How would the magnification change?

▲ **FIGURE 36–26** The horizontal and vertical scales are different here. When the object lies inside the focal point of the lens, ray tracing shows that the image formed is virtual.

We saw in Section 36–3 how the image produced by refraction at one surface acts as an object for the second surface. This principle extends to combinations of two or more lenses and lies at the heart of the design of more complicated lenses or optical instruments. Figure 36–27 gives an image construction for two thin converging lenses. The object SS' lies inside the focal length of lens 1 and thus gives rise to a virtual, enlarged image I_1I_1'. That image serves as an object S_2S_2' for lens 2. Ray tracing uses the parallel ray $I_1A_2F_2I$ and I_1P_2I to determine the position of the real image, but the particular rays chosen really follow paths like SA_1F_1AI and SP_1BI. This example shows that it is possible to obtain a magnified *real* image with two converging lenses in conditions where it is not possible with one lens.

In Example 36–9, the object for the second lens is a negative distance from the lens.



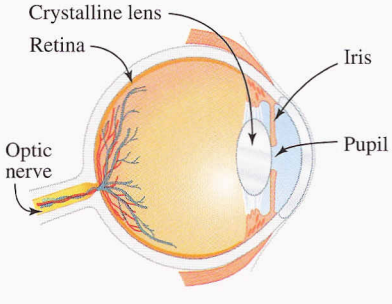
▲ **FIGURE 36–27** Ray tracing shows how two converging lenses produce a real magnified image.

EXAMPLE 36–9 Consider the two-lens arrangement shown in Fig. 36–28, with the source just outside the focal point of lens 1. The focal length of each lens is known. You place your eye at the position shown and look for the image. Use ray-tracing techniques to describe qualitatively that image.

Setting It Up If these were not already included in the figure, the starting point would be to draw in the focal points F_1 and F_2, the source distance s_1, and the lens separation distance L. The figure should be to scale. Note that with the eye placed as shown, the "image" in question is the one that is produced by lens 2 using the image produced by lens 1 as a source.

Strategy We must use ray tracing to find the image position i_1 produced by lens 1 due to the source position s_1, then a second round of ray tracing with i_1 acting as the source position s_2 for lens 2. We choose rays 1 and 4 from our list of rays (see the Problem-Solving Techniques box on p. 1004) and successively follow them through the lens arrangement.

Working It Out We trace rays 1 and 4 in Fig. 36–28 through lens 1 and find their intersection at point i_1. Ray tracing requires some accuracy, and therefore we have not drawn the figure in a rough style. If we extend the path of the rays, we see they are refracted by lens 2 and pass into the eye. Extensions of the rays that enter the eye give an image i_2 that is behind the lens and very far away. That is because we have placed the relative position of the two lenses so that the image I_1 formed by lens 1 is very close to the focal point F_2 of lens 2, so that the image I_2 formed by lens 2 is very distant. The image in this case will be very large. (Note that to keep the exercise simple, we have not actually traced the principle rays for lens 2 formed by I_1.)



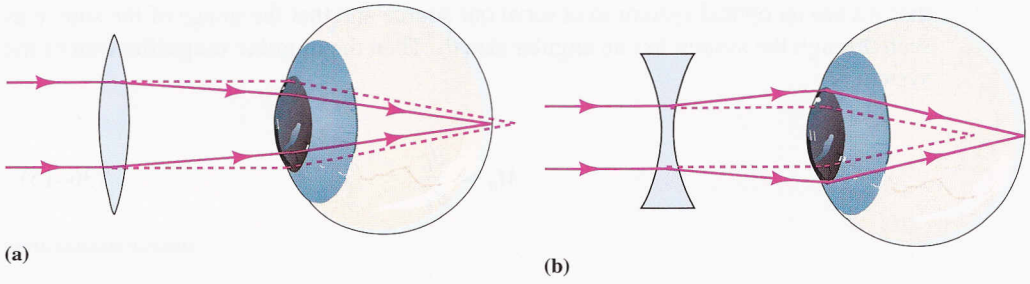
▲ **FIGURE 36–28** Ray tracing for the arrangement of the example.

This arrangement describes a **compound microscope**. The lens near the original source is called the *objective* lens, and the lens near the eye is called the *ocular* or *eyepiece*.

What Do You Think? Should lens 2 be moved up or down to obtain a taller final image?

36–5 Optical Instruments

The example of the compound microscope above shows how an arrangement of thin lenses can work together to produce some desired optical goal. As we implied, real camera lenses are in fact combinations, often rather complicated ones, of thin (or thick) simple lenses. There are many other examples of combinations that fulfill precise needs, and we look at some in this section. We start with the instrument that takes the light reflecting off the ink on this page and transforms it into a form that your brain can use to reconstruct the image.



▲ **FIGURE 36–29** Schematic diagram of the human eye and some of its important features.

The Eye

The typical vertebrate eye—the basic structure of which is shown in Fig. 36–29—is a remarkable optical instrument. Light enters the eye through the *pupil*, the size of which can be changed by contraction or expansion of a membrane called the *iris* according to the intensity of the incident light. The light then passes through a convergent *crystalline lens* into a chamber filled with the *vitreous humor*, a fluid with index of refraction near that of water. The light is focused onto the back of the eye, the *retina*, which is covered with sensitive receptor cells. The stimulation of these cells by light produces a message that is sent to the brain along the *optic nerve*, and the brain reconstructs the image.

When a normal eye is relaxed, objects at infinity form an image precisely on the retina, a distance of about 1.7 cm from the lens. When objects are brought closer, the lens is compressed by surrounding muscles and becomes more convergent. The focal length is reduced, and the image continues to be focused on the retina. There is a limit to how much the muscles can compress the lens—this limit is the lens's power of *accommodation*. Objects closer than the *near point*, about 25 cm from the lens (or less for younger people), appear blurred. The near point tends to increase with age because the lens becomes unable to compress as far as it once did, and the image of a near object

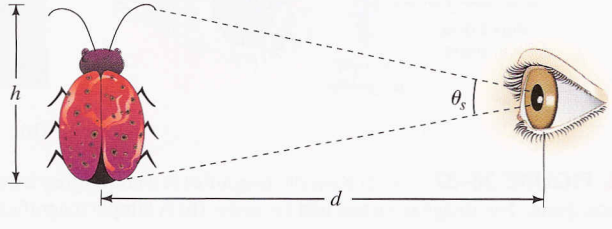
▲ **FIGURE 36–30** The dashed lines indicate the paths rays would take if no correcting lens were present. The solid lines mark the path of rays when a correcting lens is included. (a) A converging lens causes rays from an object, in this case at infinity, to focus closer to the lens of the eye. Such a lens corrects farsightedness by allowing the near point to be moved closer to the eye. (b) A diverging lens causes rays from an object, in this case at infinity, to focus farther from the lens of the eye. Such a lens corrects nearsightedness.

is beyond the location of the retina. Converging lenses correct this problem (Fig. 36–30a). In cases of nearsightedness, the image of an object at infinity is in front of the retina. A diverging lens will provide the necessary correction (Fig. 36–30b).

The Camera

With one important difference, the camera is optically equivalent to an eye. There is a converging lens in front, and the *film* (or receiving surface in a digital camera), which plays the role of the retina, is in back. There is an *aperture*, an opening equivalent to the pupil, and a *shutter*, which provides an approximation to an instantaneous image to avoid blurring of the picture due to motion. The difference between the simple camera and the eye is that the focal length of the lens changes in the eye, whereas the focal length is fixed in a simple camera. Instead, the camera lens moves in and out (changing the image distance) to enable objects of different source distances to produce a focused image on the film.

Angular Magnification



For optical instruments used for observing the world closely, *angular magnification* is a critical concept, and we shall discuss it before we cover some other instruments.

From Eq. (36–7), we see that the magnification of a lens or mirror is infinite when $s = f$. This is less important than it might appear to be because the image distance i also becomes infinite in that case. More important than the actual size of the image is the angle the image takes up in our field of vision. Given the limits of our own vision, *it is this angular coverage that determines how much detail we can see in an observed source.*

Imagine that you are a distance d from some object of height h (Fig. 36–31). For a source that does not cover an enormous part of your vision, the angular size θ_s of the source is

$$\theta_s \cong \frac{h}{d}. \tag{36–14}$$

For normal, unaided vision, this angular size can be maximized when the object is brought to the near point of vision, around $d = d_{\text{min}} = 25\text{ cm}$, and it is $\theta_s \cong h/(25\text{ cm})$ that is used as a reference for the angular magnification. Suppose now

◀ **FIGURE 36–31** The angular size of an object, θ_s, is the relevant quantity for our ability to see detail in the object.

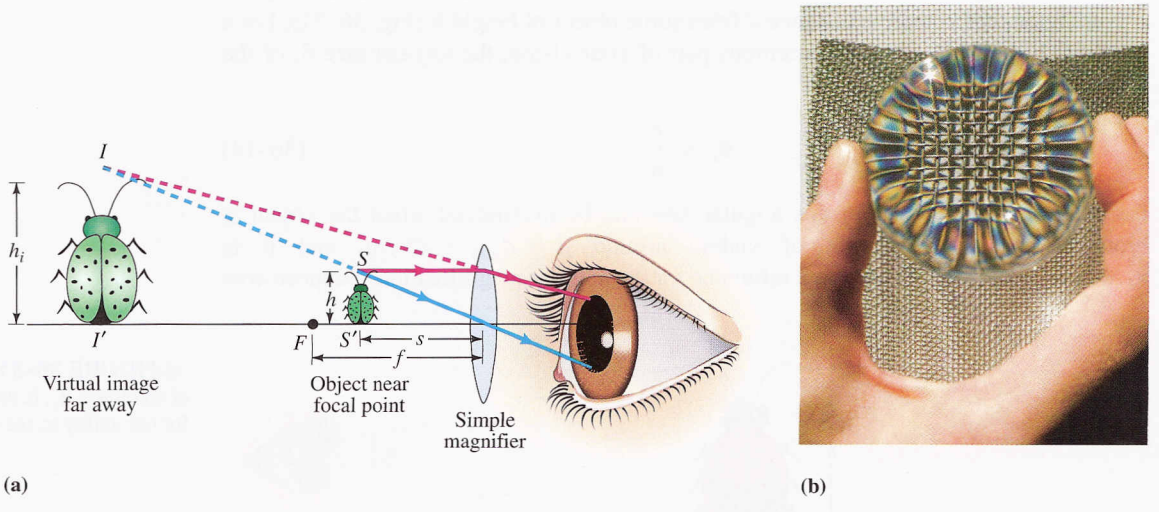
that we use an optical system to observe our source and that the image of the source as seen through the system has an angular size θ_i. Then the **angular magnification** of the system is

$$M_\theta \equiv \frac{\theta_i}{\theta_s}. \tag{36–15}$$

ANGULAR MAGNIFICATION

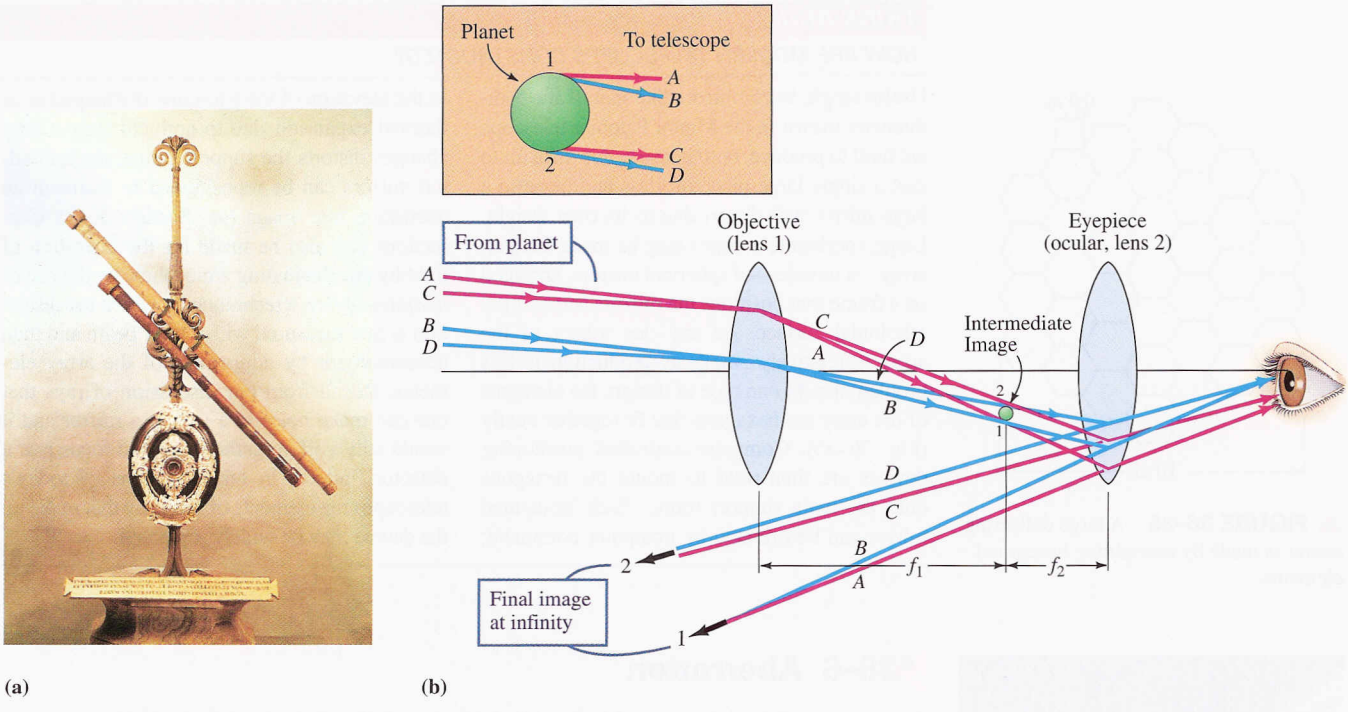
We do not bother with signs here and keep track only of the magnitudes of the angular sizes. If we know the angular magnification of two elements that are superposed in an optical system, then the net angular magnification is the product of the angular magnifications of each element.

The Simple Magnifier



A converging lens has a positive focal length. By Eq. (36–2), $\frac{1}{i} = \frac{1}{f} - \frac{1}{s}$. For a real object, i passes from positive (real image) to negative (virtual image) as the object moves toward the lens through the point $s = f$. At this point, i shifts to $-\infty$. A *simple magnifier* is a converging lens with the object placed near $s = f$ (Fig. 36–32). If the object size is h, the image size is, by definition, $h_i = Mh$, where $M = i/s$ is the magnitude of the magnification. The image size is infinite if i is infinite, but the *angular size of the image is finite*. When $s = f$, we have for the angular size

$$\theta_i = \frac{h_i}{i} = \frac{Mh}{i} = \frac{h}{s}\bigg|_{s=f} = \frac{h}{f}. \tag{36–16}$$



Note that we have no trouble seeing an image at infinity. At the near point, $d_{\text{min}} = 25$ cm, the angular size of our object is $\theta_{\text{object}} = h/d_{\text{min}}$. Thus the angular magnification of the magnifier is

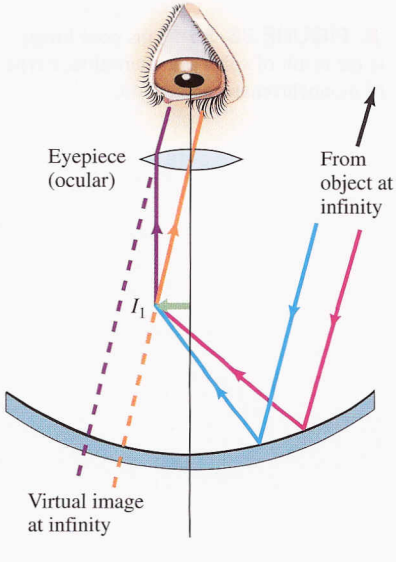
$$M_\theta = \frac{\theta_i}{\theta_{\text{object}}} = \frac{h/f}{h/d_{\text{min}}} = \frac{d_{\text{min}}}{f}. \tag{36–17}$$

If we choose a converging lens with a focal length of 2 cm, we get an angular magnification of $(25\text{ cm})/(2\text{ cm}) = 12.5$.

▲ **FIGURE 36–32** (a) The simple magnifier is a converging lens with an object placed near the focal point. The image is virtual and far away. (b) A simple magnifier in use.

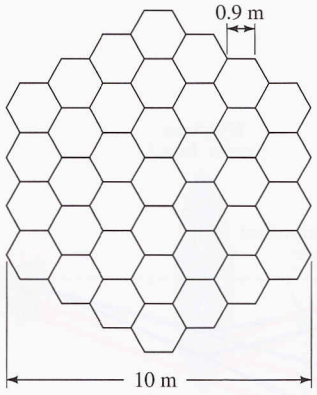
▲ **FIGURE 36–33** (a) Galileo's refracting telescope, used for viewing distant objects. (b) Schematic diagram of a refracting telescope.

The Telescope



The **telescope** magnifies very distant objects. It was invented in Holland at the beginning of the seventeenth century and made an impact on astronomy soon thereafter. Galileo built his own telescope in 1609 (Fig. 36–33a).

The *refracting telescope* (a telescope with only refracting elements) is a system designed around the fact that the original object is very distant—in effect at infinity (Fig. 36–33b). The first lens, the *objective*, creates an intermediate image very close to the focal point of that lens. If that point coincides with the focal point of the eyepiece, then the eyepiece acts as a simple magnifier. The final image is magnified. Let's calculate the angular magnification for an object that has angular size θ_s. (The Moon, for example, has angular size of $1/2°$. With the naked eye, we can distinguish stars separated by about $1'$ of arc [$1/60$ of $1°$].) If the original object has size h_0, the objective produces an image of size $h_1 = Mh_0 = ih_0/s = i\theta_s = f_1\theta_s$. The final image then has an angular size given by Eq. (36–16) with $h \to h_1$ and $f \to f_2$, namely, $\theta_i = h_1/f_2 = \theta_s f_1/f_2$. In turn, the angular magnification is

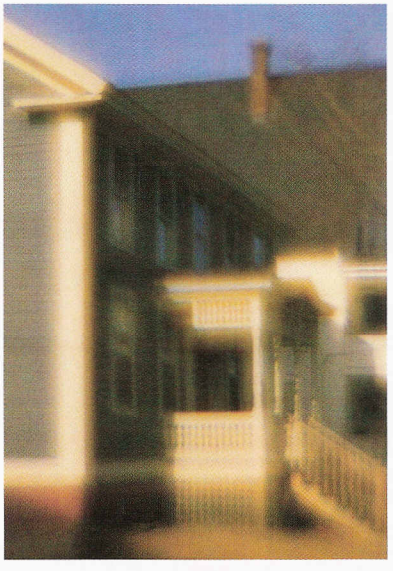


$$M_\theta = \frac{\theta_i}{\theta_s} = \frac{f_1}{f_2}.$$

This quantity will be large for large f_1: The objective lens of a telescope should have as long a focal length f_1 as is practical, and that is why a refracting telescope is long.

The study of distant galaxies depends on an examination of the spectrum of the light they emit and of their energy output. The incident light from very distant objects is rather low in intensity, and more light is needed at the eyepiece in order to study spectra. To be most efficient at collecting light, the diameter of the optical system must be large. Large lenses are more difficult to construct than large mirrors, so most large telescopes are *reflecting telescopes* rather than refracting telescopes. In a reflecting telescope, a mirror replaces the objective for the purpose of creating an intermediate image, which is then magnified by the eyepiece (Fig. 36–34). Another advantage of such a telescope is that it has no chromatic aberration (see Section 36–6).

▲ **FIGURE 36–34** Schematic diagram of a reflecting telescope.

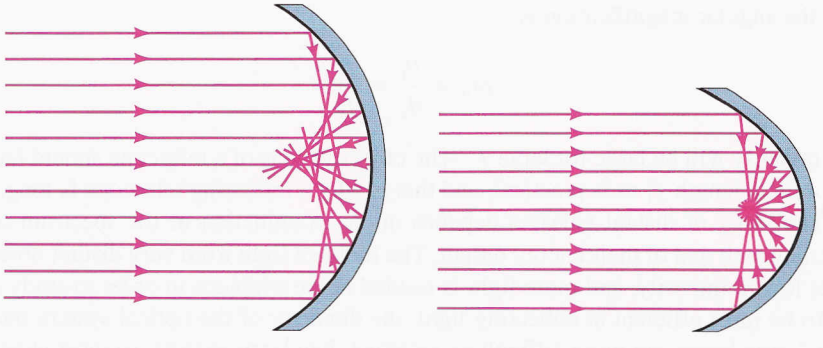


▲ **FIGURE 36–35** A large collecting mirror is made by assembling hexagonal elements.

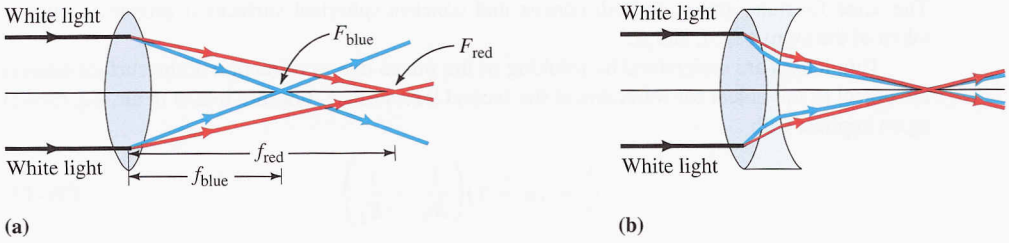
THINK ABOUT THIS. . .

HOW ARE MODERN TELESCOPES CONSTRUCTED?

Useful single large mirrors like that of the 5-m-diameter mirror in the Mount Palomar telescope are hard to produce, both because it is difficult to cast a single large piece of glass and because a large mirror will distort due to its own weight. Large, modern telescopes may be made from an array—a mosaic—of spherical mirrors, arranged on a frame that positions the mirrors across a paraboloidal surface. As any one mirror of the array is relatively small, its production is less problematic. In one type of design, the elements of the array are hexagons that fit together neatly (Fig. 36–35). Computer-controlled positioning devices are then used to mount the hexagons onto the main support frame. Each hexagonal mirror can be oriented by computer command; as the elevation of the telescope is changed or as thermal expansion due to ambient temperature changes distorts the support frame, the individual mirrors can be repositioned to maintain an aberration-free image (see Section 36–6). Corrections can also be made for the distortion of light by our fluctuating atmosphere by the use of *adaptive optics*, a technique by which the distortion is first measured with a laser beam and then accounted for by adjustment of the array elements. Recall from our discussion of rays that one can make holes in a lens or a mirror and it would still work to gather light and focus it at a detector. Indeed, in other versions of today's telescopes the elements of the array that make up the device may be widely separated.



▲ **FIGURE 36–36** This poor image is the result of spherical aberration, a type of monochromatic aberration.



*36–6 Aberration

An accurate calculation would show that all rays that arrive at a spherical mirror or refracting surface from infinity cross in a small but finite region rather than at a single point. This is but one example of **aberration** (Fig. 36–36). Aberration should be distinguished from *distortion*, in which an image is not identical in form to the object, as in a fun-house mirror. For scientific purposes, the fun-house image is not necessarily a bad one, because every ray from the object is correctly positioned at a precise location in the image. Aberration concerns what we might call the quality of an image, not its geometric form.

We can distinguish two important types of aberrations in geometric optics. *Monochromatic aberrations* describe the fact that, in real optical systems, the rays from a given point on an object are not focused on a single image point (Fig. 36–37a). The correction for this type of aberration depends on the application. An optical system that collects images only from distant objects will have no aberration when a parabolic surface is used (Fig. 36–37b). Although such surfaces are difficult to construct from glass, a pool of mercury spinning about a vertical axis forms a parabolic surface, and such surfaces are employed in some modern telescopes. These telescopes only point up! Mosaic telescopes can also avoid monochromatic aberration. Alternatively, this type of aberration is minimized when the spherical section of the lens surface or mirror is small, although then the system collects less light.

▲ **FIGURE 36–37** (a) In monochromatic aberrations, all the rays from infinity do not pass through the same point for a spherical mirror, so the focus is not sharp. (b) This type of aberration is eliminated by use of a parabolic mirror.

▲ **FIGURE 36–38** (a) In chromatic aberrations, the focal point of a converging lens may be different for different wavelengths. Here we show rays only for red light and blue light. (b) This type of aberration is eliminated by combining the lens with another lens with a different dispersion.

Chromatic aberrations appear in refracting systems but not in mirrors. We treated dispersion in Chapter 35, in which the index of refraction of a material depends on the wavelength of the light. The optical path of a ray at one wavelength will differ from that of a ray at another wavelength (Fig. 36–38a). If a given point on an object is the source of a mixture of wavelengths (as is true of white light), then the image of this point is spread out according to the wavelength. A simple correction for chromatic aberration is to use filters that allow only a narrow band of wavelengths to pass. More commonly, several lenses are superposed (Fig. 36–38b). Different elements are designed to have canceling dispersion to minimize the net dispersion.

A good camera lens may consist of a dozen elements of different types of glass, with complicated geometric relations, which, in the case of zoom lenses, are also variable. Unfortunately, even with all the corrections such lenses provide, the wave nature of light provides a fundamental and unavoidable limitation on the ability of optical systems to produce sharp images (see Chapters 37 and 38).

Summary

Geometric optics is based on two basic laws of the behavior of light rays: In reflection, the angle of incidence on a reflecting surface is equal to the angle of reflection. In refraction, Snell's law, $n_1 \sin\theta_1 = n_2 \sin\theta_2$, holds, where θ_1 and θ_2 are the angles of incidence and refraction, respectively, for a ray incident from medium 1 on medium 2. Ray tracing is a technique that allows us to locate the image of a given source.

A spherical reflecting or refracting surface forms an image of an object that is a distance s from the surface. Bundles of light rays pass through an image point (for a real image) or are directed as though they all come from such a point (for a virtual image). The image point is a distance i from the surface. One limit of such a surface is the plane mirror, for which the distance of the virtual image from the mirror is given by $i = -s$.

Parallel rays falling on a spherical reflecting or refracting surface approximately converge to the focal point, a distance f from the element. For a mirror, $f = R/2$ [Eq. (36–1)], where R is the radius of curvature of the spherical section. The distance of the object and the distance of the image from the surface, and the focal length for a spherical mirror are related by

$$\frac{1}{s} + \frac{1}{i} = \frac{1}{f}. \qquad (36\text{–}2)$$

Equation (36–2) applies to both convex and concave mirrors if proper account is taken of the signs of s, i, and R. The image size is magnified by a factor M, the magnification, times the object size, where

$$M = -\frac{i}{s} = \frac{f}{f - s}. \qquad (36\text{–}6,\ 36\text{–}7)$$

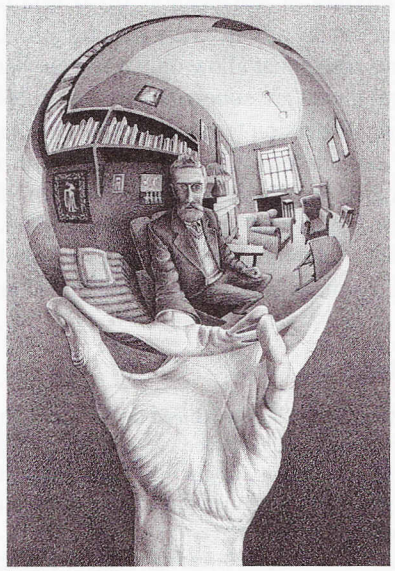
For a positive M, the image is upright; for a negative M, the image is inverted.

For a spherical boundary between a medium of refractive index n_1 and a medium of refractive index n_2, with light incident from medium 1, Eq. (36–2) is replaced by

$$\frac{n_1}{s} + \frac{n_2}{i} = \frac{n_2 - n_1}{R}. \qquad (36\text{–}10)$$

The same formula applies to both convex and concave spherical surfaces if proper account is taken of the signs of s, i, and R.

Thin lenses are understood by thinking of the image due to refraction at the surface nearest the object as the object for refraction at the second lens surface. For thin lenses in air, Eq. (36–2) again applies, with



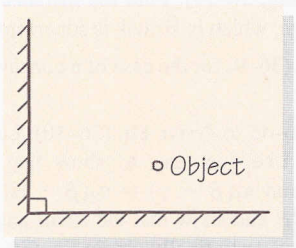
$$\frac{1}{f} = (n - 1)\left(\frac{1}{R_1} - \frac{1}{R_2}\right). \tag{36–13}$$

Moreover, Eqs. (36–6) and (36–7) apply also to thin lenses.

Thin lenses can be used singly or in combination to make up optical instruments, including magnifiers, eyeglasses, cameras, microscopes, and telescopes. Angular magnification, which measures the ratio of the angular size of an object as seen through the instrument to the object's angular size as the naked eye sees it, is a fundamental consideration for those instruments whose explicit purpose is to magnify, as is the quality of the image they produce.

Understanding the Concepts

1. Why is "AMBULANCE" written on the front of an ambulance?
2. Consider a large room with walls covered with mirrors; at the center of the room is a candelabra with burning candles. Is the room brighter than a comparable room with black drapes in place of the mirrors?
3. The image of a distant candle is projected by a converging lens on a screen placed at the focal length of the lens. A piece of paper is taped over the lower half of the lens. Will only half of the image be seen?
4. Draw a right-handed coordinate system and its image in a plane mirror. Is the image a right-handed or a left-handed coordinate system? (In a right-handed system, the vector product $\hat{i} \times \hat{j}$ points along $\hat{k}$.)
5. A physicist stands in front of a mirror. The floor is the xy-plane at $z = 0$; the mirror is the xz-plane. He has learned that reflections involve the change $(x, y, z) \rightarrow (-x, -y, -z)$. Will he be surprised when he looks in the mirror? What is the rule that gives him the correct description of what he sees?
6. Would a dental mirror, the small mirror a dentist uses to examine your teeth, be concave, convex, plane, or sometimes one or another?
7. The sideview mirrors of some cars are labeled "Objects seen in this mirror may be closer than they appear." Is the mirror plane, convex, or concave?
8. For each of the simple lenses shown in Fig. 36–23, Eq. (36–6)—for magnification—shows that the size of the image of a ball placed at the focal point is infinite. Can you see by ray tracing why this must be?
9. Figure 36–39 shows the reflection made by a spherical surface. Parts of all four walls of the room are visible in the image. Why?
10. To form a taller image in Example 36–5, the object in Fig. 36–15 should be moved (a) to the left, (b) to the right, (c) can't be done.
11. Does the focal length of a lens change when the lens is in water?
12. When a magnifying glass is lined up perpendicular to the line between it and the Sun, a hot spot forms on the side of the lens away from the Sun. What is the relation between the distance of this hot spot from the lens and the focal length of the glass? Why does the spot become hot?
13. A camera works by forming a real image on a film plate. Can a camera take a picture of a virtual image?
14. In William Golding's novel *The Lord of the Flies* (1954), some boys rediscover fire with the aid of the Sun shining through the eyeglasses of Piggy, a nearsighted boy. Has Golding made a mistake?



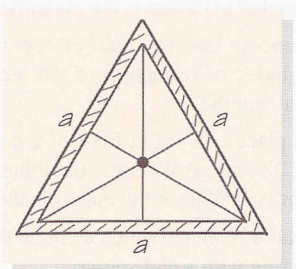
▲ **FIGURE 36–39** Question 9.

15. Are any principal rays useful for a point *on* the axis of an optical system?
16. You recently noticed that someone who used to wear thick glasses now wears glasses that are much thinner. Assuming that their eyesight has not improved, why might this be?
17. When you have an eye exam, even one as simple as reading an eye chart, the examiner may dilate (open) the pupil by putting drops in your eye. Why is that useful?
18. The n-dependence of the bending of light allows for the making of a flat eyeglass lens with material in which the index of refraction varies with position. Sketch the profile of the index of refraction for a converging lens constructed in this way.
19. Legend has it that Archimedes, acting as an advisor to the ruler of Syracuse, devised an optical system made of shields that could concentrate sunlight sufficiently well to set enemy boats on fire from a distance. How plausible is this legend?
20. Can the image ever be smaller than the object for a converging lens?

Problems

36–1 Images and Mirrors

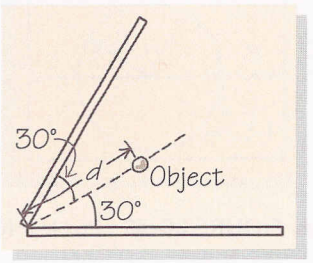
1. (I) Consider two mirrors at right angles to each other (Fig. 36–40). How many virtual images will a pointlike light source have?



▲ FIGURE 36–40 Problem 1.

2. (I) Consider two parallel mirrors that face each other, placed along the x-axis at $x = a$ and $x = -a$. Assume that a point source of light is placed at $x = x_0$ between the mirrors. What are the locations of the four images of the point source with the smallest values of image distance i?

3. (I) Two mirrors, each 2.0 m wide, are placed facing each other and parallel to each other and are separated by 10 cm. A ray of light enters the gap between them, grazes the edge of one mirror and strikes the other mirror at an angle of 30° with respect to the normal to the mirrors. At each reflection, the intensity of the light beam is attenuated by 5 percent. By how much is the beam attenuated when it finally leaves the space between the mirrors?



4. (II) A mirror is exactly half your height, and the top of the mirror is aligned with the top of your head. (a) If your eyes were at the top of your head, how close would you need to be to the mirror in order to be able to see your feet? (b) If your height is 158 cm and your eyes are 12 cm below the top of your head, what would have to be done with the mirror so that you could see both the top of your head and your feet?

5. (III) A kaleidoscope contains three plane mirrors forming a prism with an equilateral triangular base of side a (Fig. 36–41). Consider a small object placed on the axis of the kaleidoscope. Construct the position of the images formed by single as well as double reflection. How far are these images from the axis?

▲ FIGURE 36–41 Problem 5.

6. (III) Suppose that two plane mirrors meet at an angle of 60° (Fig. 36–42). An object is placed between the mirrors on the line that bisects this angle. Use graphical methods or trigonometric methods to locate all the images.

▲ FIGURE 36–42 Problem 6.

36–2 Spherical Mirrors

7. (I) A dime 60 cm away from and on the optical axis of a concave spherical mirror produces an image 20 cm away from the mirror. If the dime is moved on the axis to 35 cm from the mirror, where will the image move? How large is the radius of the sphere of which the mirror is a section? Draw the system for the second case described.

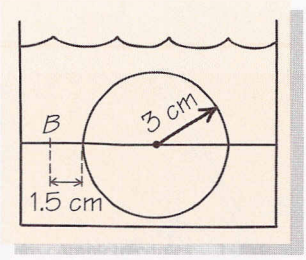
8. (I) A paper clip is placed on the axis 28 cm away from a convex mirror, part of a sphere of radius 44 cm. Where will the image be located, and what is the magnification? Make a sketch, including rays.

9. (I) An object of height 2.0 cm is placed 20 cm from a concave mirror. The real image is found to be 8.0 cm from the mirror. On which side of the mirror is the image and how tall is it? Is it inverted?

10. (I) A concave mirror has a radius of curvature of 176 cm. What is the size of the image of an object 6.00 cm tall that is placed 133 cm from the mirror?

11. (I) A concave mirror is cut from a spherical surface of radius of curvature 2.0 m. A pencil 10 cm long is placed perpendicular to the axis of the mirror at a distance of 80 cm from the mirror. Where is the image and how large is it?

12. (II) Consider an object in front of a convex mirror. A plane mirror is placed along the axis between the object and the convex mirror, and moved along till the images of the object in the two mirrors coincide. If the distance of the object to the plane mirror is x and the distance of the plane mirror to the convex mirror is y, what is the focal length of the convex mirror?



13. (II) A bird flies from far away toward a concave mirror, with constant speed v. What is the velocity of the image as a function of the distance of the bird from the mirror? When does the bird meet its image? [*Hint*: Use the relation between source distance and image distance and differentiate with respect to time.]

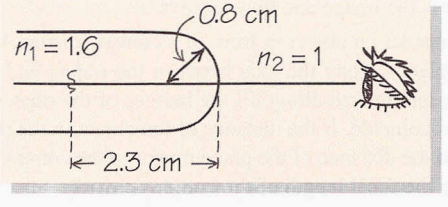
14. (II) By using the same reasoning that we used in the text for the case of the concave mirror, show that the reflection of ray 1 in Fig. 36–11 appears to originate at point F, independent of the angle θ. Your argument shows that, at point F, there is an image of a source point at infinity.

15. (II) Use ray tracing for parallel rays far from, as well as near to, the optical axis to show that parabolic mirrors more accurately focus parallel rays than do spherical mirrors.

36–3 Refraction at Spherical Surfaces

16. (I) A sphere of glass ($n = 1.50$) of radius 3.0 cm is immersed in water ($n = 1.33$). A small flower (at point B) is 1.5 cm outside the sphere (Fig. 36–43, see next page). What are the location and nature (real or virtual) of the flower's image made by refraction at the first surface?

▲ **FIGURE 36–43** Problem 16.



17. (I) An object is placed 15 cm in air from the convex surface (radius of curvature 10 cm) of a very thick piece of glass ($n = 1.5$). Where is the image?

18. (I) The single refracting surface of a piece of glass in air has a radius of curvature $R = 8.5$ cm. A ray parallel to the axis of the curved piece of glass is bent toward the axis inside the piece of glass and crosses that axis at a point 13 cm into the glass. What is the index of refraction of the glass?

19. (I) A fish is located at a distance of 40 cm from the glass pane of an aquarium. How far from the glass does the fish appear to be located to an observer looking from the outside? (Use $n_{\text{water}} = 1.33$.)

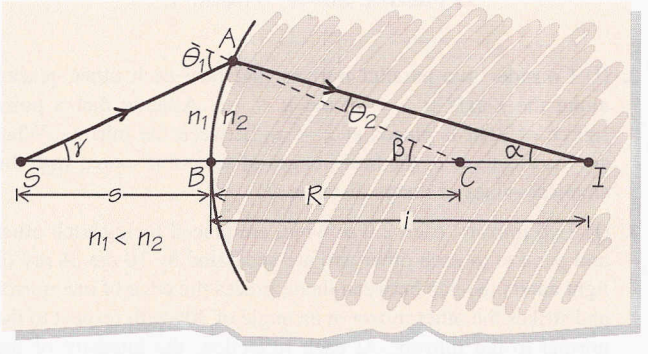
20. (I) A small fish is cast into the center of a glass sphere of radius $R = 5$ cm and $n = 1.5$. Where will an observer see the fish? Where will the observer see a decorative background pattern painted on the back side of the sphere?

21. (II) A glass rod of refractive index $n = 1.6$ and diameter 1.6 cm has a hemispherical cap (Fig. 36–44). There is a fault in the glass 2.3 cm from the end. Can you see this fault if you look at the rod through the spherical cap? From about how far away should you look?

▲ **FIGURE 36–44** Problem 21.

22. (II) By applying Eq. (36–10), show that, if light is incident on a convex refracting surface with $n_2 > n_1$ (see Fig. 36–18), there is a critical distance s_c such that the image of an object closer than s_c will be virtual. Find s_c, and show by ray tracing that the virtual image when $s < s_c$ is upright and magnified.

23. (II) Consider the situation described in Problem 22. Use ray tracing to find the image when $s = s_c$, and when $s = 3s_c$.



24. (II) Consider a convex spherical boundary between two media with an upright object whose extreme point is at S, as in Fig. 36–18. Suppose that $n_2 < n_1$ rather than $n_2 > n_1$. Find the nature of the image (inverted or upright, virtual or real, reduced or magnified) by tracing rays from S. Is there a critical distance at which the nature of the image changes, as in Problem 22?

25. (II) A convex spherical boundary produces an image whose distance from the boundary surface is governed by Eq. (36–10). Suppose that $n_2 > n_1$. (a) Show that when an object is very far from the surface, the image is a distance $i = n_2R/(n_2 - n_1)$ from the surface, and that the image is inverted, reduced, and real. (b) What is the distance s at which the image distance becomes infinite? (c) What is the position of the image for s just less than the critical value found in part (b)? Is it real? (d) As s continues to decrease, what happens to the position of the image?

26. (II) Consider a concave surface of radius of curvature R that separates two media with indices of refraction n_1 and n_2, where $n_2 > n_1$ (see Fig. 36–19). Find the distance s of an object for which the image, which is virtual, is superimposed on the object.

27. (II) Derive Eq. (36–9) for the case of a concave surface shown in Fig. 36–17.

28. (II) Use Fig. 36–45 to derive Eq. (36–10). Let $n_1 < n_2$ and use small angles. Use geometry to show that $\theta_2 = \beta - \alpha$ and $\theta_1 = \beta + \gamma$, and $n_1(\beta + \gamma) = n_2(\beta - \alpha)$. Use the exact relation $AB = R\beta$ and show that the small-angle approximations give $AB = s\gamma = i\alpha$ to finally obtain Eq. (36–10).

▲ **FIGURE 36–45** Problem 28.

29. (III) In deriving Eq. (36–10) in the previous problem, we took $n_1 < n_2$ in Fig. 36–45. Make a new drawing appropriate to $n_2 < n_1$ for a convex surface. Apply the same kind of reasoning, using small angles to show that the same algebraic formula applies whatever the relative sizes of n_2 and n_1.

30. (III) Show that Eq. (36–10) holds for a concave refracting surface with $n_2 > n_1$ by drawing a figure analogous to Fig. 36–45 (Problem 28) and by making small-angle assumptions.

36–4 Thin Lenses

31. (I) The image of an object placed 24 cm away from a thin lens forms at a distance of 51 cm on the other side of the lens. (a) What is the focal length? (b) What type of lens is it? (c) Is the image real? upright? (d) What is the magnification?

32. (I) A double concave lens has radii of curvature of 6.0 cm and 7.5 cm. If the index of refraction of the lens material is 1.56, what is the focal length?

33. (I) An apple is placed 15 cm in front of a diverging lens with a focal length of 22 cm. (a) Where is the image? (b) Is the image real? (c) upright? (d) What is the magnification?

34. (I) Find the condition under which a single thin lens produces a real image, starting with a real source.

35. (II) We want to form an image of an insect magnified twofold by using a converging lens with a focal length of 25 cm. (a) Where should the object be placed for the image to be real? (b) Repeat part (a) for a virtual image.

36. (II) An object 4.5 cm high is placed on one side of a thin converging lens of focal length 43 cm. What are the location, size, and orientation of the image when the object is (a) 86 cm from

the lens, (b) 50 cm from the lens, (c) 40 cm from the lens, (d) 15 cm from the lens?

37. (II) The two surfaces of a thin lens have radii of the same sign and magnitude. Show by ray tracing that the focal length of this lens is infinite. Is the image produced by this lens real or virtual?

38. (II) A thin converging lens forms an image of a distant mountain at a distance of 38 cm from the lens. (a) What is the focal length of the lens? (b) A pine cone is placed 75 cm from the lens. Describe the resulting image: its magnification and distance from the lens, and whether it is real or virtual, upright or inverted. (c) The lens glass has an index of refraction of 1.55. The lens is immersed in water, index of refraction 1.33. What is its focal length in water?

39. (II) Consider the thin lenses shown in Figs. 36–23a through 36–23d. Suppose that in each case the magnitudes of the radii of curvature are $R_1 = 25$ cm and $R_2 = 60$ cm, and that $n = 1.55$. (a) Find the focal lengths for each of the four lenses, and use the sign of the focal lengths to obtain the locations of the image of a source 10 m from each lens. (b) In each case, is the image upright or inverted, real or virtual? (c) Calculate the magnification M from Eq. (36–6) and check that it is consistent with your results in part (b).

40. (II) An object is placed 25 cm to the right of each of the lenses of Problem 39. For each case, locate the image, state whether it is upright or inverted and real or virtual, and give the magnification.

41. (II) Repeat Problem 40 for an object placed 65 cm to the right of each of the lenses.

42. (II) Consider an object on the left side of a thin lens with $R_1 > 0$ and $R_2 < 0$. The image will be on the right of the lens. Let X_0 be the distance of the object from the focal point on the left and X_1 be the distance of the image from the focal point on the right. Show that $X_0X_1 = f^2$. This was Newton's original formulation of the lens equation, given in his *Opticks* in 1704.

43. (II) Show that the thin lens equation [Eq. (36–12)] follows from Fermat's Principle, according to which all light rays leaving an object and traveling to the image do so in minimum times. [*Hint*: You may need the following geometric result. Consider a line that is drawn perpendicular to a particular radius at a distance $R - x$ from the center. Then the distance from the radius to the point where the line touches the circle, y, is given by the relation $y^2 = x(2R - x)$ which for small x reduces to $y^2 = 2Rx$.]

44. (II) Two thin lenses of focal length f_1 and f_2, respectively, are aligned along the same axis and placed very close together. Show that the focal length f of the combination is given by

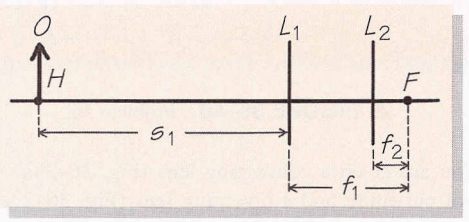
$$\frac{1}{f} = \frac{1}{f_1} + \frac{1}{f_2}.$$

36–5 Optical Instruments

45. (I) The eyes of an elderly person have near points of 70 cm. What must the focal length of corrective lenses be in order for this person to read a book at a distance of 30 cm?

46. (I) A nearsighted person has near and far points of 12 cm and 41 cm, respectively. (The *far point* is the farthest point at which a person can see clearly.) (a) Determine the lens required for this person to be able to see clearly at infinity. (b) What does the lens correction of part (a) do to the near point? Can the person still easily read a book?

47. (I) You have a thin lens with $f = 9$ cm. If you want to see an insect magnified by a factor of 3, how close should you hold the glass to the insect? (Let the image be virtual.)



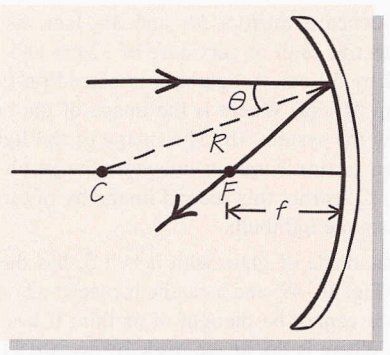
48. (I) What is the magnification of a telescope that has an objective lens with a focal length of 80 cm and an eyepiece with a focal length of 1.7 cm?

49. (I) You are trying to construct a compound microscope given two lenses with focal lengths $f_1 = 1.0$ cm and $f_2 = 4.0$ cm. How far apart should you place the lenses in order to obtain an angular magnification of 60?

50. (II) The two lenses of a telescope with magnification of 120× are separated by 70 cm. What are the focal lengths of the lenses?

51. (II) Calculate the angular magnification of the reflecting telescope shown in Fig. 36–33b.

52. (II) Galileo's original telescope had a convex objective and a concave eyepiece. The focal points of the two lenses coincided, as shown in Fig. 36–46. What is the angular magnification for a distant (but not infinitely far) object, and what is it for an infinitely far object?



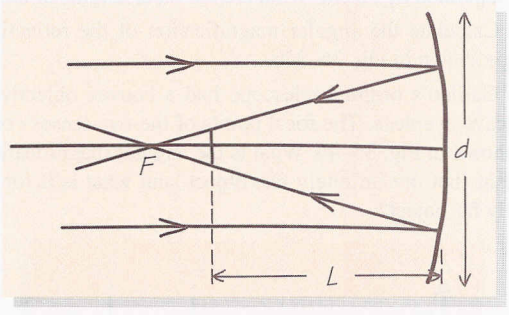
▲ **FIGURE 36–46** Problem 52.

*36–6 Aberration

53. (II) Consider a spherical mirror without making the paraxial approximation (Fig. 36–47). Show that when a ray parallel to the axis makes an angle θ with the radius R at the point of contact, then f, here the distance at which the ray crosses the axis, is given by

$$f = R\left(1 - \frac{1}{2\cos\theta}\right).$$

Show that for small angles, this formula reduces to $f = R/2$. Note that F is not the focal point here (there is no sharp focus), but only the point at which some particular ray crosses the axis.



▲ **FIGURE 36–47** Problem 53.

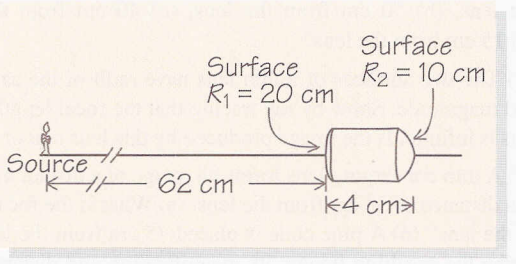
54. (II) Use the result of Problem 53 to calculate the spread in values of f for a spherical mirror of radius 0.18 m and arc length 46 cm.

55. (II) The index of refraction of optical glass used for a thin lens with $R_1 = +20.00$ cm and $R_2 = +28.75$ cm is $n = 1.48523$ for light of wavelength $\lambda = 587.6$ nm and $n = 1.48135$ for light of wavelength $\lambda = 768.2$ nm. What is the difference in the focal length for these two wavelengths?

General Problems

56. (II) Consider a circular concave mirror of focal length f and diameter d, where $f \gg d$. This mirror's optical axis is aligned with the Sun. What is the area of the spot that contains the reflected rays as a function of the distance L from the mirror if $L < f$ (Fig. 36–48)? Sunlight has an intensity I as it arrives at the mirror. Find the intensity of the reflected rays as a function of L. Treat the Sun as a point source.

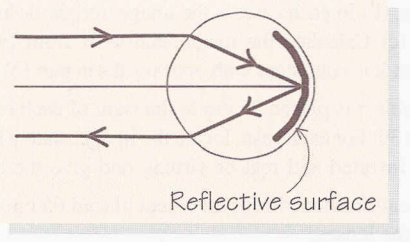
▲ **FIGURE 36–48** Problem 56.



57. (II) You are given a converging lens (Fig. 36–23a) with equal radii of curvature and a diverging lens (Fig. 36–23c) with the same radii of curvature as those of the converging lens. The lenses are made of material with $n = 1.50$, and the radii of curvature are all 35 cm. They are placed at opposite ends of a tube 15 cm long, and the nearer lens is 10 cm from an object. What is the location of the image that results from the two refractions? Does it make a difference whether the converging or the diverging lens is closer to the object?

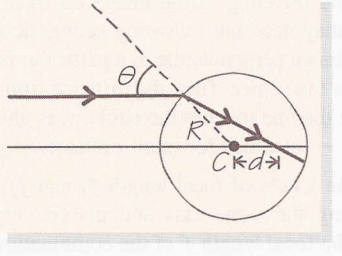
58. (II) Consider a 45-cm-long cylinder of glass in air, with $n = 1.6$, like the cylinder shown in Fig. 36–21. The two ends are shaped into sections of spheres; each has radius 18 cm. A small object is placed perpendicular to the optical axis at a distance of 12 cm from one of the spherical surfaces. (a) Find the location of the object's image due to refraction at surface 1. (b) Let this image be the object for surface 2, and find the location of *its* image as light passes through surface 2. (c) Use ray tracing to determine if the final image is upright or inverted.

59. (II) Two concave mirrors M_1 and M_2 face each other. They have respective radii of curvature of 32 cm and 14 cm and are separated by 50 cm. A lightbulb is placed on the optical axis 7 cm from M_1. (a) Where is the image of the bulb formed by M_1? Draw the system. (b) The image of the lightbulb formed by M_1 can in turn form an image as the result of reflections from M_2. Construct this second image by ray tracing, starting from the source lightbulb.



60. (II) A lens, made of glass with $n = 1.5$, has the configuration shown in Fig. 36–49, and a candle is placed 62 cm from surface 1. The lens cannot be thought of as thin; it has a thickness of 4 cm. (a) Where is the image made by surface 1? Is it inverted? What is the magnification? (b) By using the image made by surface 1 as an object for surface 2, find the final image's location relative to the candle as well as the magnification of the image. Is it inverted or upright?

61. (II) A thin lens with focal length f_1 is placed a distance d in front of a concave mirror with focal length f_2. What is the focal length of the combination?



▲ **FIGURE 36–49** Problem 60.

62. (II) Consider the sphere of glass with $n = 2$ in Fig. 36–50. Any incoming ray is parallel to an axis through the middle of the sphere and will be refracted, striking the rear surface of the sphere at the axis. Demonstrate that this holds true for paraxial rays. If the back surface is painted with a reflecting material, symmetry shows that the ray will come back out in the opposite direction. Tiny spheres of this type are used for highway reflectors.

▲ **FIGURE 36–50** Problem 62.

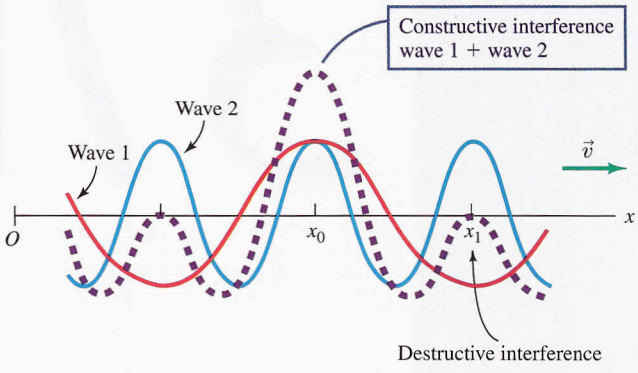
63. (III) Rays of light strike a spherical glass surface parallel to the optical axis (Fig. 36–51). The incoming ray makes an angle θ with the normal to the surface. Show that the rays will cross the optical axis at a distance $d = R/\left(\sqrt{n^2 - \sin^2\theta} - \cos\theta\right)$ beyond the center of the sphere, where n is the index of refraction of the glass. To what does this expression reduce for small angles?

▲ **FIGURE 36–51** Problem 63.

64. (III) The index of refraction of a particular type of glass varies from 1.615 (for blue light) to 1.596 (for red light). Use the result of Problem 63 to calculate the color spread on the axis for light that strikes a hemispherical cap at the end of a glass rod, at an angle $\theta = 0.8$ rad. Take the radius of curvature of the sphere to be $R = 1.50$ cm. What is the spread for paraxial rays?

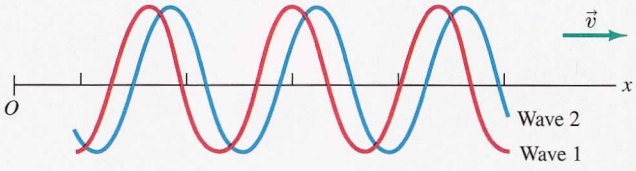
65. (III) An optical system contains a thin lens, $n = 1.4$, with positive curvature of radius $R_1 = 25$ cm for surface 1 and negative curvature of radius $R_2 = -25$ cm for surface 2. This lens collects light from the right side. Where to the left of the lens should a flat plate of thickness t of the same glass be placed, and how thick should it be, if you want the light that radiates from a distant object to be focused on a screen 35 cm to the left of the lens?

Chapter 37



◀ The brilliant colors of the peacock's feathers are due not to pigmentation, but to interference of the light reflected from them.

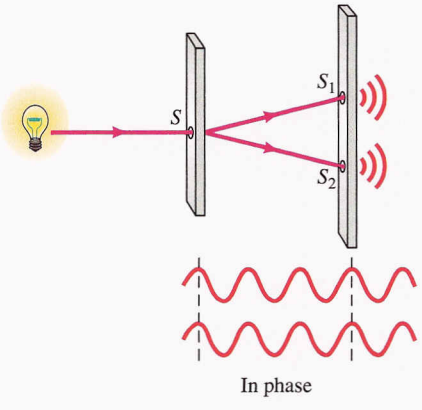
Interference



In Chapters 35 and 36, we emphasized the geometrical properties of light. We discussed reflection and refraction by treating light in terms of rays, but did not address the fact that light is a wave phenomenon. However, if we look more carefully at the behavior of light when obstacles or holes have dimensions comparable to the wavelength of the light, geometric (or ray) optics is inadequate, and the wave nature of light becomes important. Geometric optics cannot explain the colors observed in oil slicks or soap bubbles, and if we look closely at shadows, we find that they are not completely sharp, in contradiction to the predictions of geometric optics. These phenomena are due to interference and diffraction, the subjects of this chapter and Chapter 38, subjects already discussed in terms of mechanical waves in Chapter 15. *Physical optics*, which takes into account the wave nature of light, explains a wider range of observations than does geometric optics.

37–1 Young's Double-Slit Experiment

When two or more harmonic waves superpose, they interfere—whether they are water waves, waves on a string, sound waves, or light waves. We saw how this worked for waves in mechanical systems in Chapter 15. Here we shall see how interference between two light waves occurs because *the electric (or magnetic) fields of the two*

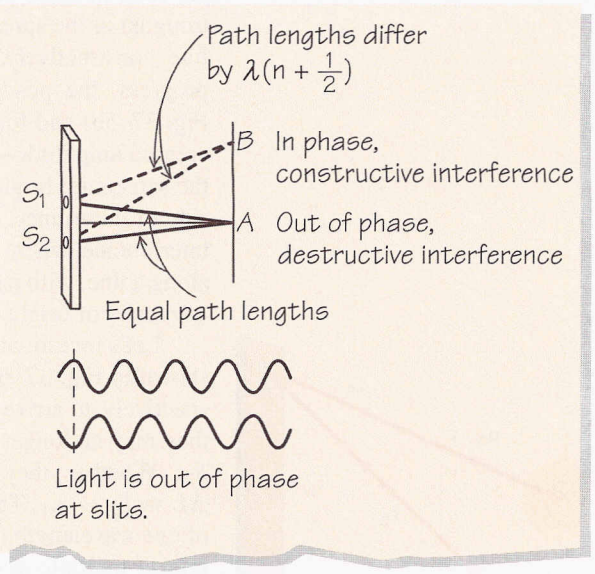


▲ **FIGURE 37–1** Constructive interference between two waves occurs at point x_0 when the peaks coincide. Destructive interference between two waves occurs at point x_1 when their amplitudes cancel.

▲ **FIGURE 37–2** Two coherent waves have a constant phase difference.

waves add vectorially. Consider the superposition of two light waves from different sources at particular points in space that are propagating along the x-axis at a given time (Fig. 37–1). Where the two waves add to produce a wave with a larger amplitude (we refer here to, say, the electric field amplitude), we say that the waves interfere constructively, as, for example, at point x_0 in Fig. 37–1. The two waves interfere destructively where they cancel each other, as they do, for example, at point x_1. Any degree of interference between maximally constructive or maximally destructive is possible.

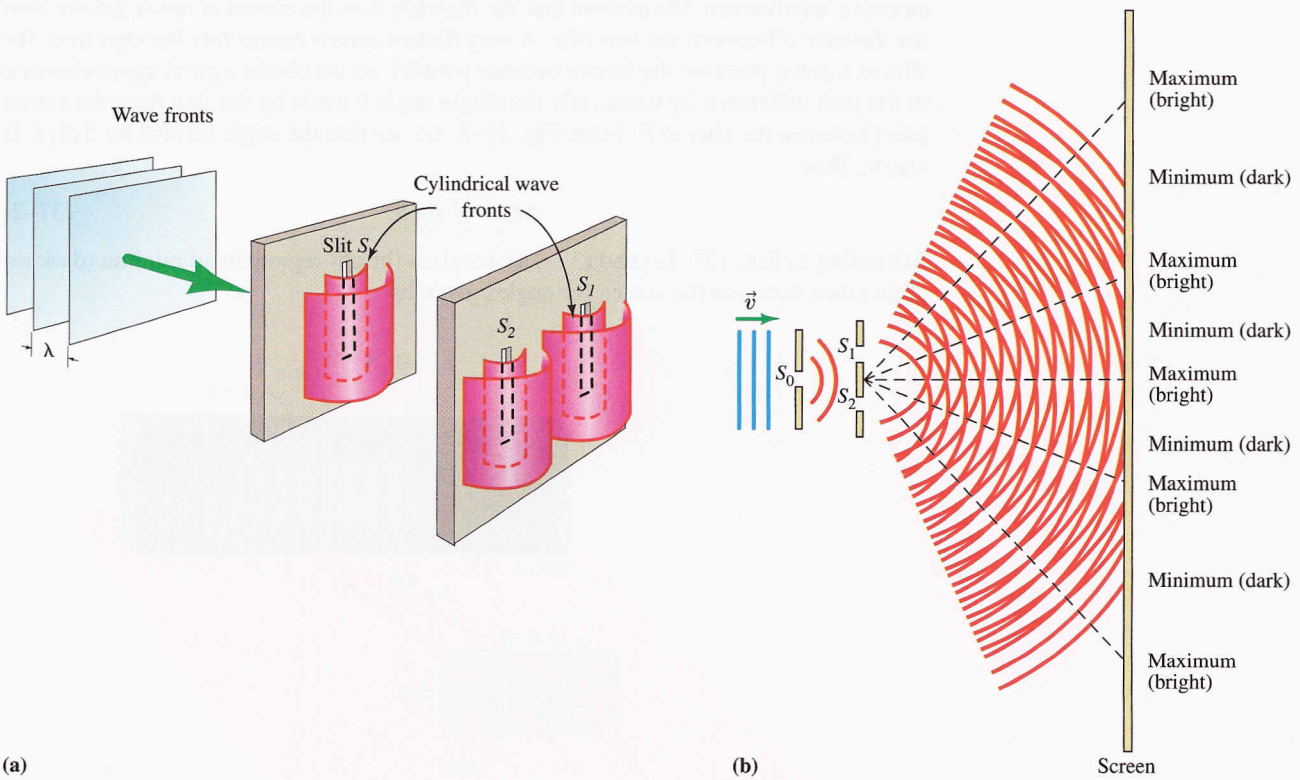
Light waves from two sources can produce an interference pattern in space when there is a definite relation between the respective wavelengths and phases *at their respective sources*. In other words, the waves must be *coherent*. The two light waves shown in Fig. 37–2 each have the same wavelength and a constant phase difference. We can also call monochromatic waves from a single source coherent when those waves form a long train of purely harmonic form. The "coherent" single source becomes two coherent sources that can interfere when the light is split; the interference occurs when the optics are arranged so that the two parts recombine later. A laser emits very long wave trains like these, and it is easy to demonstrate the interference pattern produced by laser light in the classroom (see Chapter 38). If the waves emitted at one or both sources consist of a mixture of waves of different wavelengths and phases, then there is no interference pattern. For example, an incandescent lightbulb produces light from many independent atomic sources at different times and places within the filament—this light is *incoherent*.



▲ **FIGURE 37–3** The light waves that pass through slits S_1 and S_2 are coherent. These waves are in phase if the light travels the same distance from S to S_1 as the distance from S to S_2. Even when the path lengths are different, there is a definite constant phase difference.

Thomas Young observed interference phenomena between two sources of light at the very beginning of the 19th century—he was the first to see such effects in light. One can produce coherent light at two sources by illuminating a single aperture S (a slit or a hole) with a source of monochromatic light. If the source of this light is a lightbulb, the light comes in series of bursts from individual atomic sources, a quantum phenomenon. (The monochromaticity can be taken care of with a prism.) These bursts last for a time on the order of $\tau \cong 10^{-8}$ s, and the length of the resulting individual wave trains is therefore $c\tau$, or several meters. The aperture S must be so small that only one wave train enters at a time. The single wave train of light that passes through illuminates two other apertures, S_1 and S_2 (Fig. 37–3). We can suppose that the size of the two apertures is the same, so that the amplitudes of the waves that come from them are identical. *These two apertures are two sources of coherent light.* If S_1 and S_2 are equidistant from S, the light from S travels the same distance to reach S_1 and S_2, and the light is in phase as it passes through the two apertures (Fig. 37–3). If S_1 and S_2 are not equidistant from S, the light waves that pass through them are still coherent because they have a definite, time-independent phase difference.

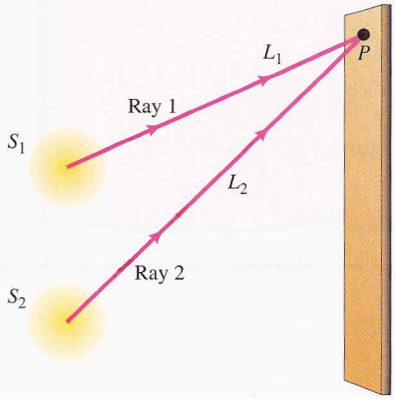
CONCEPTUAL EXAMPLE 37–1 Will there be interference between the (monochromatic) light passing through the slits of S_1 and S_2 if the light exiting the two slits is exactly 180° out of phase?



Answer We rearrange the slits of Fig. 37–3 as shown in Fig. 37–4 to make the light exiting the two slits to be π rad out of phase. The two sources of light have a strict coherence. At any point equidistant from the two slits (point A in Fig. 37–4, for example), the sources of light will remain out of phase and will interfere destructively. On the other hand, the two waves will be in phase at a point such as B placed so that its distance from the two slits differs by $\lambda(n + 1/2)$, where $n = 0, 1, 2, \ldots$ is an integer. At these points there will be constructive interference (Fig. 37–4). Similar remarks can be made if the phase difference for the light passing through the two slits has *any* value, as long as it is a definite value and not something that is constantly changing.

▶ **FIGURE 37–4** The light sources at S_1 and S_2 are out of phase. Whether they are out of phase or in phase at points A and B depends on the difference in path lengths to these points.

The Two-Source Interference Pattern



Let's review the spatial interference pattern produced when light from two sources of coherent waves interfere, a subject we developed in Chapter 15. We suppose that we have two sources, S_1 and S_2 (vertical slits), that emit monochromatic light in phase (Fig. 37–5a). Figure 37–5b is a view from above. Waves of the same frequency and phase emanate from S_1 and S_2 in the form of spreading cylinders from the sources, and these

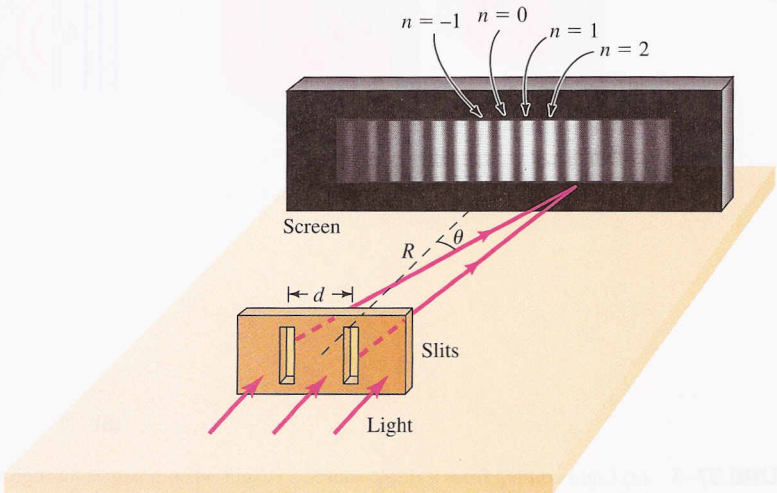
▲ **FIGURE 37–5** (a) Light coming from a single source S is split when it passes through the two slits S_1 and S_2, which act as two coherent sources, producing coherent cylindrical waves. (b) The view from above. Constructive interference occurs everywhere along the directions where the concentric circles, representing the crests of the spreading waves, overlap, because the waves are in phase along these directions. Alternating bright and dark places will be observed on a distant screen.

are seen in cross-section as circles in the figure. The circles represent the crests (or troughs) of the spreading waves. Where the crests (or troughs) overlap, the waves interfere constructively. The pattern of these overlap points is apparent: As the waves progress, the positions of these points advance (indicated by the dashed lines in Fig. 37–5b) and form lines. There is constructive interference—wave motion with increased amplitude—*all along* these lines; therefore, the places where the lines intersect the screen are bright. There is partial constructive interference in the regions on either side of these lines, and destructive interference in between the regions of constructive interference, where the screen is dark. (Again, the interference is maximally destructive along a line, with partial destructive interference in a region around that line.) The result is a series of bright and dark areas on the screen.

Let's investigate this double-slit configuration more closely. Consider the geometry shown in Fig. 37–6. Along ray 1 and ray 2, the waves travel distances L_1 and L_2, respectively, to arrive at point P on the screen. Because the rays travel different distances, they may no longer be in phase at P, although they were in phase at the sources S_1 and S_2. Whether they are in phase or not depends on the *path-length difference* $\Delta L = L_2 - L_1$. The waves arrive in phase if ΔL is zero or if ΔL is an integral multiple of one wavelength ($\Delta L = \lambda n$), but will be 180° out of phase if this difference is a half-integer multiple of one wavelength [$\Delta L = \lambda(n + 1/2)$]. The interference is constructive where the waves are in phase and destructive when the waves are 180° out of phase:

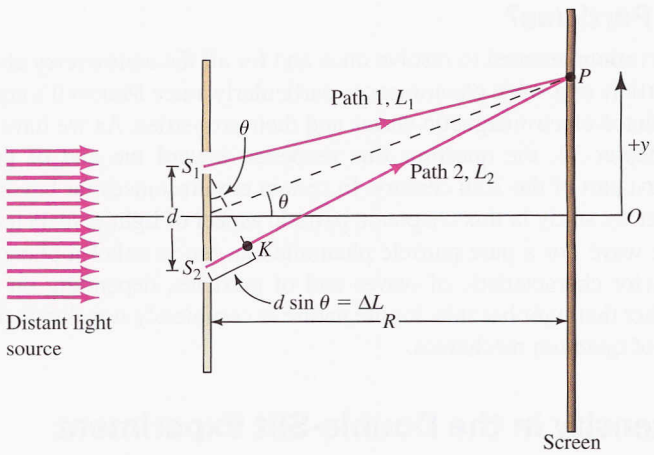
▲ **FIGURE 37–6** Light waves, indicated by rays 1 and 2, may not be in phase at point P despite being in phase at their sources, S_1 and S_2.

$$\text{for constructive interference:} \quad \Delta L = n\lambda, \quad n = 0, \pm 1, \pm 2, \ldots; \tag{37–1a}$$



$$\text{for destructive interference:} \quad \Delta L = \left(n + \frac{1}{2}\right)\lambda, \quad n = 0, \pm 1, \pm 2, \ldots. \tag{37–1b}$$

The resulting series of bright and dark lines on the screen is indicated in Fig. 37–5 and Fig. 37–7.



The geometry shown in Fig. 37–8 determines conditions for constructive and destructive interference. We assume that the distance R to the screen is much greater than the distance d between the two slits. A very distant screen means that the rays from the slits to a given point on the screen become parallel, so we obtain a good approximation to the path difference by using only the single angle θ made by the line from the center point between the slits to P. From Fig. 37–8, we see that the angle formed by S_2S_1K is also θ. Thus

$$\Delta L = d \sin\theta. \tag{37–2}$$

According to Eqs. (37–1a) and (37–1b), maxima (bright regions) and minima (dark regions) thus occur on the screen for angles given by

▲ **FIGURE 37–7** The interference pattern produced by double vertical slits is a series of alternating bright and dark vertical lines on a screen. The falloff of the intensity toward the edge of the figure is a single-slit effect (see Chapter 38).

▲ **FIGURE 37–8** The geometry used to find the interference-pattern conditions for the light that reaches point P. The path-length difference $\Delta L = d \sin \theta$.

$$\text{for constructive interference:} \quad \sin \theta = n\frac{\lambda}{d}, \quad n = 0, \pm 1, \pm 2, \ldots; \tag{37–3a}$$

$$\text{for destructive interference:} \quad \sin \theta = \left(n + \frac{1}{2}\right)\frac{\lambda}{d}, \quad n = 0, \pm 1, \pm 2, \ldots. \tag{37–3b}$$

INTERFERENCE CONDITIONS FOR TWO SOURCES

The point that is aligned with the sources ($\theta = 0$) is a maximum ($n = 0$). Alternating minima and maxima lie on either side of this centerline. The value of n that labels the maxima is known as the *order*. The central maximum is the zeroth order, and the maxima on either side of the central maximum are first-order maxima ($n = \pm 1$). If θ is small, so that $\sin \theta \cong \theta$, the maxima and minima are equally spaced in θ. This experiment shows conclusively that light behaves as a wave. Geometric optics cannot explain the result shown in Fig. 37–7.

EXAMPLE 37–2 In a double-slit experiment, y is the distance along the screen from the center maximum. Find the positions of the maxima as a function of y. If the source-to-screen distance $R = 3.0$ m, the source separation $d = 0.20$ mm, and light comes from a helium–neon laser ($\lambda = 633$ nm) far away, determine y for the ninth-order maximum.

Setting It Up Fig. 37–8 illustrates the experimental schematic and shows the path difference $\Delta L = L_2 - L_1$.

Strategy Geometry tells us that $\Delta L = d \sin \theta$, and then the values of θ for which maxima occur is given by Eq. (37–3a). After determination of the angles, we use $y = R \tan \theta$ to find the desired y-values. If $R \gg y$, $\tan \theta \cong \sin \theta$, and we can directly insert the value of $\sin \theta$ from Eq. (37–3a) for the maxima.

Working It Out The maxima are located at

$$y = R \tan \theta \cong R \sin \theta = R\frac{n\lambda}{d}. \tag{37–4}$$

For the ninth order, we have $n = 9$, and $y = 9\lambda R/d$. If we substitute the given values for λ, R, and d, we get for the ninth-order maximum

$$y = \frac{9(633 \times 10^{-9}\ \text{m})(3.0\ \text{m})}{0.20 \times 10^{-3}\ \text{m}} = 8.5\ \text{cm}.$$

The distance between each of the maxima is therefore about 1 cm.

What Do You Think? Could such measurements be used to determine the wavelength λ? *Answers to* ***What Do You Think?*** *questions are given in the back of the book.*

CONCEPTUAL EXAMPLE 37–3 Show that the observed pattern of lines on the screen in the double-slit experiment spreads out as the wavelength increases and/or the separation between the sources decreases.

Answer Equation (37–4) shows that the distance between adjacent maxima on the screen equals $\lambda R/d$. With R a constant, the separation Δy is proportional to λ/d. The pattern is most evident—it spreads over large angles—when the wavelength is comparable to the source separation. Thus to see the interference pattern in a water ripple tank where the wavelength is measured in centimeters, the slit separations should be on the order of centimeters. This is a feature characteristic of all wave phenomena.

Waves or Particles?

Young's observations seemed to resolve once and for all the controversy about whether light was a particle or a wave phenomenon, particularly since Maxwell's equations successfully predicted electromagnetic waves and their properties. As we have already described in Chapter 34, the question was reopened toward the end of the 19th and through the first part of the 20th century. In certain circumstances far beyond the physical realms that we study in this chapter, a particle aspect of light reveals itself. Light is neither a pure wave nor a pure particle phenomenon, but is rather a phenomenon that displays behavior characteristic of waves and of particles, depending on the circumstances. The fact that light has this double nature is completely nonclassical, explicable only in terms of quantum mechanics.

37–2 Intensity in the Double-Slit Experiment

The previous discussion relied on geometrical arguments to determine the angles for which maxima and minima can be obtained. We now turn our attention to the *intensity* of the light that reaches the screen. In this section, we are going to assume that the two sources are both slits that are very narrow. The case where even a single slit has a finite width is by itself interesting, and we'll reserve that case for Chapter 38.

The intensity (or brightness, for light) measures the energy delivered by a wave per unit time per unit area. The energy in a given mechanical wave or superposition of waves is proportional to the displacement squared. For light, the quantity that plays the role of displacement is the electric (or magnetic) field. The intensity of a light wave (the energy delivered by the wave per unit time per unit area) is the time average of the Poynting vector (see Chapter 34), which is proportional to the product of electric and magnetic field vectors in the wave. Because the magnetic field is itself proportional to the electric field in an electromagnetic wave, the intensity is proportional to the electric field squared ($I \propto E^2$). In order to find the intensity of a collection of waves, we add the electric fields of all the waves and square the sum of the net field. For example, with two sources of equal intensity I_0, the maximum electric field is twice the electric field E_0 from each source, so

$$\frac{I_{\max}}{I_0} = \frac{(E_0 + E_0)^2}{E_0^2} = 4,$$

where $I_{\max}$ is the maximum intensity. The maximum intensity $I_{\max} = 4I_0$. Similarly, the minimum intensity occurs when the electric fields exactly cancel, and $I_{\min} = 0$.

The simple argument just given, which is based on energy, is so useful that we shall develop it further. The intensity at any point P on the screen in Fig. 37–8 is proportional to the net Poynting vector, which is in turn proportional to the square of the net electric field. The net instantaneous electric field $\vec{E}_{\text{net}}$ at P is the sum of the instantaneous electric fields of the light waves emitted at the two sources: $\vec{E}_{\text{net}} = \vec{E}_1 + \vec{E}_2$. The net Poynting vector therefore has magnitude $S = (\vec{E}_1 + \vec{E}_2)^2 = E_1^2 + E_2^2 + 2\vec{E}_1 \cdot \vec{E}_2$. But light waves oscillate rapidly, and thus it is the *time average* of the Poynting vector (that is, the intensity, I) at P that is of interest.

It is the coherence of the two light waves that is important for the time-averaged intensity value. If we denote time averages with triangle brackets, then

$$I_{\text{net}} \propto \langle E_1^2 \rangle + 2\langle \vec{E}_1 \cdot \vec{E}_2 \rangle + \langle E_2^2 \rangle. \tag{37–5}$$

For incoherent light, there is no correlation—no definite phase relation—between the electric fields from the two sources. One moment the sources have one relative phase, the next moment the relative phase is different, and *the term* $\langle \vec{E}_1 \cdot \vec{E}_2 \rangle$ *is zero*. Thus

$$I_{\text{incoh}} = I_1 + I_2. \tag{37–6}$$

For coherent waves, $\langle \vec{E}_1 \cdot \vec{E}_2 \rangle$ in Eq. (37–5) is not zero. If, at a given time, there is constructive interference at point P, where $\vec{E}_1 = \vec{E}_2$, the constructive interference will persist because the waves are coherent. Similarly, if there is destructive interference at a

given time, where $\vec{E}_1 = -\vec{E}_2$, it also persists through later times. For destructive interference, $\langle \vec{E}_1 \cdot \vec{E}_2 \rangle \propto -I_1$, and Eq. (37–5) gives $I_{\text{net}} = I_1 - 2I_1 + I_1 = 0$.

Suppose then that the electric fields of the light waves from our coherent sources S_1 and S_2 at a single point P in space are identically oriented and have magnitudes

$$E_1 = E_0 \sin \omega t, \tag{37–7a}$$

$$E_2 = E_0 \sin(\omega t + \phi). \tag{37–7b}$$

The phase difference ϕ for E_2 results from the path-length difference between the waves. If $\phi = 2\pi n$, where n is an integer, the fields are identical, and there is constructive interference. This phase difference of $2\pi n$ corresponds to a path-length difference of $\Delta L = n\lambda$. The ratio of ϕ to $2\pi n$ is the same as ΔL to $n\lambda$, so we have

$$\frac{\phi}{2\pi n} = \frac{\Delta L}{n\lambda};$$

$$\frac{\phi}{2\pi} = \frac{\Delta L}{\lambda}. \tag{37–8}$$

For the distant-screen geometry of Fig. 37–8, we can use $\Delta L = d \sin \theta$ [Eq. (37–2)] to transform Eq. (37–8) to

$$\phi = 2\pi \frac{\Delta L}{\lambda} = \frac{2\pi}{\lambda} d \sin \theta. \tag{37–9}$$

Now the net electric field at P has magnitude

$$E_{\text{net}} = E_1 + E_2 = E_0[\sin \omega t + \sin(\omega t + \phi)].$$

If we apply the equation $\sin \theta_1 + \sin \theta_2 = 2 \cos[(\theta_1 - \theta_2)/2] \sin[(\theta_1 + \theta_2)/2]$ (see Appendix IV–4), with $\theta_1 = \omega t$ and $\theta_2 = \omega t + \phi$, we find

$$E_{\text{net}} = 2E_0 \cos\left(\frac{\phi}{2}\right) \sin\left[\omega t + \left(\frac{\phi}{2}\right)\right]. \tag{37–10}$$

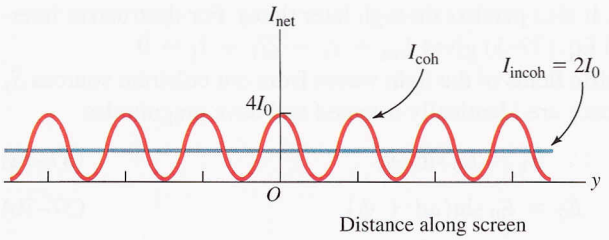
The Poynting vectors $\vec{S}_1$ and $\vec{S}_2$ of the light from the individual sources have magnitudes

$$S_1 \propto E_1^2 = E_0^2 \sin^2(\omega t) \quad \text{and} \quad S_2 \propto E_2^2 = E_0^2 \sin^2(\omega t + \phi), \tag{37–11}$$

respectively, whereas the net Poynting vector at P has magnitude

$$S_{\text{net}} \propto E_{\text{net}}^2 = 4E_0^2 \cos^2(\phi/2) \sin^2\left[\omega t + \left(\frac{\phi}{2}\right)\right]. \tag{37–12}$$

To find the intensities (the time averages of the Poynting vectors), we need know only that the time average of $\sin^2(at + b) = \frac{1}{2}$. If we write the individual intensities as $I_0 \propto E_0^2/2$, then the net intensity from the two sources in terms of I_0 is



$$I_{\text{net}} = 4I_0 \cos^2\left(\frac{\phi}{2}\right). \tag{37–13}$$

When the phase ϕ in Eq. (37–7b) is related to the path-length difference by Eq. (37–8), then Eq. (37–13) for the intensity on the distant screen becomes

$$I_{\text{net}} = 4I_0 \cos^2\left(\frac{\pi d}{\lambda} \sin \theta\right). \tag{37–14}$$

This is the expression for the intensity in Young's classic double-slit experiment.

The maxima and minima occur at the angles specified by Eq. (37–3). Figure 37–9 is a plot of the intensity at the screen as a function of $\sin \theta$. This figure also serves as a plot of the intensity as a function of the distance y from the center maximum along the screen: For small θ, $y \cong R \sin \theta$, where R is the distance from the screen. If the apertures are narrow vertical slits, then the bright maxima on the screen are vertical lines called *fringes*.

▶ **FIGURE 37–9** The net intensity of light from the double slit as a function of the distance from the center point on the screen ($y \cong \sin\theta$). Compare the results for coherence and incoherence. The same amount of light energy reaches the screen in both cases, but in the coherent case, it occurs in peaks and valleys. We have assumed that each slit is infinitely narrow; that is why the falloff visible at the edges of Fig. 37–7 is not visible here.

We have also plotted in Fig. 37–9 the intensity $2I_0$ that would be present on the screen if the light sources were incoherent, represented by the blue line in the plot. The result for incoherence is constant and shows no interfering maxima and minima. However, *averaged over the entire screen*, the energy reaching the screen is exactly the same in the two cases, as required by the conservation of energy. To average the energy that reaches the screen in the case for coherence, we need only use the fact that the average of the cosine-squared factor in Eq. (37–14) is $\frac{1}{2}$, and $4I_0 \times \frac{1}{2} = 2I_0$. The energy emitted at each source is the same whether the light from these sources is coherent or incoherent, and the total energy arriving at the screen must also be the same as that emitted. The energy is spread evenly over the screen when the sources are incoherent, whereas it is distributed in peaks and valleys when the sources are coherent.

EXAMPLE 37–4 Suppose you live at point H, 20 km from a vertical radio dipole antenna that broadcasts at a frequency of 1100 kHz from point B. How well your radio picks up the signal is a direct function of the intensity of the signal. A second antenna is constructed at point A, located $d = 100$ m from the first, so that AB makes an angle of 15° (0.26 rad) with AH. The two antennas are fed by the same source, and the two signals are in phase at the sources—they have the same wavelength and are coherent. Find the new intensity at your radio in terms of the old intensity. Is your signal improved?

Setting It Up The diagram in Fig. 37–10, which is a vertical view, helps us determine the path difference to the house from the two sources.

Strategy The situation is like the double-slit situation for light because there are two sources of coherent radiation, with the difference that in this case the relevant wavelengths are much longer. Because the distance from the transmitting antennas is much greater than their separation distance, the geometrical approximations we used in discussing the double-slit experiment apply. These approximations tell us that the difference in distances between the house and the two antennas is $R_A - R_B = d\cos\theta$ (Fig. 37–10). To find the net electric field at the house, we add the fields from each source, using the same methods that we did for light. Note that the electric fields, which are parallel to the antennas, are vertical (perpendicular to the page).

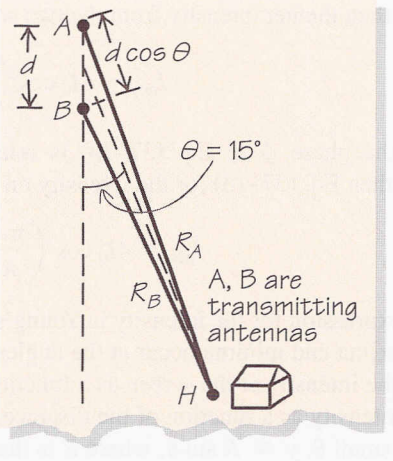
Working It Out Suppose that the first antenna (at point B) broadcasts a signal whose z-component at point H is $E_B = E_0\cos(\omega t)$ and that the original intensity is $I_0 = CE_0^2$, where C is some constant. The second antenna's electric field takes the same form except that there is a phase difference due to the fact that the antenna is a distance $R_A - R_B$ farther away:

$$E_A = E_0\cos(\omega t + \phi),$$

where $\phi = 2\pi(R_A - R_B)/\lambda = (2\pi d\cos\theta)/\lambda$. The net field at point H is then

$$E_{net} = E_A + E_B = E_0[\cos\omega t + \cos(\omega t + \phi)].$$

This sum is similar to the one we needed in order to find Eq. (37–10), $E_{net} = 2E_0\cos(\phi/2) \times \sin[\omega t + (\phi/2)]$. The net intensity is given similarly in Eq. (37–13),



$$I_{net} = CE_{net}^2 = 4CE_0^2\cos^2\left(\frac{\phi}{2}\right) = 4I_0\cos^2\left(\frac{\phi}{2}\right).$$

It remains to calculate the factor $\cos^2(\phi/2)$ and see by what factor the intensity is changed. We require that

$$\cos\left(\frac{\phi}{2}\right) = \cos\left(\frac{2\pi d\cos\theta}{2\lambda}\right) = \cos\left(\frac{\pi d\cos\theta}{\lambda}\right).$$

We have $d = 100$ m and $\theta = 0.26$ rad. The wavelength λ comes from the frequency $f = 1100\text{ kHz} = 1.1 \times 10^6$ Hz. We get $\lambda = c/f = (3.0 \times 10^8\text{ m/s})/(1.1 \times 10^6\text{ s}^{-1}) = 270$ m. Thus

$$\cos\left(\frac{\phi}{2}\right) = \cos\left[\frac{\pi(100\text{ m})(\cos 0.26\text{ rad})}{270\text{ m}}\right] = \cos(1.12\text{ rad}) = 0.43.$$

▲ **FIGURE 37–10** R_A and R_B are the distances between your home and two antennas at points A and B, respectively.

The net intensity $I_{net} = 4I_0 \cos^2(\phi/2)$ is a factor $4[\cos^2(\phi/2)] = 4(0.44)^2 = 0.77$ times the original intensity I_0. The signal you receive at your radio at point H has actually become weaker because there is partial destructive interference between the signals of the two antennas at that point.

What Do You Think? Suppose that the length of the cables from the radio station to the two transmitting antennas were each changed by different amounts. Will the signals still interfere at your house?

37–3 Interference from Reflection

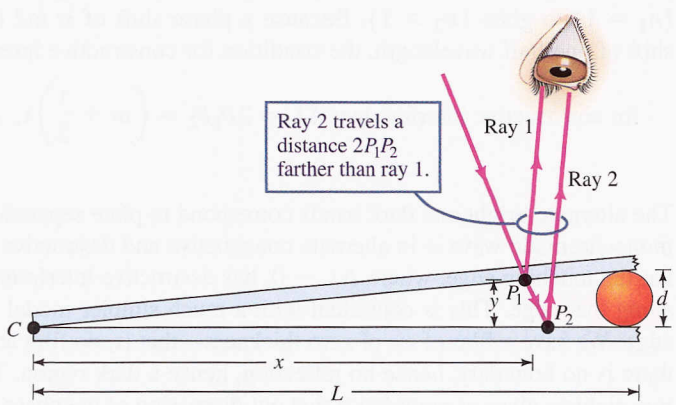
A ray in air, say, may be partly reflected from a surface and partly transmitted through the surface into a medium such as glass. The transmitted ray may then be subsequently reflected from a second surface and reemerge into the air. If the original wave train is long compared with the distance traversed in the glass, the two reflected rays are coherent and can interfere.

Interference Fringes from the Space Between Two Glass Plates

Let's look at two glass plates, each with one very flat surface. They have been placed together with a spacer at one side, so that the flat surfaces touch along one side and are separated by a small distance d at the other (Fig. 37–11). When these plates are illuminated from above with monochromatic light, a series of alternating light and dark bands is seen, starting with a black band along the side where the plates touch.

To study this phenomenon further, let the plates have indices of refraction n, the space between the plates be air ($n = 1$), and the wavelength of the light be λ. We can think of the light as consisting of rays perpendicularly incident on the plates. These rays are *perpendicular to the wave fronts*; when we speak of rays interfering, we are referring to the interference of the waves that form those fronts. In this situation, the rays can reflect and refract to form new rays in various ways, but one possibility leads to the observed interference here: An incident ray in Fig. 37–11 passes almost vertically through the top piece of glass and is partly reflected (ray 1) and partly transmitted (ray 2) at point P_1 on the bottom surface of the top plate. Ray 2 then continues through the air gap and is reflected at point P_2 at the top of the bottom plate. To a good approximation, ray 2 travels a distance $2P_1P_2$ in air farther than ray 1, because the incident ray is almost vertical. Rays 1 and 2, exiting at the top, will interfere, resulting in the series of bright and dark bands corresponding to different values of $2P_1P_2$.

Now, if the points P_1 and P_2 move systematically closer to the side where the plates touch (point C), the path-length difference distance $2P_1P_2$ decreases, and we expect to see a series of bright and dark regions corresponding to constructive and destructive interference. What happens when the plates touch at point C? Observation reveals that there is a dark line at the edge where the plates touch, indicating destructive interference. But at point C each of the rays travel exactly the same distance, so the destructive interference cannot come from any path-length difference. The only explanation is that *destructive interference occurs because one of the rays undergoes a 180° phase change during reflection.* The light undergoes a phase change of 180° when it is reflected at P_2, whereas the light undergoes no such change when it is reflected at P_1. Let us consider the origin of this fact.



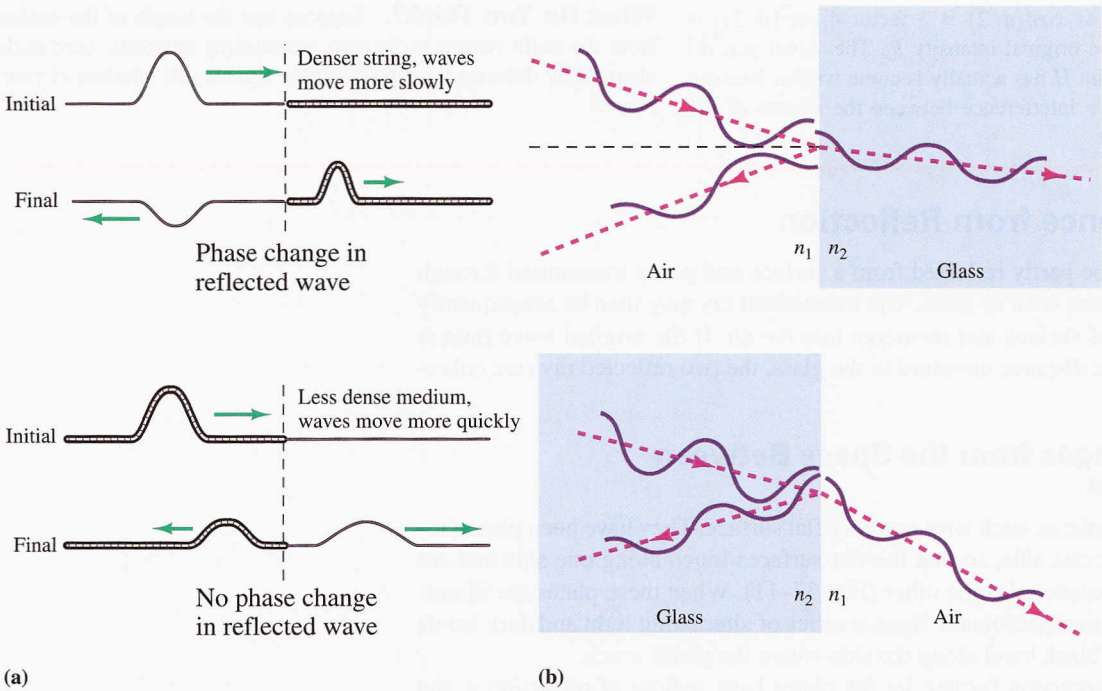


FIGURE 37–11 Two pieces of glass are placed together with a spacer (exaggerated in size) at one edge. The adjacent surfaces are flat on the scale of the wavelength of light.

▲ **FIGURE 37–12** (a) The phase change of light upon reflection is similar to the inversion that occurs when a pulse that moves along a string meets a denser string. No phase change occurs when the string encounters a less dense string. (b) For light, a phase change of 180° occurs when the second medium has a higher index of refraction. When the second medium at the reflection boundary has a lower index of refraction, there is no phase change in the reflection.

In Section 15–5, we discussed a corresponding phenomenon in the reflection of one-dimensional waves on strings. When two strings of different densities are connected (Fig. 37–12), the connection point forms a boundary at which there may be reflection and transmission. We showed that if the density on the side from which the wave comes is less than the density on the far side of the boundary, then the reflected wave is inverted, corresponding to a phase shift of 180° if the wave is harmonic. Similarly, if the pulse comes from a string of larger density than the string on the far side of the connection point, the pulse is not inverted on reflection.

Electromagnetic waves behave similarly: Maxwell's equations determine the form of the electric and magnetic fields of an electromagnetic wave at a boundary between two dielectric media. The electric field changes sign or does not change sign according to whether the wave speed ($v = c/n$) in the medium on the far side of the boundary is greater than or less than the wave speed in the medium from which the wave comes. (There is no such change of sign for the magnetic field of the wave.) When the electric field changes sign, the result is a 180° phase change in the reflected electromagnetic wave. The result for the phase change can therefore be stated as:

The phase of an electromagnetic wave that moves from a medium of index of refraction n_1 toward a medium with index of refraction n_2 will change by 180° upon reflection when $n_2 > n_1$ and will not change when $n_2 < n_1$.

This information allows us to understand the interference pattern for the plates. The phase change of 180° occurs only for the reflection at P_2 because ray 2 goes from air ($n_1 = 1$) to glass ($n_2 > 1$). Because a phase shift of π rad (180°) corresponds to a shift of one-half wavelength, the condition for constructive interference becomes

$$\text{for constructive interference: } \Delta L = 2P_1P_2 = \left(m + \frac{1}{2}\right)\lambda, \quad m = 0, \pm 1, \pm 2, \ldots. \tag{37–15}$$

The alternate bright and dark bands correspond to plate separation distances for which a monochromatic wave is in alternate constructive and destructive interference. In particular, the touching edge, where $\Delta L = 0$, has destructive interference; there is a dark band along that edge. This is consistent with a much simpler model of what happens at that edge: We have a film of air of zero thickness—that is, no film at all—and it is as though there is no boundary, hence no reflection, hence a dark region. The consistency of these two pictures gives us confidence that our discussion of the phase change is correct.

EXAMPLE 37–5 Two flat glass plates of length $L = 10\,\text{cm}$ touch at one end but are separated by a wire of diameter $d = 0.01\,\text{mm}$ at the other end (Fig. 37–11). Light shines almost perpendicularly on the glass and is reflected into the eye as shown. What is the distance x between the observed maxima if the incident (violet) light has $\lambda = 420\,\text{nm}$?

Strategy We must here take the conditions for constructive interference that we previously described and translate those conditions into a band separation. We utilize Eq. (37–15) for the constructive interference condition, and by noting that $2y \cong 2P_1P_2$, where y is the spacing between the plates, we have

$$2y = \left(m + \frac{1}{2}\right)\lambda, \quad m = 0, \pm 1, \pm 2, \ldots.$$

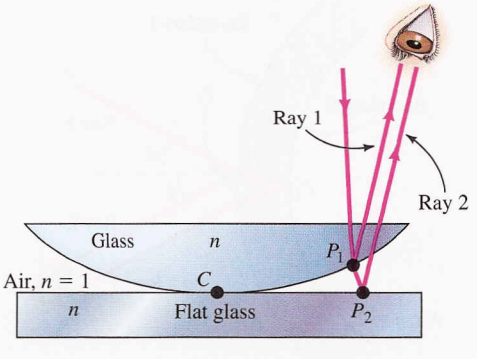
To translate this condition into a condition for the x-position of the bands we use a geometrical relation between similar triangles in Fig. 37–11: $x/y = L/d$ or $x = yL/d$.

Working It Out We insert the y-values for constructive interference into our equation for x and find the x-positions where there is constructive interference:

$$x = \frac{L}{d}y = \frac{L}{d}\frac{1}{2}\lambda\left(m + \frac{1}{2}\right).$$

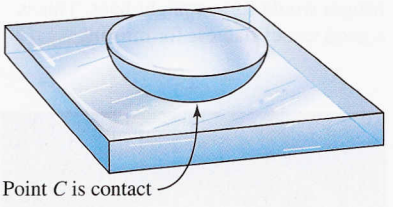
The difference in x from one maximum to another corresponds to a shift in m of 1, so

$$\Delta x = \frac{L}{d}\frac{\lambda}{2}\left\{\left(m + \frac{1}{2}\right) - \left[(m - 1) + \frac{1}{2}\right]\right\} = \frac{L}{d}\frac{\lambda}{2}$$
$$= \frac{(10 \times 10^{-2}\,\text{m})(420 \times 10^{-9}\,\text{m})}{(0.01 \times 10^{-3}\,\text{m})2} \cong 2\,\text{mm}.$$



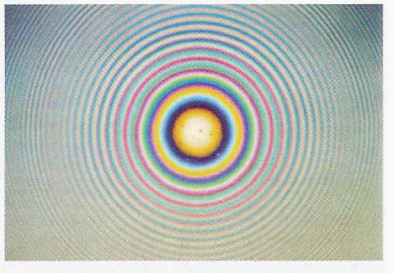
For glass plates 10 cm long, there will be about 50 bands of constructive interference.

What Do You Think? Would the number of bands of constructive interference increase or decrease if red light is used instead of blue light?

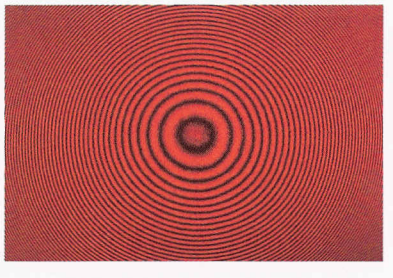


Newton's Rings

Newton's rings form a variant on Example 37–5; they are named after Isaac Newton, who studied them in the 1700s along with his contemporaries Robert Hooke and Robert Boyle. Here, a curved piece of glass is placed on a flat piece of glass and illuminated from above with white light (Fig. 37–13a). Observation from above reveals rings of color (Fig. 37–13b). If monochromatic rather than white light shines down on the glass, then a series of bright and dark concentric rings appear (Fig. 37–13c). Most significantly, the region around point C—the place where the glass pieces touch—is dark (Fig. 37–13c). From our earlier discussion, we know why this occurs: The region around C can be thought of as a region without a reflecting boundary at all or the result of a phase change where ray 2 reflects from the second glass surface with no phase shift due to different path lengths.

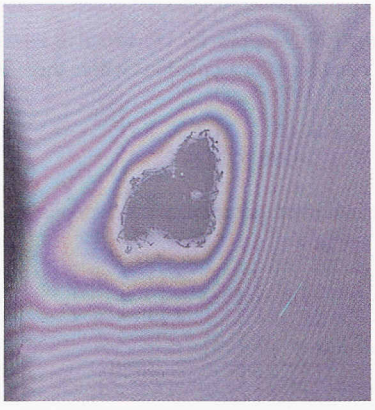


How do we explain the colors we observe when white light such as sunlight, which consists of all wavelengths, is incident on the glass? Refer to Fig. 37–14. For a particular radial distance from point C, there may be only one wavelength in the visible range, say, for the color blue, for which there is *destructive* interference. At that radius, we see the color of sunlight with blue subtracted. If we look slightly farther away from C, where the distance P_1P_2 is greater, there will be destructive interference for a slightly larger wavelength, say, for green, and we see sunlight with green subtracted. These colors are not as vivid as those of the rainbow because they remain mixtures of different frequencies with some frequencies subtracted.



▲ **FIGURE 37–14** The geometry used to obtain the conditions for constructive interference in Newton's rings. The two rays moving toward the eye interfere after they reflect from different surfaces.

(a)



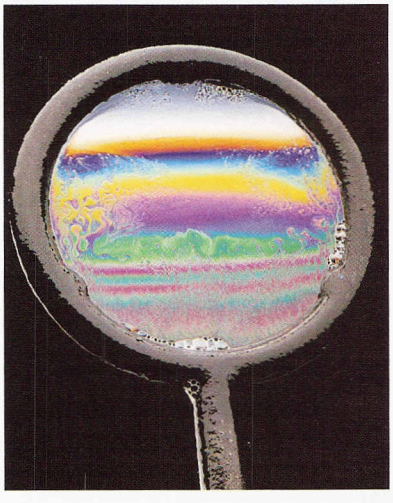
(b)

(c)

▲ **FIGURE 37–13** (a) A piece of glass whose bottom surface is curved rests on a flat glass surface. (b) The system is illuminated with white light from above, and a vertical view reveals colored rings called Newton's rings. (c) Concentric rings of alternating bright and dark appear when Newton's rings form from monochromatic light.

▲ **FIGURE 37–15** Fringes that occur when two nonflat pieces of glass are placed on top of one another. If each surface were perfectly flat and parallel, there would be no interference pattern. If the surfaces were flat but not parallel, the fringes would form straight lines. This is a good test of flatness for mirrors.

THINK ABOUT THIS. . .

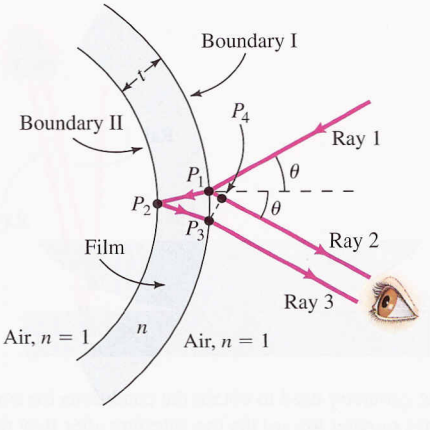


HOW WOULD YOU CHECK THE FLATNESS OF A GLASS SURFACE?

The interference phenomena we have described in this section give us a practical method for determining how flat a given glass surface is (Fig. 37–15). If the surface to be tested is placed on top of an *optical flat* (a glass with a surface known to be flat to a fraction of a wavelength of visible light), then if the tested surface is indeed flat, no regions of constructive interference will appear. In practice, a tiny spacer may be placed between the piece to be measured and the optical flat to open a wedge-shaped space between them. If the two pieces are so nearly flat and parallel that, without the spacer, *no* interference fringes are observed, the pieces may bond together and be virtually impossible to pull apart! In effect, the two pieces become one. (Weeks of grinding and much money will have been lost if this happens).

Mirrors are commercially available that are flat to better than 5 percent of one wavelength, or about 25 nm. They are used in lasers as well as in *interferometers*—devices that use the interference of light to measure distance down to a fraction of one wavelength (see Section 37–4).

Thin-Film Interference



The colors seen in soap bubbles and oil slicks are a manifestation of *thin-film interference*, which is another example of interference from reflection (Fig. 37–16). The interference occurs between the light reflected from the two surfaces of the thin film that forms the bubble. Consider light ray 1 that is incident on the thin film in Fig. 37–17. Part of the light is reflected at boundary I and forms ray 2. Part of ray 1 is refracted at boundary I and then reflected at boundary II. This light wave is partly refracted again at boundary I before forming ray 3.

▲ **FIGURE 37–16** The colors of films of soapy water are due to thin-film interference of light.

Because rays 2 and 3 both originate from ray 1 at point P_1, the conditions for constructive or destructive interference depend on the path-length difference $\Delta L = P_1P_2P_3 - P_1P_4$ as well as on any phase changes that may occur during the reflection. The rule discussed earlier for phase changes upon reflection indicates that ray 1 undergoes a phase change upon reflection at surface I but not at II. Thin films such as soap bubbles have varying thicknesses, so different wavelengths will interfere destructively on different parts of the bubble, and the colors that appear in the reflected light represent the original light minus the wavelength that interferes destructively. There is also an enhancement of those colors for which there is constructive interference. For an oil film floating on water, the oil may have an index of refraction between that of air and water, in which case there is a 180° phase change at *both* the air-oil surface and the oil-water surface. The phase changes due to reflection then cancel each other in the interference from light reflected from these two surfaces, and any phase difference is due only to a difference in the path length.

A feature in thin-film interference that does not arise in the case of Newton's rings is that the additional path length lies *within* the thin film of material. The phase change is then computed according to Eq. (37–9), but *the wavelength that appears is the wavelength within the material*, $\lambda_{\text{film}} = \lambda/n$, where n is the index of refraction of the material.

▲ **FIGURE 37–17** Geometry for thin-film interference. A light ray reflects from both the front and back boundaries of the film, and the reflected waves interfere.

EXAMPLE 37–6 The soap bubble shown in cross section in Fig. 37–17 has thickness t and index of refraction n. Light of wavelength λ in air falls vertically on the bubble and is reflected back. (a) Express the condition for constructive interference for the reflected light. (b) If $t = 400$ nm and $n = 1.3$, what color or colors will interfere constructively in the reflected light?

Strategy (a) There is constructive interference when $\phi = 2\pi m$, where m is an integer. To find the value of ϕ, note that when the incident light in Fig. 37–17 is vertical, distance $P_1P_4 = 0$. Light reflects at P_1 and P_2, undergoing a 180° phase change only at P_1, where the index of refraction of the medium on the far side—the soap film—is greater than that of air. The path-length difference is $\Delta L = 2t$, and the phase difference $\phi_{\Delta L}$ between the two reflected waves due to ΔL is found from Eq. (37–8) in terms of the wavelength λ_n in the soap film:

$$\frac{\phi_{\Delta L}}{2\pi} = \frac{2t}{\lambda_n} = \frac{2tn}{\lambda}.$$

The overall phase difference between the two reflected waves is then $\phi = \pi + \phi_{\Delta L}$, where π appears as an additive factor because of the 180° phase change at P_1.

Working It Out We have

$$\phi = \pi + \phi_{\Delta L} = \pi + \frac{4\pi tn}{\lambda} = 2\pi m.$$

Thus

$$\text{for constructive interference: } 4nt = (2m - 1)\lambda, \quad m = 1, 2, 3, \ldots. \tag{37–16}$$

Strategy (b) We need only solve the condition for constructive interference [Eq. (37–16)] for λ.

Working It Out Given $t = 400$ nm and $n = 1.3$, we have

$$\lambda = \frac{4nt}{2m - 1} = \frac{4(1.3)(400\text{ nm})}{2m - 1} = \frac{2100\text{ nm}}{2m - 1}.$$

For $m = 1$ through $m = 4$, these values of λ are

$$\lambda \cong 2100\text{ nm}, 700\text{ nm}, 420\text{ nm}, 300\text{ nm}.$$

Only the wavelengths 700 nm (red) and 420 nm (violet) are in the visible spectrum and these are the colors that interfere constructively in the reflected light.

What Do You Think? Estimate the wavelength of the color, if any, that is missing between the maxima at 700 nm and 420 nm.

EXAMPLE 37–7 A thin film of water, $n_2 = 1.33$, floats on cinnamon oil, which is denser than water and has index of refraction $n_3 = 1.65$. White light reflected at 45° has a maximum intensity for a wavelength around 600 nm. What is the minimum possible thickness of the film?

Setting It Up Figure 37–18 illustrates the paths of the two reflected rays that arrive in parallel at a distant point.

Strategy *Both* reflected rays undergo a phase shift of 180°, so that no net phase difference is associated with reflection. There is still a phase shift associated with different path lengths for the two rays—the phase shift ϕ_1 from the additional path P_1P_4 of ray 1,

$$\frac{\phi_1}{2\pi} = \frac{P_1P_4}{\lambda};$$

and the phase shift ϕ_2 for the additional path $P_1P_2 + P_2P_3$ of ray 2,

$$\frac{\phi_2}{2\pi} = \frac{P_1P_2 + P_2P_3}{\lambda_{H_2O}} = \frac{(P_1P_2 + P_2P_3)n_2}{\lambda}.$$

Note that the relevant wavelength for ray 1 is λ, the wavelength in air ($n_1 = 1$), whereas the relevant wavelength for ray 2 is $\lambda_{H_2O} = \lambda/n_2$. It is the difference $\phi_2 - \phi_1$ that enters into the net phase difference between the two waves. The geometry necessary to calculate the path lengths is shown in Fig. 37–18. Once we know the phase difference, the usual conditions relate it to constructive and destructive interference; we will want to solve the condition for a first maximum to find the thickness t.

Working It Out The net phase difference is

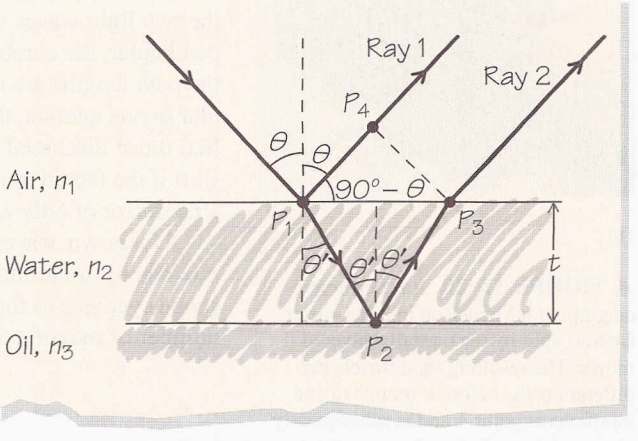
$$\phi = \phi_2 - \phi_1 = (P_1P_2 + P_2P_3)\frac{2\pi n_2}{\lambda} - (P_1P_4)\frac{2\pi}{\lambda}.$$

The incident ray enters at an angle θ perpendicular to the surface and is either reflected at angle θ or refracted into the water at angle θ'. We note that $P_1P_2 = P_2P_3 = t/(\cos\theta')$. Also, $P_1P_4 = P_1P_3\cos(90° - \theta) = (2t\tan\theta')\cos(90° - \theta)$. The phase difference is then

$$\phi = \left(\frac{2t}{\cos\theta'}\right)\frac{2\pi n_2}{\lambda} - (2t\tan\theta')\cos(90° - \theta)\frac{2\pi}{\lambda}.$$

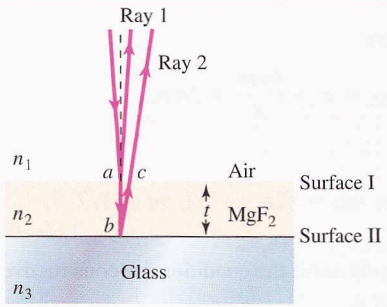
We solve the equation for t, the film thickness:

$$t = \frac{\lambda\phi}{4\pi}\frac{1}{(n_2/\cos\theta') - \tan\theta'\cos(90° - \theta)}.$$



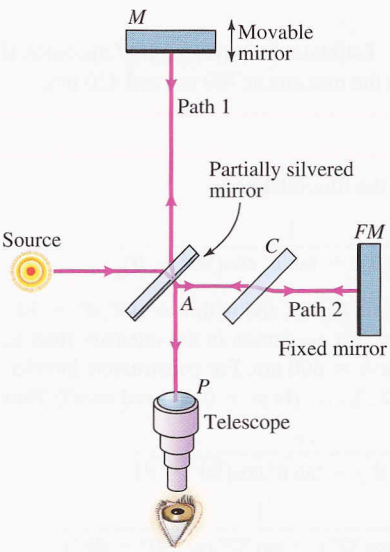
From Snell's law, $\sin\theta' = (\sin\theta)/n_2$, and with $\theta = 45°$, $\theta' = 32°$. The problem states that there is a maximum in the intensity (that is, constructive interference) for $\lambda = 600$ nm. For constructive interference, $\phi = m(2\pi)$, $m = 1, 2, 3, \ldots$. (Is $m = 0$ allowed here?) Thus

$$t = \frac{\lambda m(2\pi)}{4\pi}\frac{1}{(n_2/\cos\theta') - \tan\theta'\cos(90° - \theta)}$$

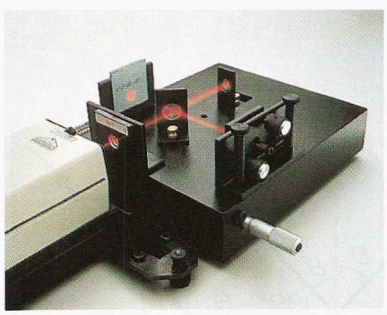


$$= \frac{600\text{ nm}}{2}m\frac{1}{(1.33/\cos 32°) - \tan 32°\cos(90° - 45°)}$$

$$= (266\text{ nm})m.$$



The minimum film thickness, for $m = 1$, is 266 nm.



▲ FIGURE 37–18

▲ **FIGURE 37–19** Thin coatings of materials can serve to reduce reflection by taking advantage of destructive interference. MgF_2 is often used as a coating. Here the incident and reflected rays are essentially vertical.

(a)

(b)

▲ **FIGURE 37–20** (a) Schematic diagram of a Michelson interferometer. Light is split by the partially silvered mirror. The resulting light travels two different paths before it returns to and interferes at point *A* and is subsequently observed through the telescope. (b) A modern Michelson interferometer.

THINK ABOUT THIS. . .

WHY DO SOME EYEGLASSES REFLECT LIGHT WHILE OTHERS DON'T?

The lenses of many eyeglasses, cameras, and other optical devices are coated with a thin layer of material whose purpose is to reduce the intensity of the reflected light through destructive interference. Many optical devices have multiple lenses, and if each lens typically reflects 4 percent of the energy of incident light, there may be an intolerable loss of light that is meant to be transmitted.

If light is reflected directly back from both surfaces in Fig. 37–19, and if the coating material has an index of refraction between that of air and the glass beneath it, there is a phase change in each reflection. Destructive interference will occur when the difference $2t$ in optical path lengths is a half-integer multiple of the wavelength λ_n within the coating and t is the thickness of the coating; in other words,

$$2t = \left(m + \frac{1}{2}\right)\lambda_n = \left(m + \frac{1}{2}\right)\frac{\lambda}{n}. \qquad \text{(AB–1)}$$

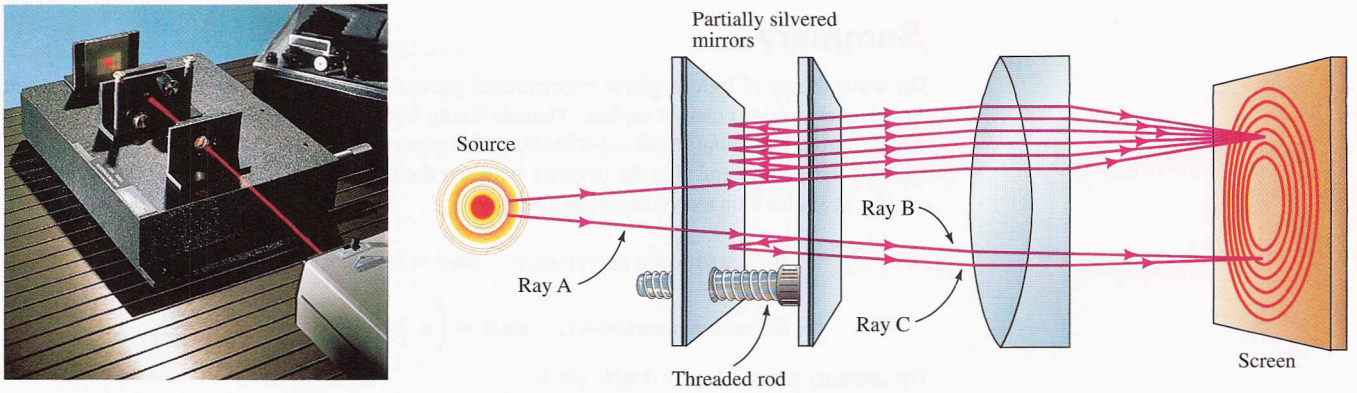
The coatings are applied as thinly as possible (that is, for $m = 0$). For $m = 0$ the coating thickness must be

$$t = \frac{\lambda}{4n}, \qquad \text{(AB–2)}$$

what is called a *quarter-wave* thickness. Of course, there can be destructive interference for only one wavelength in the visible range of light. A 100-nm thickness of MgF_2, a material commonly used to coat glass lenses, reduces reflectivity at 550 nm, in the middle of the visible range. The reflected light consists of red and blue light, which explains why such lenses have a purple cast to them. Antireflective coatings also increase the intensity of the transmitted light, and for this reason they are used to coat solar cells (components of solar batteries).

Sometimes we want to *increase* the intensity of reflected light. Lasers require mirrors that reflect light strongly at their operating wavelengths. For this purpose, a single coating must have thickness $t = \lambda/2n$, so that there will be constructive interference between the two reflected light waves. Multiple coatings are even more effective in increasing the reflected intensity. It is possible in this way to reflect more than 99 percent of the energy.

*37–4 Interferometers



Optical interferometers are devices that utilize the interference between light waves to measure quantities such as wavelength, small path-length differences, wave speeds, and indices of refraction, all to high precision. Figure 37–20a is a schematic diagram of one type of optical interferometer called the **Michelson interferometer** (Fig. 37–20b). In this device, developed by Albert Michelson in the 1880s, a light source is split by a beam splitter — for example, a partially silvered mirror—into two coherent waves that may travel different distances or through different media before they rejoin and interfere.

Monochromatic light from the source in Fig. 37–20a is split at the mirror at point *A*. The two beams then travel along paths 1 and 2 before they rejoin at *A*. The recombined beam is formed from the superposition (and therefore interference) of the two beams that arrive at *A*. The element *C* (a *compensator*) is added to make sure that the two light waves travel through the same amount of glass. If the path lengths are exactly the same, the two light waves will constructively interfere. With mirrors *M* and *FM* precisely perpendicular, the combined beam undergoes constructive interference and is bright. But if the path lengths are not precisely the same because the mirrors are not quite perpendicular to one another, the interference will produce alternating dark and bright lines, much like those discussed in Example 37–3, between two flat glass plates. The fringes will shift if the (screw-mounted) movable mirror is moved slightly. A movement of the movable mirror of only $\lambda/2$ will cause a shift from one fringe maximum to the adjacent one.

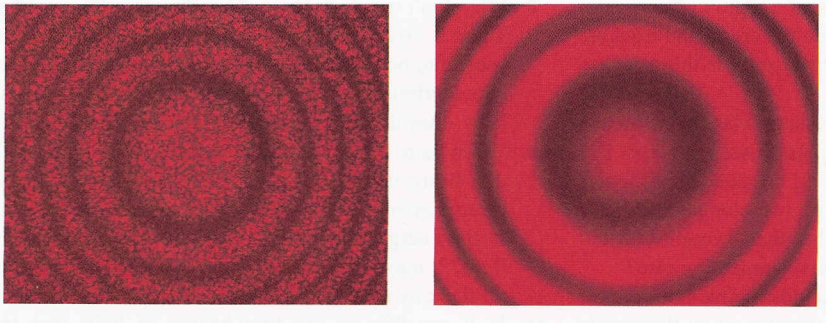
Unknown wavelengths of light can be determined by accurately measuring the movement of the mirror and counting the number of maxima that pass across the telescope eyepiece as the mirror moves. If ΔL is the mirror movement distance and N is the number of maxima that pass across the eyepiece for this movement, then

$$N = \frac{\Delta L}{\lambda/2} = \frac{2\Delta L}{\lambda},$$

or solving for the unknown wavelength,

(a) (b)

▲ **FIGURE 37–21** (a) A Fabry–Perot interferometer. (b) Schematic diagram of a Fabry–Perot interferometer. Some of the light is transmitted and some reflected at the partially silvered mirrors. Rays B and C may constructively or destructively interfere, depending on the extra path length of ray C. Multiple reflection is an important part of the operation of the Fabry–Perot interferometer and serves to make the maxima sharper and more easily locatable.



$$\lambda = \frac{2\Delta L}{N}. \qquad (37\text{–}17)$$

If the wavelength is known, the same technique can be used to measure very small distances, in this case, ΔL.

The Fabry–Perot Interferometer

The most widely used interferometer is the *Fabry–Perot interferometer* (Fig. 37–21a), invented by Charles Fabry and Alfred Perot and illustrated schematically in Fig. 37–21b. It contains two end plates (partially silvered mirrors) that are precisely parallel and flat and are connected by a rod that allows the distance between the plates to be changed smoothly by a screw thread. An incident laser beam (ray A) is partly transmitted (ray B) and partly reflected; the reflected ray is in turn partly reflected and partly transmitted to make ray C, which interferes with ray B. The major improvement incorporated into the Fabry–Perot interferometer is that the plates are silvered such that multiple reflections are possible, and the interference is between the multiple rays formed by these multiple reflections. The multiple reflections reinforce the regions of constructive interference, making the maxima stronger. The maxima become easier to locate and the pattern becomes more distinct. It then becomes easier to tell when these maxima have been shifted, so distances can be measured with more precision. If we compare Figs. 37–22a and 37–22b—interference patterns produced by a Michelson and by a Fabry–Perot interferometer, respectively—the greater sharpness of the Fabry–Perot pattern is evident.

To measure distances with a Fabry–Perot interferometer, we begin with the plates at known positions and then count the number of interference maxima changes (fringes) as the plate separation varies by the desired distance. Because the location of maxima can be determined to great accuracy, the distance change can be measured to within an error of only a fraction of a wavelength of the laser light. The fringe counting is done automatically by electronic sensors. The number of fringes involved in distances of about 1 m is on the order of the number of wavelengths of visible light contained in 1 m, around 50 million.

(a) (b)

◀ **FIGURE 37–22** The interference patterns produced by (a) a Michelson interferometer and (b) a Fabry–Perot interferometer. The Fabry–Perot fringes are noticeably sharper.

Summary

The wave theory of light explains experimental phenomena such as interference and diffraction that geometric optics cannot explain. Thomas Young was the first to substantiate the wave nature of light through his double-slit experiment, which produces interference maxima and minima. If λ is the wavelength and d is the distance between the (narrow) slits, there will be maxima and minima at angles θ on a distant screen given by

$$\text{for constructive interference:} \quad \sin\theta = n\frac{\lambda}{d}, \quad n = 0, \pm 1, \pm 2, \ldots; \tag{37–3a}$$

$$\text{for destructive interference:} \quad \sin\theta = \left(n + \frac{1}{2}\right)\frac{\lambda}{d}, \quad n = 0, \pm 1, \pm 2, \ldots. \tag{37–3b}$$

The intensity pattern for the double slit is

$$I_{\text{net}} = 4I_0 \cos^2\left(\frac{\pi d}{\lambda}\sin\theta\right). \tag{37–14}$$

where I_0 is the maximum intensity for a single slit and I_{net} is the total observed intensity.

We have looked at a variety of common situations where the geometry and other properties of reflecting surfaces results in characteristic interference patterns. Newton's rings appear when light shines vertically down upon a curved glass that rests on a flat piece of glass. The light reflecting from two surfaces interferes. For monochromatic light, alternating rings of bright and dark are observed. For sunlight, colored rings are observed. In both cases, the center is dark because the phase of an electromagnetic wave will change by 180° upon reflection when the wave moves from one medium to another of higher index of refraction. The condition for constructive interference in Newton's rings is

$$\Delta L = \left(m + \frac{1}{2}\right)\lambda, \quad m = 0, \pm 1, \pm 2, \ldots, \tag{37–15}$$

where ΔL is the difference in path length of the interfering rays.

Thin-film interference is responsible for the colors observed in bubbles and oil slicks. For light falling perpendicularly from air onto the surface of the film of thickness t, the condition for constructive interference is

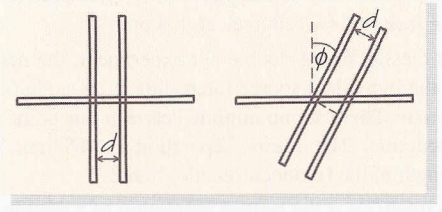
$$4nt = (2m - 1)\lambda, \quad m = 1, 2, 3, \ldots, \tag{37–16}$$

where n is the index of refraction of the film. Light reflected from the two surfaces of the thin film interferes destructively for some wavelengths but not for others. If the incident light is white, the wavelength undergoing destructive interference is subtracted from the reflected light. This phenomenon is used in the application of thin coatings to lenses and other optical surfaces in order to reduce the intensity of reflected light.

Optical interferometers utilize the interference of light waves to measure distances with great precision. Two interferometers with practical applications are the Michelson interferometer and the Fabry–Perot interferometer.

Understanding the Concepts

1. Why is a laser a more practical source of coherent light than a bright lightbulb and a series of slits?
2. In Fig. 37–5b, the intersections represent places where constructive interference occurs on the crests of the advancing wave fronts. The troughs also reinforce each other between the circles. Do such reinforced troughs also represent a region of constructive interference? In the regions between the crests and troughs, where each wave is zero, the waves add to zero. Is this a region of constructive interference?
3. In Fig. 37–5b, the intersections represent sites where constructive interference occurs. Will these bright spots be seen in air, or is a screen required for us to see the alternating bright and dark spots?
4. We refer to lines, or fringes, when we use two elongated slits for interference. If we used two holes rather than two slits, would we still observe lines or would we observe something else?
5. Why does a single thin coating produce destructive interference in the reflection of light for only one wavelength in the visible region of light?
6. When we look up, stars twinkle and planets do not, while astronauts in orbit do not see any twinkle at all. Can you explain this?
7. In discussing interference from thin films, we have mentioned viewing the reflected light from afar. Why? Is there no interference if the light is viewed from close to the film?
8. Why don't we study (or see) interference effects with thick films?
9. There is no light intensity and therefore no energy at an interference minimum from two sources of coherent light. Yet each of the two interfering sources alone would produce energy at that point. Why does this situation not violate the conservation of energy?
10. When there is a minimum in the intensity of light reflected from thin films, there is less energy in the reflected beam. Does this mean that energy conservation is violated? If not, what happens to the energy that would otherwise have been in the reflected light? It may be helpful to think about what the light that passes all the way through a Newton's rings apparatus must look like.
11. Is it possible to use two beams of light that travel in the z-direction—one polarized with its electric field vector aligned



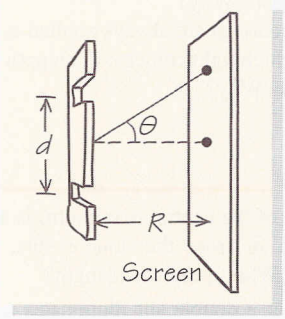
along the x-direction, and the other polarized with its electric field vector aligned along the y-direction—to make an interference pattern?

12. We estimated in Example 37–5 that almost 50 bands of constructive interference can occur along the glass plates. Can all these bands be observed? Will the color still appear blue?
13. The discussion of antireflective coatings suggested that the index of refraction of the coating material should be in between that of air and that of the glass that it coats. Why? (See Problem 52.)
14. In our discussion of Newton's rings, we did not consider light that reflects from the top surface of the curved piece of glass, nor that from the bottom surface of the bottom plate. Why not?
15. In Example 37–4, a second antenna has been constructed whose signal is as strong as that of the first, yet the signal you receive weakens. How is this consistent with the conservation of energy?
16. For small angles, the maxima for the double slit interference pattern (see Fig. 37–7) are equally spaced. Is this true for larger angles, ones for which the small-angle approximations are no longer useful?
17. How is it possible to use interferometry to measure a small fraction of a wavelength when the distance between maxima represents a full-wavelength difference?
18. When you look into a good-quality camera lens, you will see a color tint (generally purple). What is the origin of the observed color?
19. It might appear that a given antireflective coating will work for any surface to which it is applied, provided that the thickness of the coating is given by Eq. (AB–2) on p. 1042; however, this is not true. Why not? You can go back to the discussion of the energy in reflection (in Chapter 36) to find out why the index of refraction of the surface to be coated must be considered.
20. Why is it important that each slit be as narrow as possible in the double-slit experiment?
21. When you look out of a window with mini-blinds, you don't see interference effects. Why?
22. Antireflective coatings are always applied to the front surface—the side from which light comes—of an optical element, never to the back surface. Why?

Problems

37–1 Young's Double-Slit Experiment

1. (I) A coherent source of monochromatic light of unknown wavelength shines on double slits separated by 0.20 mm. Bright spots separated by 0.70 cm appear on a screen 3.0 m away. What is the wavelength of the light?
2. (I) Red light ($\lambda = 630$ nm) shines on a double slit with slit separation $d = 0.25$ mm. How far away from the central axis will the first minimum be on a screen 2.0 m from the double slit?
3. (I) A double-slit interference experiment is done in a ripple tank. The slits are 3.5 cm apart, and a viewing screen is 0.8 m from the slits. The wave speed of the ripples in water is 0.12 m/s, and the frequency of the vibrator producing the ripples is 12 Hz. How far from the centerline of the screen will the first maximum be found?
4. (I) The source for a double-slit experiment has a wavelength of 525 nm. The slits are a distance of 120 μm apart, and a screen is 40 cm away from the wall that contains the slits. How far from the center will the third maximum occur?
5. (I) Light of wavelength 590 nm falls on a wall with two slits 0.12 mm apart. A photographic plate is placed at a distance R from the wall. The $n = 3$ maximum appears 18 cm from the central maximum on the photographic plate. How far is the plate from the wall?
6. (I) Two small speakers are 65 cm apart. They broadcast a signal of frequency $f = 380$ Hz; the signals are in phase. A sensitive microphone is placed 2.5 m from the midpoint of the two speakers, on the line perpendicular to the line joining the two speakers. Is the intensity of sound a minimum or a maximum there? How far would the microphone have to be moved along an arc of radius 2.5 m centered on the midpoint in order to pick up a signal of maximum intensity?
7. (II) A double-slit experiment produces fringes on a distant screen. How does the linear separation between the bright maxima on the screen change when (a) the wavelength of the light doubles? (b) The separation between the slits doubles? (c) The distance between the slits and the screen doubles? (d) The intensity of the light doubles?
8. (II) A laser emitting light with $\lambda = 595$ nm shines on a double slit with a separation of 0.15 mm and produces interference fringes. If the maxima are separated by 0.50 cm, how far away is the screen on which the fringes are observed?
9. (II) In a double-slit experiment to determine an unknown wavelength of light, the measured total distance between 16 maxima (8 on each side of the central maximum) is 16.8 cm. The screen is located 3.45 m from the double slits, whose centers are 0.21 mm apart. What is the wavelength?
10. (II) Suppose that a double slit illuminates a distant screen. The light from sources S_1 and S_2 has come from a single monochromatic source S that is one-half wavelength closer to S_1 than to S_2. Use the geometry of Fig. 37–8 for the relation between the screen and the double slit to express the locations of maxima and minima. Is the point at $\theta = 0$ a maximum, a minimum, or neither?
11. (II) A double slit with variable separation d is superimposed on a single slit at right angles to the double slit, leading to a two-point source (Fig. 37–23). Then the double slit is rotated relative to its original direction by an angle ϕ. If light of wavelength λ shines through the system, determine the position of the interference maxima on a screen a distance R away. Do the fringes move inward or outward as ϕ increases?



▲ **FIGURE 37–23** Problem 11.

12. (II) Two microwave sources are 18 cm apart. They radiate coherently with a frequency of 3.7×10^{10} Hz but with a phase difference α between the two sources. A microwave detector is moved along a line 1.6 m away from the sources. How far from the center ($\theta = 0$) will the first maximum occur, as α varies from 0 to 2π?
13. (II) Two sources radiate at almost identical frequencies f and $f + \Delta f$. How fast will the interference fringes on a screen a distance R away move, assuming that the sources are a distance d apart and that the velocity of wave propagation is v? Evaluate the result for two sources in a ripple tank ($f = 10$ Hz, $\Delta f = 10^{-6} f$, $R = 1$ m, $d = 5$ cm, $v = 0.15$ m/s). Do the same for an optical double-slit experiment ($f = 4.7 \times 10^{14}$ Hz, $\Delta f = 10^{-6} f$, $R = 1$ m, $d = 0.25$ mm, $v = 3.0 \times 10^8$ m/s). What can you conclude about the degree of coherence in the two cases?

14. (II) Light of two different wavelengths, λ_1 and λ_2, is incident on a double slit. On a distant screen, the twentieth maximum of λ_1 overlies the nineteenth minimum of λ_2. Show that the relative difference $(\lambda_1 - \lambda_2)/\lambda_1$ is small, and find a numerical value for this ratio.

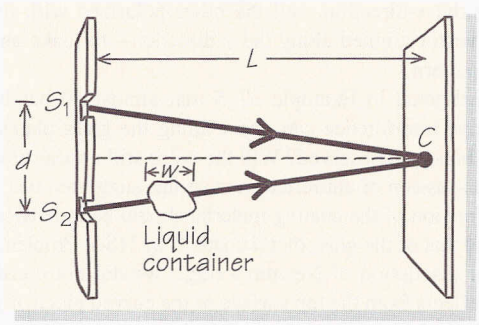
15. (II) Consider two narrow slits illuminated from behind; the light impinges on a screen that is close rather than far (Fig. 37–24). Assume that the wavelength of the light λ is comparable to the separation d between the slits and to the screen distance R. The angle θ is measured from the point midway between the slits. (a) Show that the point corresponding to $\theta = 0$ continues to be a maximum of the pattern of light that reaches the screen. (b) At what angle θ is there a first maximum? (c) Show that your result for part (b) reduces to the distant-screen result for $R \gg d$ (and $R \gg \lambda$).

▲ FIGURE 37–24 Problem 15.

37–2 Intensity in the Double-Slit Experiment

16. (I) Light of wavelength 500 nm shines on two slits separated by 0.3 mm. Find the intensity ratio I/I_0 at positions 0.6 mm and −0.5 mm from the central maximum on a screen 1 m from the slits.

17. (I) Two coherent light sources of the same wavelength, each with intensity of 1.0×10^3 W/m^2, interfere at a point at which the phase difference is 60°. What is the net intensity of light at this point?



18. (I) The net intensity from two coherent sources of equal strength is exactly twice the intensity due to either source at a certain point in space. What is the phase difference between the waves arriving from the two sources at that point?

19. (I) In a classic Young double-slit experiment, the net intensity is 1/4 of the individual source intensities at an angle of 27° off the central axis. There are no minima between this point and the central maximum. The source separation is 485 nm. What is the wavelength of the (monochromatic) light?

20. (I) The intensity at the central maximum of a double-slit diffraction pattern is I_{max}. If the wavelength of the light is 490 nm and the nearest location of maximum intensity is 1.7×10^{-3} rad from the central axis, what is the separation of the slits?

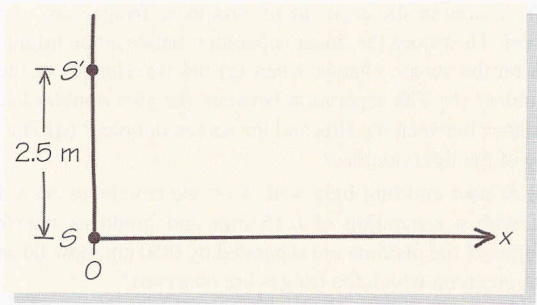
21. (II) Use the result of Young's classic double-slit experiment to find the average intensity on the screen by integrating the intensity over the surface of the screen. This result should be twice the average intensity from one slit alone and shows that energy conservation holds even when there is interference.

22. (II) Consider the double-slit arrangement shown in Fig. 37–25. The center of the screen C is a point of constructive interference. A container of thickness w, holding a liquid of refractive index n, is placed in the path of the ray from slit S_2 to C. Plot, qualitatively, the intensity of light at C as a function of w, assuming that the separation between the slits is d, and that the screen is a distance L from each slit. Ignore any intensity loss due to absorption in the fluid or at the fluid boundaries.

▲ FIGURE 37–25 Problem 22.

23. (II) The *angular width* of a maximum of the intensity pattern due to double-slit interference is defined to be the angular separation $\Delta\theta$ of the points where the intensity is half its maximum value. Express the width of the central maximum in terms of the wavelength and the slit separation. Are the widths of all the maxima the same?

24. (II) A He–Ne laser, $\lambda = 633$ nm, shines on double slits separated by 0.35 mm. At what minimum angle θ is the intensity 50 percent of the maximum? If the screen is located 1.8 m away, what is the distance between the two angles on either side of the maximum for which this intensity occurs? This distance is the *full width at half maximum* of the central peak.



25. (II) Two point sources of radio waves, 12 m apart, radiate in phase with a frequency of 3.8×10^7 Hz. (a) If the average intensity of each single source is 5.0×10^{-4} W/m^2 at a certain distance, what is the direction in which the combined intensity is maximized? (b) What is the magnitude of the maximum intensity? (c) At what angle will the intensity have fallen to half its maximum value?

26. (II) Suppose that the two slits in a double-slit experiment are not exactly the same size, so the electric field from one of the slits at a particular point P on the screen is $E_1 \sin(\omega t)$, whereas the other one is $E_2 \sin(\omega t + \phi)$, where the phase ϕ is due to the path-length difference [compare Eq. (37–7a, b)]. Show that the intensity at P is given by

$$\langle I_{net} \rangle = \langle I_1 \rangle + \langle I_2 \rangle + 2\sqrt{\langle I_1 \rangle \langle I_2 \rangle} \cos\phi,$$

where $\langle I_1 \rangle$ and $\langle I_2 \rangle$ are the intensities due to the light from the individual slits. [*Hint*: You will need $\langle \sin^2(\omega t) \rangle = \frac{1}{2}$; $\langle \sin(\omega t) \cos(\omega t) \rangle = 0$.]

27. (II) Point sources S and S' radiate with the same intensity and the same frequency, corresponding to a wavelength of 0.020 m (Fig. 37–26). They are 45° out of phase and 2.5 m apart. Plot the intensity as a function of distance along the x-axis for values of x much larger than the source separation.

▲ FIGURE 37–26 Problem 27.

28. (III) Find an expression for net intensity for the situation in Problem 27 in terms of x, the wavelength (λ), and the source separation (d). Take into account that the electric field of the electromagnetic wave decreases as the inverse power of the distance between the source and the receiver, and that the distance between source S and any point on the axis is different from the distance between source S' and that point. [*Hint*: Use the results of Problem 26.]

37–3 Interference from Reflection

29. (I) Consider the two glass plates of Example 37–5 and the configuration of Fig. 37–11. The plates are 25 cm long. When light of wavelength 656 nm from hydrogen shines down perpendicularly to the glass, 102 interference fringes appear. How thick is the wire that separates the two glass plates at one end?

30. (I) Two rectangular pieces of glass are laid on top of one another on a plane surface. A thin strip of paper is inserted between them at one end, so that a wedge of air is formed. The plates are illuminated by perpendicularly incident light of wavelength 615 nm, and 17 interference fringes per centimeter-length of wedge appear. What is the angle of the wedge?

31. (I) For what thicknesses of a soap bubble ($n = 1.3$) that are less than 500 nm thick will blue light ($\lambda = 420$ nm) interfere constructively?

32. (I) A thin, uniform film of oil is spread on a glass plate. The oil has an index of refraction between that of air and of the glass. Write the condition for constructive interference for light of wavelength λ in air perpendicularly incident from air and reflecting back into the air from the air–oil–glass interface.

33. (II) You are an inventor who has never heard of tinting, and you want to use a plastic film of index of refraction 1.32 to place on the outside of glass to increase reflection, thereby keeping the intensity of the transmitted light down. What is the minimum thickness of the film that will accomplish this for light of average wavelength 550 nm? As this might be too thin to work with, suggest two other thicknesses that would work.

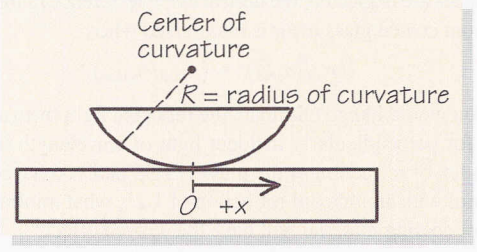
34. (II) A gardener accidentally spills oil (index of refraction 1.38) into a swimming pool. The oil spreads over the surface in a uniform way. (a) As you look directly down at the surface, you see light whose color suggests that the wavelength 520 nm is not being reflected. What is the minimum thickness of the oil film? (b) What will be the primary transmitted light frequency observed by someone swimming under water in the pool?

35. (II) A curved piece of glass in the form of the cap of a sphere of radius R is placed on a plane surface of glass. What will be the radius of the first dark Newton ring for light of wavelength λ? [*Hint*: It follows from plane geometry that, for a spherical cap, the radius of the circle bounding the cap, r, is related to the radius of the sphere R and h, the maximum thickness of the cap, by the relation $r^2 = h(2R - h)$, which can be approximated by $2Rh$ for $h \ll R$.]

36. (II) When two flat glass plates are placed on top of one another and a slip of paper is inserted between them at one edge, a thin wedge filled with air is produced between them. Interference bands form in reflection when monochromatic light falls vertically on the plates. Is the first band near the edge where the plates are in contact light or dark? Why?

37. (II) A wedge of air is formed between two glass plates that are 8.0 cm long, with one edge touching, and the other separated by a wire that is 1.0 mm in diameter. How far apart are the maxima for the reflected light with $\lambda = 655$ nm?

38. (II) Two plane glass plates touch at one end and are separated at the other by a wire, so that they form a wedge of air. When light with wavelength $\lambda = 590$ nm is reflected by the combination, 110 dark stripes appear. What can you say about the diameter of the wire?



39. (II) In a standard Newton's rings experiment, there is a dark spot where the convex surface touches the flat plate. Light of wavelength 500 nm is perpendicularly incident on the system. The convex lens is pulled slowly away from the flat plate until the minimum of the convex lens is 0.25 mm from the flat plate. A series of maxima and minima will appear at the center as the lens moves. How many maxima pass? Do the rings appear to move in to the center or away from the center?

40. (II) Consider the Newton's rings apparatus of Problem 39, with the minimum of the convex lens 0.85 mm from the flat plate. Water is poured into the space between the plates. Do the rings appear to move in to the center or away from the center, and how many maxima pass?

41. (II) A lens whose curved surface is part of a sphere of radius 5.0 m is placed over a flat glass plate and Newton's rings are observed. Determine the diameter of the fourth and seventh dark fringe for a wavelength of 520 nm.

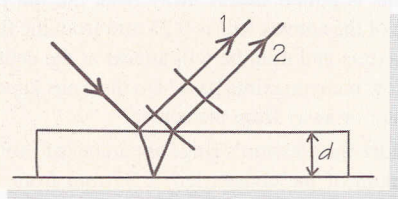
42. (II) Light with a wavelength of 560 nm gives rise to a system of Newton's rings formed with a convex lens resting on a plane surface. The twentieth bright ring is at a radial distance of 0.98 cm. What is the thickness of the air film there, and what is the radius of curvature of the lens surface?

43. (II) The radius of curvature of a convex surface used for a Newton's rings apparatus is R (Fig. 37–27). Find the position x, measured from the point where the convex surface touches the flat surface, of the nth dark ring for light of wavelength λ perpendicularly incident from above.

▲ **FIGURE 37–27** Problem 43.

44. (II) Constructive interference occurs when a soap bubble reflects light of wavelength 460 nm. What is the minimum thickness of the bubble if its index of refraction is 1.35?

45. (II) What minimum thickness of antireflective coating of MgF_2 is required to minimize the reflection of red light at 650 nm (the wavelength in air)? For MgF_2, $n = 1.38$.



46. (II) For light emitted by a He–Ne laser, $\lambda = 633$ nm, what *nonzero* minimum thickness of MgF_2 coating allows *maximum* reflectivity?

47. (II) The reflected light from an oil film floating on water shows constructive interference for light of wavelengths 434 nm and 682 nm incident along the normal. The index of refraction of the oil is $n = 1.51$. What is the film's minimum possible thickness?

48. (II) The reflected light from an oil film floating on water shows destructive interference for light of wavelengths 550 nm, 610 nm, and 685 nm incident along the normal. The index of refraction of the oil is $n = 1.40$. What is the film's minimum possible thickness?

49. (II) White light reflected at perpendicular incidence from a uniform soap film has an interference maximum at 666 nm and a minimum at 555 nm with no minima between 666 nm and 555 nm. If $n = 1.34$ for the film, what is the film thickness?

50. (II) A thin layer of CaF_2 ($n = 1.41$) is deposited onto glass, with $n = 1.52$. The layer is viewed in reflected light at 45° using a white light source (Fig. 37–28). For what layer thicknesses will light of 640 nm show constructive interference? Are there possible thicknesses for which light of 480 nm interferes constructively as well?

▲ **FIGURE 37–28** Problem 50.

51. (II) Light is perpendicularly incident on an oil film with $n = 1.2$, suspended in air. (a) If green light ($\lambda = 550$ nm) is reflected back most strongly, what is the minimum thickness of the film? (b) If n were increased, would the maximally reflected light have a longer or shorter λ? (c) If the film were suspended on the interface between water ($n = 1.33$) and air, what would be seen?

52. (II) We mentioned in Chapter 36 that when light is perpendicularly incident from a medium of index of refraction n_1 and refracts into a medium of index of refraction n_2, then the intensity of the reflected light, I_r, is related to the incident intensity, I_0, by $I_r/I_0 = (n_2 - n_1)^2/(n_2 + n_1)^2$. In order for a coating to eliminate reflections, it is not enough that the light reflecting from the two surfaces differs in phase by 180°; the interference is totally destructive only if the amplitudes are equal. Show that, when multiple reflections at interfaces are neglected, the destructive interference in light reflecting from coated glass in air is maximized when

$$(n_{air}/n_{coat}) = (n_{coat}/n_{glass}).$$

53. (II) You would like to eliminate the reflected light from a flat glass pane for perpendicularly incident light of wavelength 600 nm. If the index of refraction of the glass is 1.55 and you have a coating material with an index of refraction of 1.25, what minimum thickness of coating material will have the desired effect?

54. (II) Blue light, $\lambda = 485$ nm, is perpendicularly incident on a vertical soap film held in a plane. A sequence of bright horizontal bands appears in the reflected light (Fig. 37–16). Note the film is illuminated with white, not monochromatic, light. What is the rate of change with height of the thickness of the soap film if the horizontal bright bands are 0.6 cm apart? For the soap solution, $n = 1.36$.

55. (II) The material to be used for an antireflective coating has index of refraction of 1.25. How thick should the coating be to give the best result for $\lambda = 550$ nm and an angle of incidence of 30° with the normal?

*37–4 Interferometers

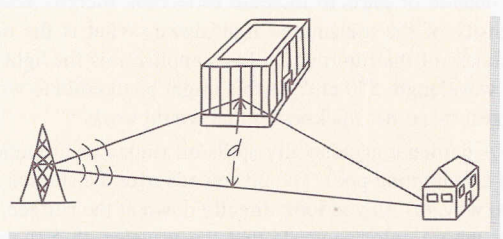
56. (I) Laser light with $\lambda = 633$ nm enters a Michelson interferometer. How many fringes will pass through the field of view if one of the mirrors is moved 0.10 mm?

57. (I) If the mirror of one arm of a Michelson interferometer is moved along the arm by 0.31 mm, 980 fringes traverse the field of view. What is the wavelength of the light used?

58. (II) A very sharp wedge of glass of index of refraction 1.55 is introduced perpendicularly in the path of one of the interfering beams of a Michelson interferometer illuminated by a narrow beam of light of wavelength 426 nm. This causes 750 dark fringes to sweep across the field of view. Calculate the thickness of the glass wedge at the point where the beam passes through it.

59. (II) Identical glass tubes, each 10 cm long, are placed in the two optical paths of a Michelson interferometer. Both of them are evacuated, then one is slowly filled with a gas until it reaches atmospheric pressure. During the filling time the pattern has moved by 90 fringes. What is the index of refraction of the gas?

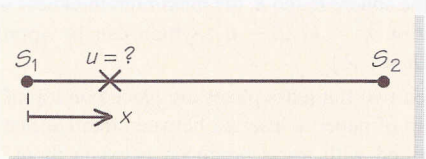
60. (II) A thin glass plate of index of refraction 1.58 is introduced into one of the beams of a Michelson interferometer. This causes a displacement of 25 fringes for light with $\lambda = 589$ nm. What is the thickness of the plate?



61. (II) A scientist wants to measure the wavelength of yellow light ($\lambda \cong 590$ nm) to a precision of 0.1 percent. The minimum motion of the movable mirror is 0.03 mm. What is the minimum number of fringe shifts that must be counted?

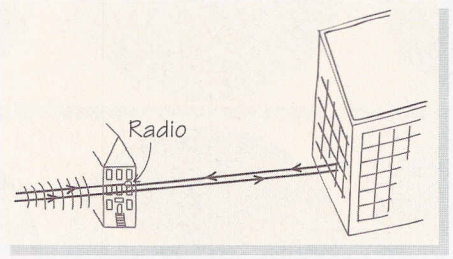
62. (II) A laser with light of wavelength 582.5 nm is used to calibrate a Fabry–Perot interferometer. As the screw controlling the position of one end plate rotates exactly 100 turns, 714 fringes are counted. Calculate the wavelength of another light source that shifts only 593 fringes for 100 turns of the screw.

General Problems



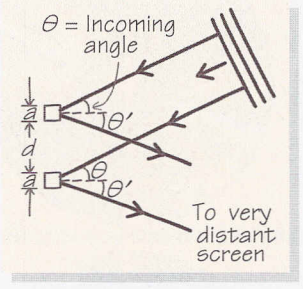
63. (II) Two ordinary lightbulbs S_1 and S_2 are 1 m apart, each emitting light waves with intensity I, mainly at a wavelength of 550 nm. What is the pattern of intensity on a screen 100 m away?

64. (II) AM radio waves with a wavelength of 480 m travel 13 km to your home. Halfway between the transmitting tower and your home, but off to the side, is a building that reflects radio waves; the reflected wave has no phase shift due to the reflection. How far off the direct line is the building if destructive interference occurs between the direct waves and the reflected waves (Fig. 37–29)?



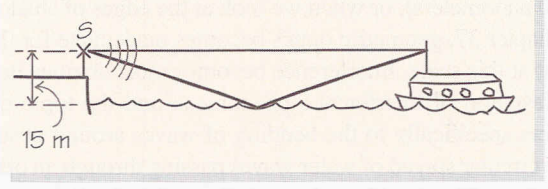
▲ **FIGURE 37–29** Problem 64.

65. (II) Two point sources of identical strength radiate in phase with the same frequency f. They are separated by a distance L. What is the energy density (discussed in Section 34–3) as a function of distance from one of the sources along the line that connects the sources in the central region, where the variation of the amplitudes with distance can be neglected (Fig. 37–30)?



▲ **FIGURE 37–30** Problem 65.

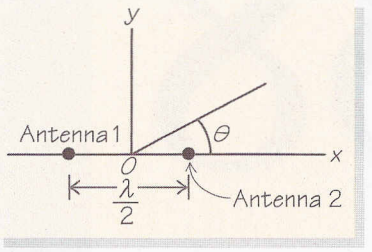
66. (II) You want to hear a radio station that broadcasts at 97.9 MHz. You live on a direct line between the antenna and a large building that acts as a mirror for the radio waves broadcast by the station; you are exactly 100 m from the building (Fig. 37–31, see next page). Calculate the intensity of the signal you receive in terms of the intensity you would receive if the building were not present. Assume that the reflection from the building is total, with no phase shift, and ignore any decrease of the signal with distance.



▲ **FIGURE 37–31** Problem 66.

67. (II) Coherent microwave radiation reflects from two identical obstacles (Fig. 37–32). Each obstacle, of size a, is much smaller than the wavelength of the radiation, λ, and much smaller than the obstacle separation d. Find an expression for the angles θ', defined in the figure, for which there are maxima on the distant screen.

▲ **FIGURE 37–32** Problem 67.



68. (II) A radio wave undergoes a phase shift of 180° when it reflects from the calm surface of the ocean. A ship in a calm port nearing a shore station receives a 230-MHz signal from the station's antenna. This antenna is located 15 m above the sea surface, as is the ship's receiving antenna. The direct and reflected signals interfere, and a succession of maxima and minima are heard in the interfering signal at the ship (Fig. 37–33). How far is the ship from the station the first time the signal passes through a minimum? How fast is the ship moving if the time between this first minimum and the next one is 170 s?

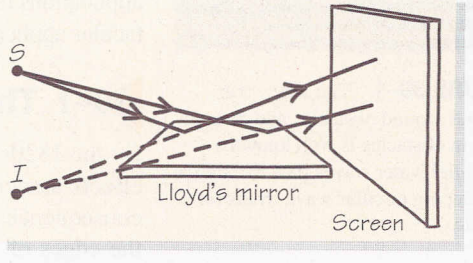
▲ **FIGURE 37–33** Problem 68.

69. (II) Sources S_1 and S_2 illuminate a distant screen; the distance to the screen is much larger than the separation between the sources. Each source emits light rays that are in phase at the sources, but the intensity I_1 of the light from S_1 is twice the intensity I_2 of the light from S_2. Give the ratio of the maximum to the minimum intensity of the light observed on the screen. (See Problem 26.)

70. (II) Figure 37–34 is an overhead view of two dipole radio antennas—vertical towers separated along the x-axis by a distance $\lambda/2$. This arrangement allows the radio signal to be beamed with greater intensities in some directions than in others, whereas either antenna alone would radiate its signal with the same intensity I_0 for any angle θ. (a) Find the intensity radiated by the antenna pair very far from the antennas as a function of θ, assuming that the signals of the two antennas are in phase. Describe the signal for all values of θ, from 0° to 360°. (b) The signal in the antennas is now 180° out of phase. How, if at all, does the distant intensity pattern change?

▲ **FIGURE 37–34** Problem 70.

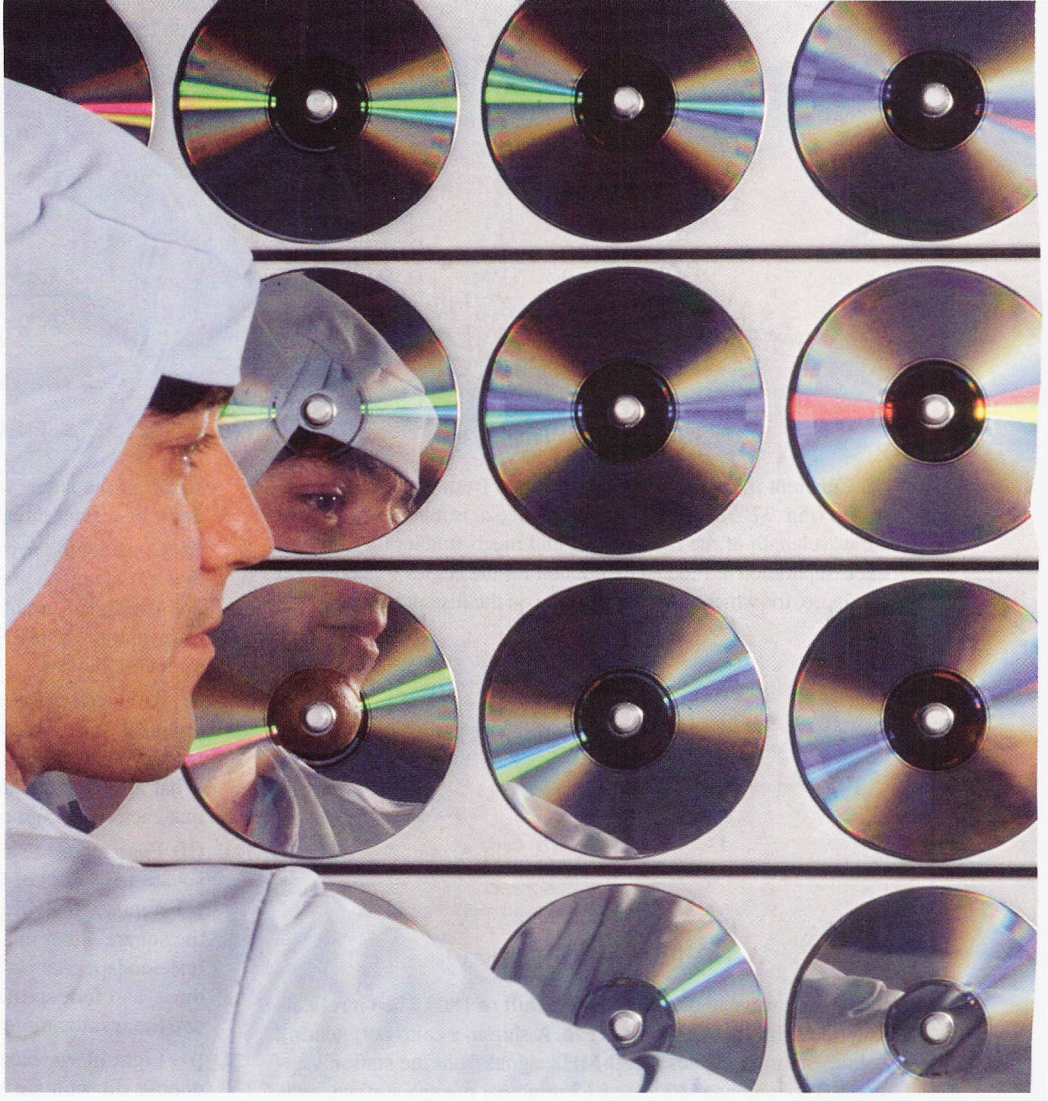
71. (II) Consider the pair of dipole antennas in Problem 70. Suppose that the antennas are separated by one-quarter wavelength and that the signal in antenna 1 lags the signal in antenna 2 by 90° (one-quarter cycle). Show that the signal has a maximum in one direction, not two.



72. (II) An interference experiment uses a triplet slit, with slit separations d. What are the positions of the maxima on a screen a distance R away, if light of wavelength λ shines through the slits. What are the intensities of the maxima in terms of the intensity that each slit would produce alone?

73. (II) Four identical loudspeakers are placed at the corners of a square with sides of length $\lambda/\sqrt{2}$. The loudspeakers emit sound coherently with wavelength λ. A listener is situated very far from the square along one of the diagonals. If the intensity with just one loudspeaker on is I_0, what are the intensities when two, three, and four speakers are on? In a table, list all combinations and the resultant intensities.

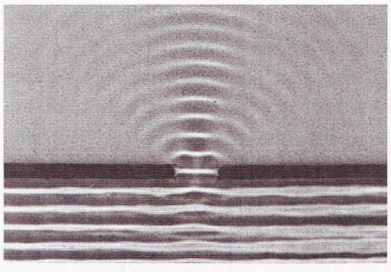
74. (II) Light of wavelength λ is incident at a normal angle θ_1 to a double slit with slit separation d. Show that if you observe the exit light at a normal angle of θ_2, interference peaks will be seen when $m\lambda/d = \sin\theta_1 + \sin\theta_2$, where m is an integer.



75. (III) Light of wavelength λ is incident on a slab of glass of thickness h and index of refraction n resting on a mirror. The ray makes an angle θ with the vertical. The light reflected at the top of the glass surface and that reflected at the mirror will interfere. For what angles will the interference be totally constructive? [For angles even slightly away from grazing incidence (see Problem 76), light undergoes no phase shift upon reflection by a conductor such as a mirror.]

76. (III) *Lloyd's mirror* is a mirror that reflects light at large angles of incidence from a point source to a screen (Fig. 37–35). As the angle of incidence nears 90° (a grazing angle), the source and image become close. (a) Will the direct light and reflected light interfere constructively or destructively in this limit? (b) Suppose that the (monochromatic) source is 20 cm from the center of the mirror and 0.50 mm above the plane of the mirror and that the screen is distant. What will the angular separation be between successive maxima of the interference pattern, where the angle is measured from the source point to the screen?

▲ **FIGURE 37–35** Problem 76.



Chapter 38

▶ The regular grooves in these compact disks act as diffraction gratings, which here exhibit maxima in reflection at angles that are different for light waves of different colors.

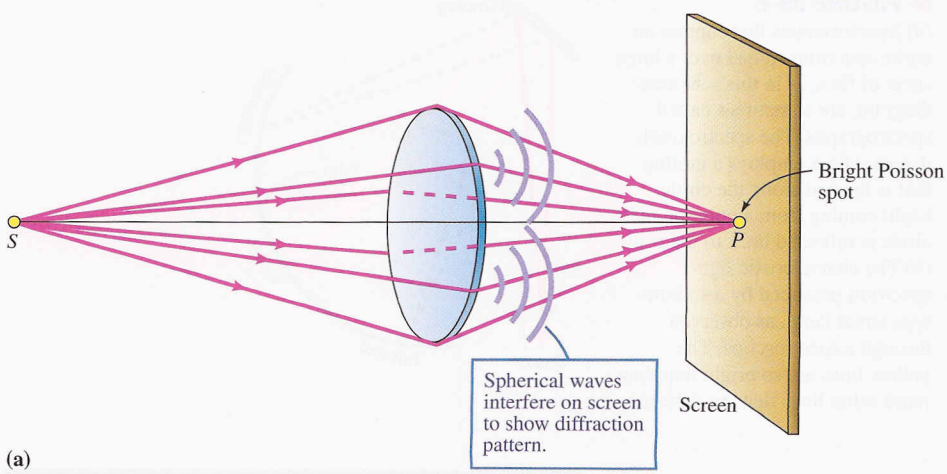
Diffraction

We can most easily discern the wave nature of light when it is incident on obstacles or apertures with sizes comparable to the wavelength of visible light (roughly 400 to 700 nanometers), or when we look at the edges of shadows at a similar scale. As we saw in Chapter 37, geometric optics becomes inadequate for the description of the behavior of light at this scale. Interference becomes most obvious here, as does *diffraction*, another manifestation of interference phenomena and the topic of this chapter. Diffraction usually refers specifically to the bending of waves around obstacles. We are already familiar with the circular spread of water waves passing through an opening narrower than their wavelength from Chapter 15, and we shall see that for light a single, narrow slit behaves similarly, producing characteristic patterns. This phenomenon is a diffractive effect. So is the pattern of maxima and minima that spreads across a screen in Young's double-slit experiment. The term diffraction also refers to interference between waves that emanate from a large number, or even a continuous set, of sources. Diffraction gratings consist of many slits or sources of coherent light, and such gratings have important applications in the study of atomic systems and crystalline materials. Holography is a spectacular application of the diffraction phenomenon with some interesting consequences.

▲ **FIGURE 38–1** The way water waves bend around obstacles and through openings in obstacles is well known. Here, parallel water waves pass through a hole, producing circular wave fronts on the far side.

38–1 The Diffraction of Light

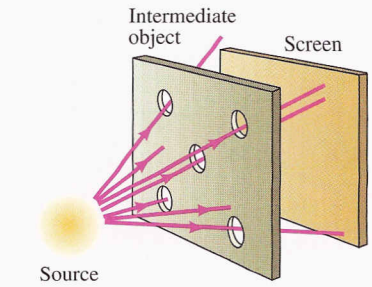
By the 1820s, Young's double-slit experiment had reinforced the wavelike interference effects associated with light, and serious attempts were under way to understand the consequences of these light waves. The bending of light waves around obstacles or at the edges of apertures (Fig. 38–1) is not part of our everyday experience. This is because *interference effects require coherent wave sources* and because *diffraction effects*



are typically most significant when the sizes of the apertures or obstacles involved are comparable to the wavelength. For light, the coherence condition is not realized in most situations, and wavelengths—several hundred nanometers—are tiny compared to the sizes of familiar objects. Nevertheless, these effects can be very important for the kind of high-precision instruments that today's technology requires.

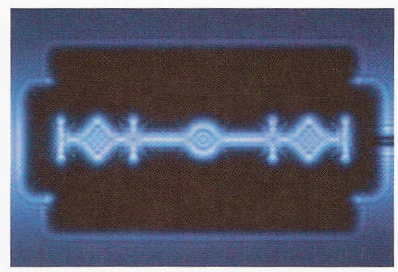
We can observe diffraction effects with a source of coherent light, an intermediate object in the form of an obstacle or a wall with holes, and a viewing screen (Fig. 38–2). For example, the shadow of a razor blade in Fig. 38–3 shows a diffraction pattern at its edges. Around 1810 the French physicist Augustin Fresnel systematically investigated the interference patterns from apertures, edges, and small obstacles, and these diffraction patterns form what is now known as *Fresnel diffraction*. Fresnel treated various interference phenomena using the Huygens construction (see Section 35–2). He showed that even a single aperture creates its own diffraction pattern, because waves passing through different parts of the aperture interfere with each other. Similarly, even a single obstacle creates a diffraction pattern because parts of the original plane wave have been blocked by the obstacle and no longer participate in the Huygens regeneration of the wave. By 1821, Fresnel's research had progressed to the point where he was able to use a primitive version of an interferometer to make the first quantitative measurement of the wavelength of light.

If both the source and the screen are far from the intermediate aperture or object that forms the pattern, the mathematics is considerably simplified (Fig. 38–4). This special case is known as *Fraunhofer diffraction*, after the Bavarian physicist Joseph von Fraunhofer, a contemporary of Fresnel. The Fraunhofer limit is easy to treat because the lines that originate at each position of the intermediate object and that reach a given point on the screen are nearly parallel; approximating them as parallel simplifies the calculation of path-length differences and phase differences. We used the geometry appropriate to the Fraunhofer case in Chapter 37 when we studied double-slit interference patterns. Starting with Section 38–2, we shall restrict ourselves to this case.

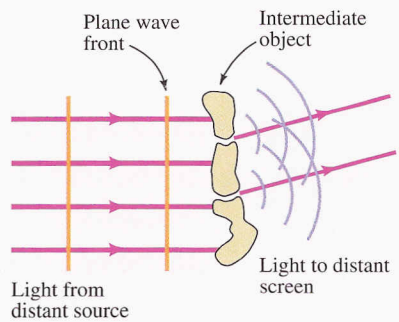


The types of things seen by Fresnel and Fraunhofer are visible to the naked eye with a little ingenuity. For example, try looking at a distant mercury-vapor street lamp through the narrowest possible slit you can make between your fingers. As you look through the slit, what do you see?

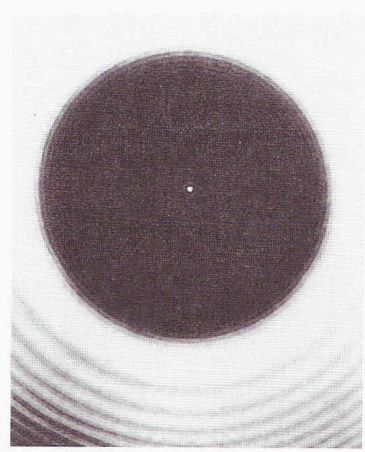
Before we proceed to more detail, let's look at one rather spectacular demonstration of diffraction effects observed by Arago in 1818. Suppose that we place a perfectly round obstacle in the path of a point source of coherent light, as in Fig. 38–5a. If every point on the rim of the disk is equidistant from the source, the light falling on the rim is perfectly in phase. According to the Huygens construction, we can think of each of these points as a new source, and they are all in phase. All the rim points are equidistant from the point P on a screen that lies on the symmetry axis between the disk and the source. Because the light reemitted in the Huygens construction from all points on the rim arrives at P in phase, there is constructive interference at P, and hence a bright spot appears on the screen at the center



(a)



▲ **FIGURE 38–5** (a) A round, opaque object in the path of a point source of coherent light. Diffraction causes a bright spot (the Poisson spot) to be seen along the optical axis at point P. (b) The Poisson spot of a penny.



▲ **FIGURE 38–2** Diffraction effects can be observed by placing an intermediate object in the path of light that passes from a source to a viewing screen.

▲ **FIGURE 38–3** The diffraction of light around a razor blade.

▲ **FIGURE 38–4** Parallel rays from a distant source are diffracted by an intermediate object and then viewed on a distant screen. When the screen is distant, we can treat the outgoing rays as parallel. This is the case of Fraunhofer diffraction.

(b)

of the shadow, a central maximum known as the *Poisson spot*. This diffractive effect is certainly inconsistent with geometric optics! Even an ordinary penny can be used as the object; the Poisson spot at the center of its shadow in Fig. 38–5b is clearly visible.

38–2 Diffraction Gratings

A simple way to generalize the double-slit interference experiment that we studied in Chapter 37 is to increase the number of narrow slits. *If the slits are regularly spaced*, then a characteristic interference pattern is obtained; a screen with such an arrangement is called a **diffraction grating**. Diffraction gratings are important for two reasons: First, the multiple slits allow more light through than do two slits, thus increasing the intensity; second, the interference maxima are much sharper than they are for two slits, allowing the wavelength of the light to be measured more precisely.

A diffraction grating can take many forms. We simply require an array of obstacles to serve as pointlike sources for the reradiation of spherical wavelets. For example, when light passes through a glass plate scratched with rulings, the scratches act as sources for the regeneration of spherical wavelets. This type of grating is called a *transmission grating*. When the scratches are made on metal plates, they act as regular point sources of reflected rather than transmitted light; this grating is called a *reflection grating*. Even the marks on an ordinary ruler can be a reflection grating for laser light. What counts is that the light be scattered from regularly spaced centers.

THINK ABOUT THIS. . .

WHAT IS THE SIGNIFICANCE OF DIFFRACTION GRATINGS?

We stated above, and we'll show below in ample detail, that light that passes through a diffraction grating exhibits very sharp interference maxima and that this enables the measurement of light wavelengths to a very high precision. The ability to produce such gratings in a reliable way in the last half of the nineteenth century led to the discovery that light is emitted by excited atoms in discrete frequencies, and this discovery laid a good part of the foundations for quantum mechanics and, eventually, to an understanding of the structure of the atom. The unique set of wavelengths (or frequencies) produced by excited states of each type of atom, ion, or molecule is called its *spectrum*. *Spectroscopes*—optical devices used to measure so-called spectral lines, which are the intensity maxima corresponding to a particular wavelength—are typically based on diffraction gratings. Figure 38–6a is a schematic diagram of a spectroscope, and Fig. 38–6b shows the result of using a spectroscope to observe the light from a distant sodium-type street lamp. Diffraction gratings are still widely used in science and technology. Today we have a good understanding of the spectra of atoms and molecules. Knowing these wavelengths, which are completely characteristic of atoms and molecules of particular species, we can use a spectroscope as a very sensitive tool to recognize the presence of particular atoms or molecules in a distant star, or in a complex material. Observation of a given set of spectral lines is conclusive evidence of the presence of the emitting atom or molecule.

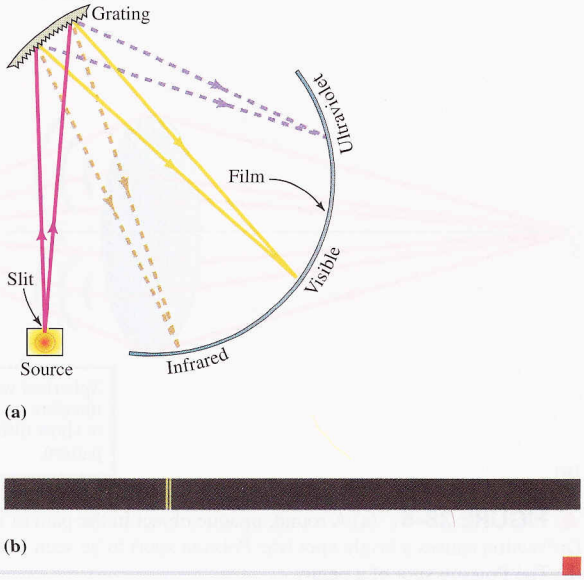


FIGURE 38–6
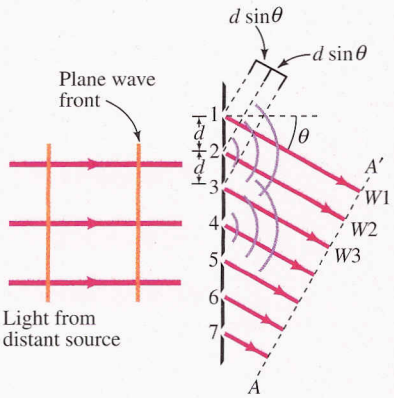
(a) Spectroscopes that capture an entire spectrum spread over a large sheet of film, as in this schematic diagram, are sometimes called spectrographs. The spectrograph depicted here employs a grating that is located along the circle. Light coming from a point on that circle is reflected back to the film. (b) The characteristic light spectrum produced by a sodium-type street lamp, as observed through a spectroscope. The yellow lines are so bright that they mask other lines that are present.



Energy Conservation and Intensity

Let's turn now to the analysis of the pattern made by a diffraction grating on a distant screen—the Fraunhofer diffraction pattern. Figure 38–7 shows a few of the slits of a grating with N slits, separated from each other by a distance d; a monochromatic plane wave of wavelength λ approaches from a distant source. The plane wave arrives with the same phase at each slit, and spherical waves are emitted in phase at each slit. Consider wave propagation along the lines labeled W, with lines $W1$, $W2$, $W3$, and so on oriented at an angle θ to the original wave-propagation direction. We allow the screen to be so distant that these lines are approximately parallel even though they all point toward a particular spot on the screen (or a lens focuses them on that spot).

If the wavelets are in phase along the front AA', defined by θ, then the light that eventually reaches the distant screen at this angle will also be in phase, and there will be constructive interference—a maximum. The condition under which the waves along AA' are in phase is that each path length differs from any other by integral multiples of the wavelength λ. The path-length difference between adjacent waves is $d \sin\theta$ (Fig. 38–7). Thus there are *principal maxima*, where the light from all the slits interferes constructively, at angles such that

$$d \sin\theta = m\lambda, \qquad \text{where } m = 0, \pm 1, \pm 2, \ldots. \tag{38–1}$$

PRINCIPAL MAXIMA FOR A GRATING

▲ **FIGURE 38–7** The geometry of a diffraction grating. Light passing through individual slits spreads in all directions. The interference of the light at a distant screen, along the lines indicated by $W1$, $W2$, $W3$, and so on, depends on the path-length differences $d \sin\theta$ between adjacent slits. The distant screen is not shown.

As is the case for the two-source pattern, the integer m specifies the *order* of the principal maxima. In this result, we see a universal diffraction phenomenon: *The pattern spreads in angle as the ratio λ/d increases*. Equation (38–1) is the same as Eq. (37–3a), which determines the maxima of the double-slit pattern. The intensity pattern on the screen, however, takes quite a different form.

Before performing the mathematical analysis for the intensity pattern, let's first do a qualitative analysis of intensity. If there were no interference whatsoever, the average intensity over the entire screen due to N slits would be NI_0, where I_0 is the average intensity for just one slit. Energy must be conserved whether or not there is interference, so the average intensity over the entire screen must be NI_0 even with interference. If the light intensity is zero in regions of destructive interference, there must be a higher light intensity in regions of constructive interference. What is the intensity at the principal maxima, where there is constructive interference? At such points, the electric or magnetic fields of the waves from all the slits add to N times the field from one slit. Because the intensity is proportional to the *square* of the fields, the intensity at any maximum is N^2 times the intensity I_0 due to one slit:

$$I_{\max} = N^2 I_0. \tag{38–2}$$

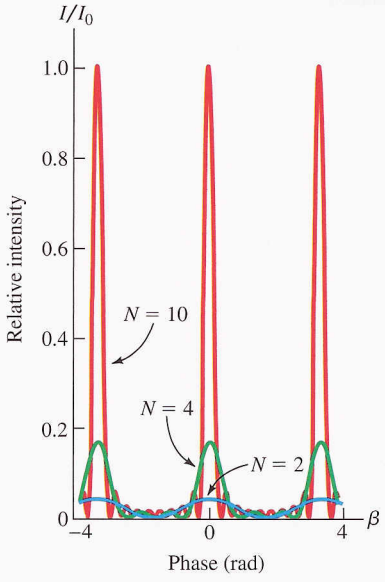
This result agrees with the calculation of the double-slit pattern, where we found that the heights of the maxima are $4I_0 = (2^2)I_0$. If the maximum intensity increases so markedly for N slits, then, in order to conserve energy, the space over which the maximum occurs must be much smaller. Suppose that the principal maxima have a *width* of $\Delta\theta$. (Qualitatively, you can think of the width as some reasonable measure of the spread in angle for which there is some substantial intensity. We make this quantitative by defining the width as the angular spread of the peak where the intensity is half its maximum height of $I_{\max}$.) To find $\Delta\theta$, we equate the intensity in a single maximum with the averaged intensity between maxima. Thus

$$\begin{aligned} I_{\max}\Delta\theta &\cong NI_0 \times (\text{angular separation of successive maxima}) \\ &\cong NI_0(\lambda/d). \end{aligned}$$

We solve this equation for the width, and when we use Eq. (38–2), we find

$$\Delta\theta = \frac{NI_0(\lambda/d)}{I_{\max}} = \frac{NI_0(\lambda/d)}{N^2 I_0} = \frac{1}{N}\frac{\lambda}{d}. \tag{38–3}$$

To summarize, we have found that *as the number of slits N increases, the height of the principal maxima increases as* N^2. *In addition, the width decreases—the principal maxima become sharper—as* $1/N$. It is this feature that makes diffraction gratings so useful. A tall and narrow peak implies that the peak is easily seen even if the source is relatively weak, and that the peak can be located with great precision. Thus the wavelengths for which the principal maxima occur can be determined with great precision from Eq. (38–1).



Intensity Pattern

Let us turn now to a more precise treatment of the pattern. We can sum the electric fields at the screen associated with each of the slits in the N-slit pattern and by squaring the time average of the *net* field we find the intensity. Although we shall not go through the details here, the result for the intensity is

$$\text{for multiple slits: } I = I_0\left[\frac{\sin(N\beta)}{\sin\beta}\right]^2. \tag{38–4a}$$

The quantity 2β is the slit–to–slit phase difference. It is given by the product of the path length difference $d \sin\theta$ (see Fig. 38–7) and the wave number $2\pi/\lambda$:

$$2\beta = \frac{2\pi d \sin\theta}{\lambda}. \tag{38–4b}$$

▲ **FIGURE 38–8** The ratio I/I_0 plotted against the phases $\beta = (\pi d \sin\theta)/\lambda$ for $N = 2$, 4, and 10 slits. The intensity pattern changes dramatically with N. The widths of the principal maxima decrease as $1/N$.

We can show that this result agrees with the earlier qualitative argument based on energy. Using Eq. (38–1), we see that $\sin\beta$ is zero at principal maxima. As $\sin\beta \to 0$, l'Hôpital's rule tells us that the ratio $\sin(N\beta)/\sin\beta$ approaches N. In this limit, Eq. (38–4a) agrees with Eq. (38–2).

Equation (38–4a) is most easily understood by plotting it, as in Fig. 38–8 for $N = 2$, 4, and 10: The ratio I/I_0 is plotted against β. The figure shows the principal maximum at $\beta = 0$ (corresponding to $\theta = 0$), the central spot on the screen, as well as the first principal maxima to the sides, corresponding to $m = \pm 1$ in Eq. (38–1). The widths of the principal maxima do indeed decrease as $1/N$. (Note that there are also $N - 2$ small secondary maxima between each pair of principal maxima. They have intensities on the order of I_0 itself. For diffraction gratings in ordinary use, N is in the thousands, so the secondary maxima can safely be ignored. They occur because there is the possibility that the light from two or more of the non-neighboring slits may be in phase at a given angle, even though the light from *all* the slits is not in phase.)

We can check our general result for N slits by setting $N = 2$ and comparing with our result for the double slit. If we let $N = 2$ in Eq. (38–4) with $\sin(2\beta) = 2 \sin\beta \cos\beta$, we find

$$I = I_0\left[\frac{\sin(2\beta)}{\sin\beta}\right]^2 = I_0\frac{(2\sin\beta\cos\beta)^2}{(\sin\beta)^2} = 4I_0\cos^2\beta.$$

This is indeed the result for two slits, given in Eq. (37–13).

Resolution of Diffraction Gratings

Angular Dispersion: Diffraction gratings were formerly used to identify the characteristic wavelengths of elements. Now that these wavelengths are known, gratings are used primarily to *identify* elements, ions, and compounds through the characteristic light they emit or as a tool for understanding the structure of molecules. Because d, the distance between slits, is usually known, the angular location of a principal maximum ($m \neq 0$) gives λ according to Eq. (38–1). In this case, an important limitation is the ability to separate the spectral lines of nearly equal wavelengths λ_1 and λ_2. Two quantities determine the effectiveness of spectroscopic instruments. One is the **angular dispersion**, defined as $\Delta\theta/\Delta\lambda$, which measures the difference $\Delta\theta$ in the angles of the principal maxima of a given order due to two nearly equal wavelengths that differ by $\Delta\lambda$. Larger values of angular dispersion are desirable when one wants to distinguish

two lines. We find the angular dispersion by considering two nearly identical wavelengths, λ and $\lambda + \Delta\lambda$, with maxima at the angles θ and $\theta + \Delta\theta$, respectively. Equation (38–1) gives us the difference in the angular position of their maxima

$$\sin(\theta + \Delta\theta) - \sin\theta = \frac{m}{d}[(\lambda + \Delta\lambda) - \lambda] = \frac{m(\Delta\lambda)}{d}.$$

If $\Delta\lambda$ is small, then so is $\Delta\theta$ and the difference $\sin(\theta + \Delta\theta) - \sin\theta$. We can approximate $\sin(\theta + \Delta\theta) = \sin\theta\cos(\Delta\theta) + \sin(\Delta\theta)\cos\theta \cong \sin\theta + \Delta\theta\cos\theta$, and hence $\sin(\theta + \Delta\theta) - \sin\theta \cong \Delta\theta\cos\theta$. The relation above can then be rearranged to read

$$\frac{\Delta\theta}{\Delta\lambda} = \frac{m}{d\cos\theta}. \tag{38–5}$$

The angular dispersion increases for higher orders, is inversely proportional to the distance between slits, and increases away from the central maximum.

Resolution: The angular dispersion alone does not tell us whether we can visually separate two similar wavelengths. This aspect of the effectiveness of a grating is characterized by the **resolving power** of the grating, defined by

$$R \equiv \frac{\lambda}{\Delta\lambda}. \tag{38–6}$$

Here, $\Delta\lambda$ is the smallest wavelength difference that can be observed with the grating. (The maxima of two wavelengths that are too close together lie so close to one another that they cannot be distinguished.) The larger the value of R, the better the grating can distinguish the relative wavelength difference of two closely spaced lines. Two closely spaced lines can be separated if the peaks are sharp. Detailed analysis of the peak widths of an N-slit system allows us to see that the resolving power of a grating is given by

$$R = mN. \tag{38–7}$$

The resolving power improves as the number of slits N increases and is better for larger orders; that is, for larger integers m. The improvement in the resolving power as N gets large is quite visible in Fig. 38–8.

EXAMPLE 38–1 Heated sodium is an easily available source of light. It emits light of a characteristic yellow–orange color with two intense wavelengths of 589.00 nm and 589.60 nm, called a *doublet*. (a) How many slits are required in a grating that resolves the doublet at the first-order maxima? (b) If the screen is 4.000 m from a grating with exactly 2000 slits/cm, what are the screen positions of the two principal maxima of first order? Assume that the screen is far enough away so that the conditions of Fraunhofer diffraction apply.

Strategy The solution to this problem lies in our discussion of the resolving power and the position of principal maxima. For part (a), the minimum resolving power needed to resolve two lines whose wavelengths differ by $\Delta\lambda$ is given by Eq. (38–6), $R = \lambda/\Delta\lambda$. Given R, Eq. (38–7) then allows us to find N. For part (b), the angular positions of the first-order principal maxima are given by Eq. (38–1) with $m = 1$.

Working It Out (a) We have $\Delta\lambda = 589.60\text{ nm} - 589.00\text{ nm} = 0.60\text{ nm}$, and hence the resolving power R is

$$R = \frac{\lambda}{\Delta\lambda} = \frac{589.0\text{ nm}}{0.60\text{ nm}} = 9.8 \times 10^2.$$

Equation (38–7), with $m = 1$, gives $N = R = 9.8 \times 10^2$. About 1000 slits are required.

(b) To use Eq. (38–1), we need the slit separation $d = 1/(2000\text{ slits/cm}) = 5.000 \times 10^{-6}\text{ m}$. Then Eq. (38–1), with $m = 1$, gives

$$\text{for } \lambda_1\text{: } \sin\theta_1 = \frac{\lambda_1}{d} = \frac{589.0\text{ nm}}{5.000 \times 10^{-6}\text{ m}} = 0.1178;$$

$$\text{for } \lambda_2\text{: } \sin\theta_2 = \frac{\lambda_2}{d} = \frac{589.6\text{ nm}}{5.000 \times 10^{-6}\text{ m}} = 0.1179.$$

The respective angles are $\theta_1 = 0.1181$ rad and $\theta_2 = 0.1182$ rad, and the distance from the centerline of the screen is $y = L\tan\theta$. These respective distances are

$$y_1 = (4.000\text{ m})\tan(0.1181\text{ rad}) = 0.4745\text{ m};$$
$$y_2 = (4.000\text{ m})\tan(0.1182\text{ rad}) = 0.4750\text{ m}.$$

The images are separated by only 0.5 mm, but this resolution is sufficient to distinguish the two spectral lines.

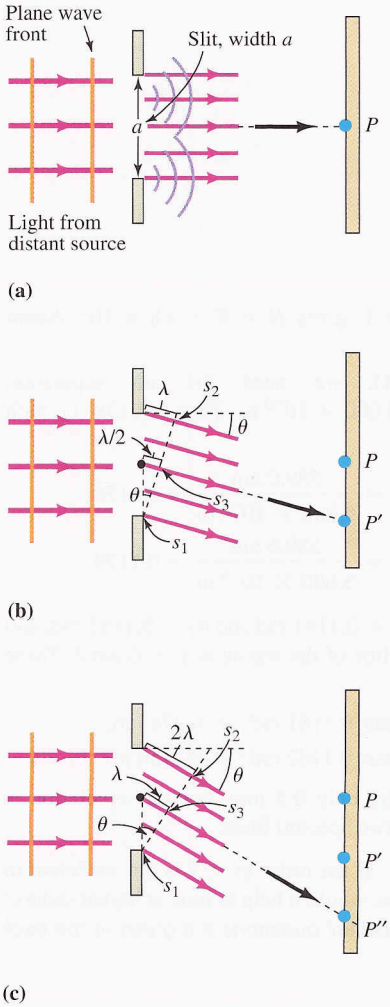
What Do You Think? If the order $m = 1$ is not sufficient to separate the two sodium lines, would it help to look at higher orders?

*Answers to **What Do You Think?** questions are given in the back of the book.*

CONCEPTUAL EXAMPLE 38–2 Take a compact disc (CD) and hold it below a lightbulb in a horizontal position such that when you look down on the CD, the reflection of the lightbulb overlaps the hole in the middle. As you tilt the CD away from the horizontal, you will see a swath of brilliant colors coming in from the rim toward the center. Why is this? Which colors come first? Will the colors repeat? Finally, could you estimate the spacing between the grooves on the CD from your experiment?

Answer The CD, which contains very finely spaced grooves, acts as a reflection grating. You start by looking straight down on the disc, that is, with an angle of reflection θ of zero. As you tilt it, you increase the reflection angle, and with it the groove-to-groove phase difference β [see Eq. (38–4b)]. This phase difference depends inversely on the wavelength λ so that it is larger for blue light than for red light, and the blue light will be seen first, with a sequence of the colors of the rainbow all the way to red light. Further tilt will bring in higher orders (secondary maxima), so there will be a repeat of the sweep of colors. Finally, β also depends on the groove spacing d, so that if you know the wavelength of, say, blue light and can estimate the tilt angle, you can measure d. You can certainly try this out for yourself (Fig. 38–9).

What Do You Think? What would you expect to see if you did the same experiment in the light of a helium-neon laser ($\lambda = 633$ nm) in an otherwise dark room?



▲ **FIGURE 38–9** The grooves on a CD can act as a diffraction grating, here separating the colors of a light bulb.

38–3 Single-Slit Diffraction

Coherent light passing through even a *single* slit produces a diffraction pattern. In the language of Huygens' principle, this pattern forms because wavelets that have regenerated at different places across the single slit interfere with each other. If the width a of the single slit is comparable to or smaller than the wavelength of coherent light that passes through it, the diffraction pattern is quite evident. We can explain it by treating the single slit as an infinitely large number of infinitesimal sources of wavelets.

Let's consider a plane light wave of wavelength λ that moves toward a wall with a narrow rectangular slit of width a ($a > \lambda$). A coherent wave arrives at the slit and regenerates spherical waves at each point across it. In Fig. 38–10a, we examine the light from the slit that continues along the initial direction toward the center point P of a distant screen. If the screen is far enough, we can assume that to a good approximation the waves from all parts of the slit travel the same distance, so that the regenerated wavelets are all in phase in this direction, and the central point of the screen is bright.

Along the direction that leads to point P' on the screen (Fig. 38–10b), with the angle given by $\sin\theta = \lambda/a$, there will be destructive interference under certain conditions. The path lengths from the tilted line s_1s_2 to point P' are all the same because the screen is distant, so we must consider only the phase relations of the light waves at line s_1s_2. The wave emitted at the top of the slit has traveled a distance λ to point s_2, and the wave emitted from the midpoint of the slit has traveled a distance $\lambda/2$ to point s_3. Thus, along the line s_1s_2, the wave emitted at the top is *out of phase* with the wave emitted at the center of the slit, and the waves will have this same phase relation at point P'. Similarly, the wave emitted just below the top of the slit is out of phase with the wave emitted from just below the center. We can follow the points *in pairs* along the slit. For every point in the top half of the slit, there is a point in the bottom half, and the waves from the two points are precisely out of phase with each other. The result is destructive interference—a minimum (or dark spot)—on the screen at P' at the angle given by $\sin\theta = \lambda/a$.

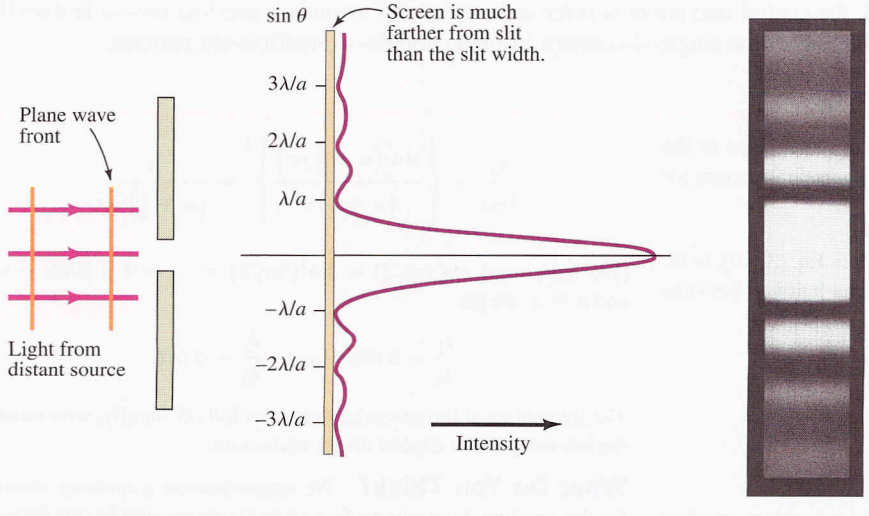
◀ **FIGURE 38–10** Monochromatic plane waves of light enter a narrow slit of width a (exaggerated here). We show three positions (P, P', and P'') on a distant screen. (a) We look along the incident direction at P. (b) We look along angle θ at P'. If the light from positions in the top half of the slit are out of phase with corresponding positions in the bottom half, destructive interference occurs at P'. (c) We look along a different angle θ at P''. Destructive interference can occur also at P'', as demonstrated by breaking the slit into halves and treating each half as we did for the direction toward point P'.

Along the direction given by $\sin\theta = 2\lambda/a$ (Fig. 38–10c), the wavelet emitted from the top of the slit travels a distance 2λ farther than the wavelet emitted from the bottom, and a distance λ farther than the wavelet emitted from the center point. We can think of the slit of width a as separated into two slits of width $a/2$. Along the direction chosen, we are in a situation similar to that in Fig. 38–10b. There is destructive interference at point P'' due to net destructive interference from both the top half and the bottom half of the slit. For example, for every wavelet emitted from a particular point in the top half of the slit, we can find a second wavelet emitted from another point in the top half that destructively interferes with the first wavelet, because their path-length difference is $\lambda/2$. The same happens for the bottom half. We will have another intensity minimum (dark spot) on the screen for angle $\sin\theta = 2\lambda/a$.

If we continue our analysis, we find that every time there is an additional path-length difference of λ between the top and bottom of the slit, destructive interference and a screen minimum result. Thus we have

$$\sin\theta = \frac{m\lambda}{a}, \qquad \text{where } m = \pm 1, \pm 2, \pm 3, \ldots. \tag{38–8}$$

MINIMA FOR A SINGLE SLIT



The value $m = 0$ is not part of this sequence of minima: For $m = 0$, $\sin\theta = m\lambda/a = 0$, and we have seen that this central point P must always be a maximum.

The interference pattern (Fig. 38–11) has the typical behavior of diffractive phenomena: Larger values of a/λ give a smaller angular spread in the interference pattern, and smaller values of a/λ give a larger angular spread. In the limit that $a \gg \lambda$, the spread decreases so much that there is only a bright central spot on the screen. Do not confuse the angular spread on the screen with a projection of a slit width in geometric optics. The screen is very distant, and if geometric optics were to hold, the projection of the slit on the screen due to direct incident light would be a line with precisely the width of the slit. *But geometric optics does not hold; the smaller the slit width compared to the wavelength, the larger the angular spread of the interference pattern.*

Approximately halfway between the successive minima, we have conditions for constructive interference and an intensity maximum (a bright region). In other words, in addition to the constructive interference at $\theta = 0$ (the central maximum), we also have

$$\text{for constructive interference: } \sin\theta \cong \frac{\left(m + \frac{1}{2}\right)\lambda}{a}, \qquad \text{where } m = \pm 1, \pm 2, \ldots. \tag{38–9}$$

We'll work out more details of the intensity pattern in the two subsections to follow.

▲ **FIGURE 38–11** The interference pattern of single-slit diffraction and the relative intensities of such a pattern. Most of the light energy is in the bright central peak. The central peak is twice as wide as the secondary peaks.

EXAMPLE 38–3 Helium–neon laser light of wavelength 633 nm passes through a single slit of width 0.10 mm. The diffraction pattern is observed on a screen 3 m away. What is the distance between the two minima on either side of the central maximum?

Strategy The conditions for the single-slit pattern apply here; in particular, the slit width a is some 160 times larger than the wavelength. We can use Eq. (38–8) to find the angular positions of the minima that correspond to $m = 1$ and -1, and with the angular positions known geometry gives the positions on the screen.

Working It Out The minima for $m = \pm 1$ occur at angles

$$\sin\theta = \frac{m\lambda}{a} = (\pm 1)\frac{633 \times 10^{-9}\ \text{m}}{0.10 \times 10^{-3}\ \text{m}} = \pm 0.0063;$$
$$\theta = \pm 0.36°.$$

At a distance of 3 m away, these minima will be (3 m) tan 0.36° = 1.9 cm from the central line ($\theta = 0$). The total distance between them is thus 2(1.9 cm) = 3.8 cm.

What Do You Think? If coherent blue light is used instead of the red light of the helium-neon laser, would the distance between minima increase or decrease?

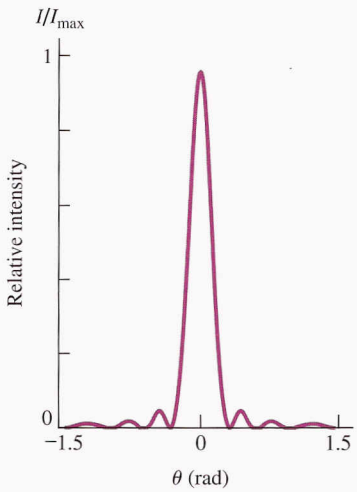
The Intensity Pattern of Single-Slit Diffraction

As we shall show in the next subsection, the intensity pattern on a distant screen due to a single slit of width a takes the form

$$\text{for single slits: } I = I_{\text{max}}\frac{\sin^2\alpha}{\alpha^2}, \tag{38–10}$$

where

$$\alpha = \frac{\pi a \sin\theta}{\lambda}. \tag{38–11}$$



As we learned at the start of this section, the angle α, which is measured in radians, is simply the phase difference between the top and the middle of the slit.

As is confirmed by Fig. 38–11, there is a central maximum at $\theta = 0$: At $\theta = 0$, Eq. (38–11) shows that $\alpha = 0$. Because the limit of $(\sin\alpha)/\alpha \to 1$ as $\alpha \to 0$, the intensity at this point on the screen is just I_{max}. The intensity drops off rapidly as α increases. The intensity is zero for angles given by Eq. (38–8), and this occurs when α is an integral multiple of π.

$$\text{for minima: } \alpha = n\pi = \frac{\pi a \sin\theta}{\lambda}, \qquad \text{where } n = \pm 1, \pm 2, \pm 3, \ldots. \tag{38–12}$$

The intensities at the secondary maxima are estimated in Example 38–4.

By looking at Fig. 38–12, for which we have chosen $a = 4\lambda$, we can identify two important features. First, the secondary maxima are not very strong—most of the light is contained in the wide central maximum at $\theta = 0$. This contrasts with the pattern made by a grating, for which there is no difference in the strength of the successive maxima. Second, the central maximum is *twice* as broad as the secondary maxima are—a feature that distinguishes the single-slit pattern from the double- or multiple-slit patterns.

▲ **FIGURE 38–12** The intensity ratio I/I_{max} as a function of angle θ [from Eqs. (38–10) and (38–11)] for the slit width $a = 4\lambda$.

EXAMPLE 38–4 Estimate the ratios of the intensities of the first and second maxima to the intensity of the central maximum for a single slit.

Strategy We can use our approximate relation, Eq. (38–9), to locate the maxima. This relation places the maxima halfway between the minima, and in terms of α this means

$$\text{for maxima: } \alpha \cong (n + \frac{1}{2})\pi, \qquad n = \pm 1, \pm 2, \ldots.$$

The intensity need only be evaluated at these locations.

Working It Out Denote the intensity at the secondary maxima by I_n. Then Eq. (38–10) gives

$$\frac{I_n}{I_{\text{max}}} = \left\{\frac{\sin\left[\left(n + \frac{1}{2}\right)\pi\right]}{\left(n + \frac{1}{2}\right)\pi}\right\}^2 = \frac{1}{\left(n + \frac{1}{2}\right)^2\pi^2}.$$

[We have used $\sin^2(\pi/2) = \sin^2(3\pi/2) = \ldots = 1$.] With $n = 1$ and $n = 2$, we get

$$\frac{I_1}{I_0} = 0.045 \quad \text{and} \quad \frac{I_2}{I_0} = 0.016.$$

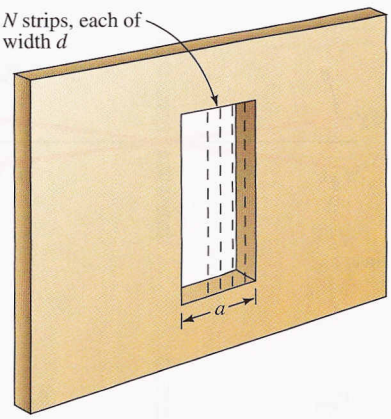
The intensities of the secondary maxima fall off rapidly, with most of the intensity in the central bright maximum.

What Do You Think? We approximated a midway location for the maxima; how can we find an exact expression for the location of the maxima in single-slit diffraction?

*Deriving Single-Slit Intensity Values

Let's imagine breaking up a single slit of width a into N strips of width d (Fig. 38–13), so that $Nd = a$. Each strip acts as a separate slit. In the limit that the number of strips $N \to \infty$, d must approach zero in order to keep a constant. Because each strip is infinitely narrow, we can treat these strips as the thin slits of a grating. We can then use the diffraction grating result of Eq. (38–4) directly to find that the intensity at the screen at angle θ is

$$I = \lim_{N\to\infty} I_0\left[\frac{\sin(N\beta)}{\sin\beta}\right]^2.$$



This expression includes a slit width $d = a/N$ that approaches zero as $N \to \infty$ through the quantity β. According to Eq. (38–4), $\beta = [\pi d \sin\theta]/\lambda = [\pi(a/N)\sin\theta]/\lambda = \alpha/N$, where the definition of α is contained in Eq. (38–11). Thus the intensity takes the form

$$I = \lim_{N\to\infty} I_0\left[\frac{\sin\alpha}{\sin(\alpha/N)}\right]^2.$$

In the limit of large N, the factor $\sin(\alpha/N) \cong \alpha/N$, and

$$I = N^2 I_0 \frac{\sin^2\alpha}{\alpha^2}.$$

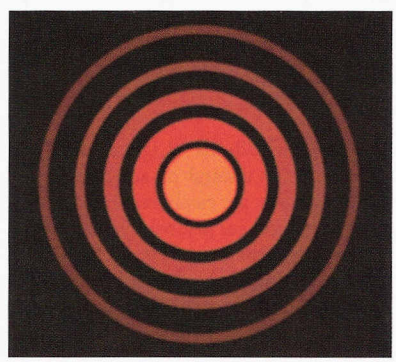
The factor I_0 is the intensity due to one of the subslits of width d. We need only interpret the factor $N^2 I_0$ as the maximum possible intensity I_{max} of the single slit of width a to get Eq. (38–10).

▲ **FIGURE 38–13** We can understand the intensity pattern of a single slit by supposing that the slit is composed of a large number of strips N and then using the result we derived for diffraction gratings.

38–4 Resolution of Optical Instruments

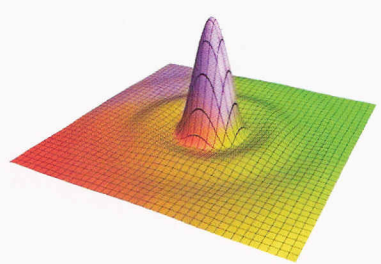
We have already seen that the ability of a grating to resolve closely spaced lines is limited by the width of the principal maxima. Similarly, the fact that there is some spreading of light in a single aperture due to diffraction *intrinsically* limits the capacity of optical instruments to resolve objects. The resolution of instruments such as telescopes or microscopes is also limited by lens aberration (see Chapter 36), but better lens design decreases aberration, and there is no theoretical limit to such improvement. The limitation due to diffraction, however, is set by the aperture of the instrument and the wavelength of light, and this limit is intrinsic to the wave nature of light.

Most optical instruments rely on circular lenses or mirrors, so we shall concentrate on circular apertures. Sir George Airy worked out the diffraction pattern from a distant point source that passes through a circular aperture (Fig. 38–14) in the 1830s. The bright central area—containing some 85 percent of the light intensity—is called an *Airy disk*. The rings outside the central area are the minima and secondary maxima of the diffraction pattern. The position of the first minimum occurs at an angle from the central axis given by



$$\theta_{min} = 1.22\frac{\lambda}{D}, \qquad (38\text{–}13)$$

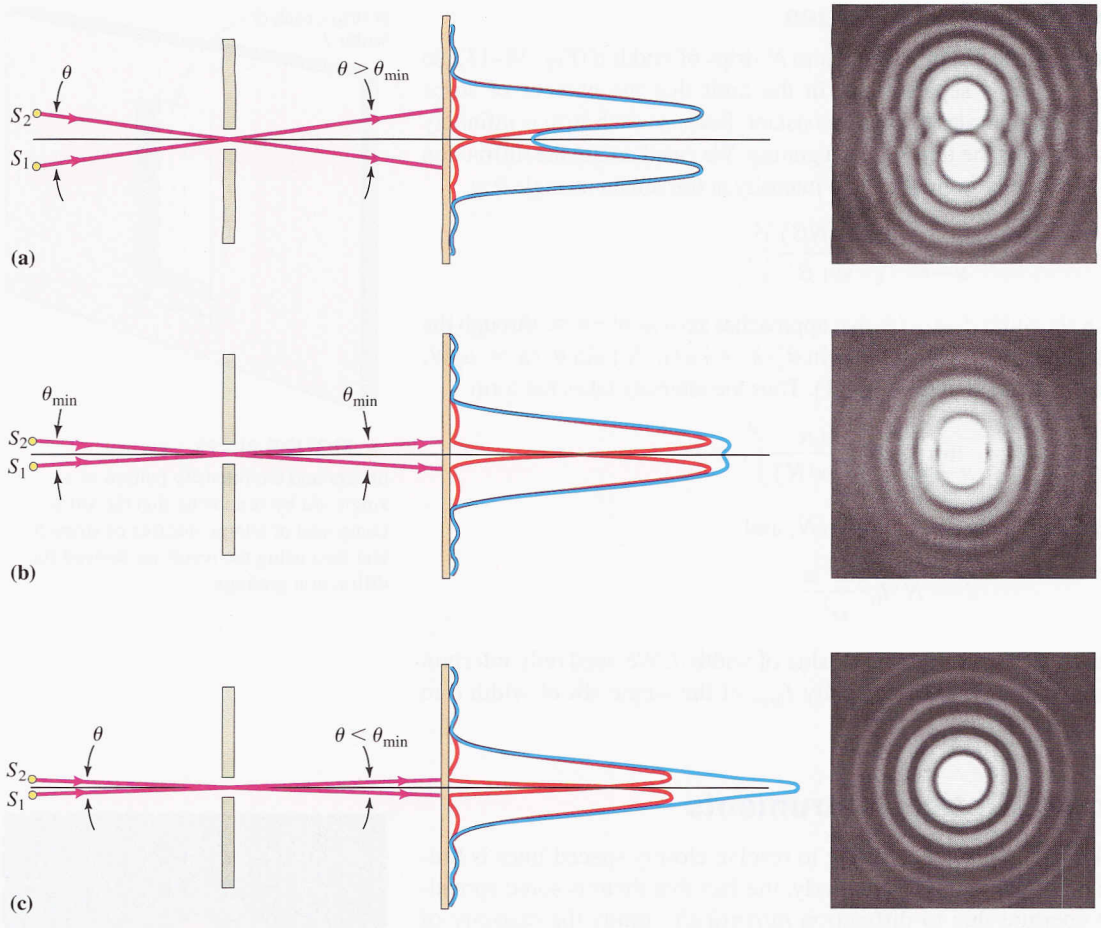
where D is the diameter of the aperture. This result can be compared to Eq. (38–8), which gives the angle of the first minimum for a slit of width $a \gg \lambda$ as $\theta_{min} = \lambda/a$. (Recall that $\sin\theta \cong \theta$ for small θ.) The factor 1.22 arises because the "width" of a circular aperture varies (in effect, $a \cong D/1.22$). But it is enough to use a factor 1 instead of the precise factor 1.22 to understand the effects of diffraction. Thus we give an approximate θ_{min} as



$$\theta_{min} \cong \frac{\lambda}{D}. \qquad (38\text{–}14)$$

MINIMUM OBSERVABLE ANGULAR SEPARATION

How does the presence of a diffraction pattern limit our ability to make images? In many applications high resolution is a necessity; for example, we may want to observe two closely spaced objects, such as a double star, or we may need to see detail in an X

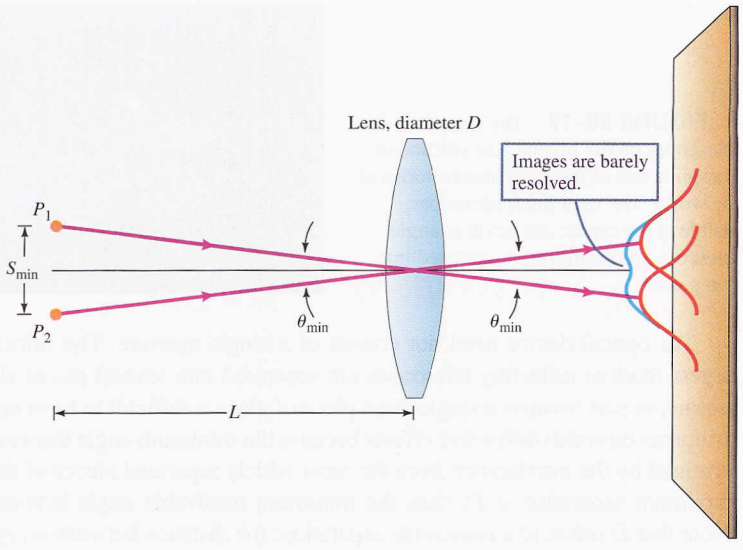


(a)

(b)

▲ **FIGURE 38–14** (a) Diffraction pattern of light from a distant source after the light passes through a circular aperture. Some 85 percent of the light intensity is contained in the bright central maximum, called the Airy disk. (b) A three-dimensional representation of the light intensity on a distant screen from a circular aperture.

▲ **FIGURE 38–15** Light from two sources passes through an aperture. (a) The objects are easily resolved. (b) The objects are just barely resolved. The angular separation is θ_{min}. (c) The objects are not resolved. The blue lines in each represent the sum of the two intensities.



ray taken of suspected stress fractures in piping for a power plant. The presence of the Airy disk means that even a very distant star does not produce a pointlike image but rather a disklike image with an angular spread described by Eq. (38–14). The image in a telescope of two stars that are so close together that their Airy disks overlap cannot be recognized as an image of two stars. In Fig. 38–15a, two objects have a sufficient angular separation θ that they are easily resolved. In Fig. 38–15b, the objects are just barely resolved. When they are even closer, as in Fig. 38–15c, the central diffraction peaks overlap too much to be resolved. It has become customary to describe the limiting case—shown in Fig. 38–15b—as the *Rayleigh criterion*:

Two point sources are just resolved if the peak of the diffraction image of the first source overlies the first minimum of the diffraction image of the second source.

The Rayleigh criterion is satisfied when the angular separation of the objects is just θ_{min}, defined by Eq. (38–13). Equation (38–14) provides an approximate alternative. Remember, the quality of the optical instruments is not the issue here; the limitation on the resolution of images is due to light's intrinsic wave character and can be improved only by making the instrument aperture larger.

The angular separation of an image formed by an optical system is also the angular separation of the objects. We can show this using the methods we used when we studied optical instruments in Chapter 36. These angular separations are the same because the principal rays through the center of a lens are undeviated. These rays are shown in Fig. 38–16 for two objects at P_1 and P_2 respectively, with the objects a distance L from a lens of diameter D. When this angle is less than that specified by the Rayleigh criterion, the objects cannot be separated. This translates into a minimum spatial separation S_{min} of the two objects through the relation $S_{min} = L\theta_{min}$:

$$S_{min} = L\theta_{min} \cong \frac{L\lambda}{D}. \qquad (38\text{–}15)$$

◀ **FIGURE 38–16** The minimum separation distance that is resolvable for a lens depends on θ_{min}.

EXAMPLE 38–5 Estimate the minimum separation between two objects such that the human eye can still perceive them as separate (the *minimum visible object separation*) if the objects are (a) at the near-point distance (25 cm) and (b) at a distance of 5 m. Take the pupil diameter to be 2.5 mm.

Setting It Up We can apply Eq. (38–15) if we can estimate the eye's aperture as well as a wavelength. You can look in a mirror and estimate the pupil diameter to be 2.5 mm, and for the wavelength, we choose a median range of visible wavelengths, about 550 nm.

Strategy This is straightforward application of Eq. (38–15).

Working It Out (a) For $L = 25$ cm (the near point), we have

$$S_{min} = \frac{L\lambda}{D} = \frac{(0.25\text{ m})(550 \times 10^{-9}\text{ m})}{0.0025\text{ m}} = 0.055\text{ mm}.$$

This is about the diameter of a thin thread or a human hair. It is also, roughly, the separation between the cells of the retina. In other words, the cells that receive light and send that message to the brain are no closer than the minimum separation that could ever be resolved, an admirable example of the economy of biological systems.

(b) At 5 m, the minimum separation distance becomes

$$S_{min} = \frac{L\lambda}{D} = \frac{(5.0\text{ m})(550 \times 10^{-9}\text{ m})}{0.0025\text{ m}} = 1.1\text{ mm}.$$

Thus, from a few meters away, we have an *intrinsic* inability to distinguish the millimeter markings on a meter stick.

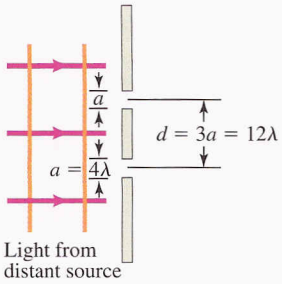
What Do You Think? What is the separation distance that can be resolved when the two separated objects are at infinity?

The Resolution of Telescopes

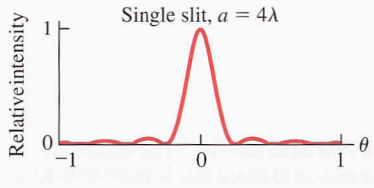
Depending on the case, diffraction effects can limit the effectiveness of telescopes. For the visible-light region of the electromagnetic spectrum, one of the world's largest telescopes is the 200-in-diameter Hale telescope on Mt. Palomar in southern California. Its diffraction limit alone implies an angular resolution of about 0.03 seconds of arc. Its real resolution is some 300 times worse than this due to the effects of atmospheric turbulence and aberration. The New Technology Telescope in Chile, another visible-light telescope, has resolved 0.36 seconds of arc, much closer to the diffraction limit. However, as the next example shows, the Hubble Space Telescope achieves a resolution that is very close to the diffraction limit.

EXAMPLE 38–6 The primary mirror on the Optical Telescope Assembly on the Hubble Space Telescope (HST), which orbits 600 km above Earth, has a diameter of 2.4 m. (a) Calculate the minimum angular separation that it might resolve for visible light (about 550 nm). (b) Assume that the telescope is viewing Earth's surface. What is the separation of the most closely spaced objects that it might resolve? Ignore all atmospheric effects.

Strategy (a) This problem is a direct application of the resolution angle of Eq. (38–14). For (b) we simply use $S_{min} = L\theta_{min}$, where $L = 600$ km and S_{min} is the separation distance.

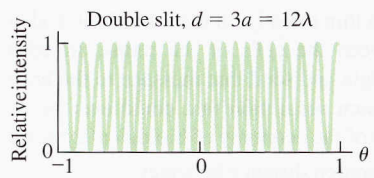


Working It Out (a) Equation (38–14) gives



$$\theta_{min} \cong \frac{\lambda}{D} = \frac{(550 \times 10^{-9}\text{ m})}{2.4\text{ m}} = 2.3 \times 10^{-7}\text{ rad} = 0.047''\text{ of arc}.$$

The actual resolution of the instrument is 0.1 seconds of arc, to a good approximation the diffraction limit. The HST can do so much better than comparable Earth-based telescopes because the HST avoids all atmospheric turbulence.



(b) $S_{min} = L\theta_{min} = (600\text{ km})(2.3 \times 10^{-7}\text{ rad}) = 0.14\text{ m} = 14\text{ cm}.$

The HST would not avoid atmospheric turbulence if it looked down, so 14 cm is better than the actual resolution that would be obtainable with this instrument if we were to point it toward the surface. Earth-observation satellites such as Landsat and Spot have resolution capabilities of a few meters, and classified spy satellites are reported to have resolutions of less than 1 m.

▲ **FIGURE 38–18** Intensity patterns as a function of observation angle θ for diffraction from multiple slits must include the effects of single-slit diffraction. For $a = 4\lambda$, (a) the intensity pattern for a single slit, (b) a double slit ($d = 12\lambda$), and (c) their product, which is the observed pattern. Missing orders occur; in this case, $d = 3a$, and the 3rd, 6th, 9th, ... orders are missing from the overall pattern.

▲ **FIGURE 38–19** Diffraction pattern for multiple slits where $d = 10a$. Note the missing orders.

▶ **FIGURE 38–17** The complex of telescopes on the Mauna Kea volcano in Hawaii is one of the great observatories of the world. The twin Keck telescopes, visible at the center, can act as a single telescope whose mirror is separated into two pieces.

An optical device need not consist of a single aperture. The mirrors of many of the largest modern reflecting telescopes are separated into several pieces (Fig. 38–17), like a mosaic, in part because a single large piece of glass is difficult to form and handle. Such instruments diminish diffractive effects because the minimum angle that can be resolved is determined by the interference from the most widely separated pieces of the apparatus. If this maximum separation is D, then the minimum resolvable angle between objects is λ/D. (Note that D refers to a *transverse* separation; the distance between an eyepiece and an objective does not enter into diffractive effects.) An array of small electronically connected optical telescopes on the Moon spread over a region with a diameter of 10 km would have a resolution 100,000 times better than that of the best telescope on Earth. Were it not for Earth's atmosphere, such an instrument could pick up a newspaper headline on Earth!

38–5 Slit Width and Grating Patterns

Our discussions of double- and multiple-slit diffraction patterns have treated each slit as a point source of light that emits a single spherical wave. The angular spread of the diffraction pattern depends on the parameter d/λ, where d is the slit separation. We have now seen that single slits of finite width have their own diffraction pattern. The angular spread of this pattern depends on a/λ, where a is the slit width. What effect does a finite slit width have on the multiple-slit pattern? For Fraunhofer diffraction, the overall intensity distribution is the product of the two intensity patterns. The pattern I_{mult}, corresponding to the double or multiple slit, is multiplied by the pattern I_{single}, corresponding to the single slit. The multiple-slit intensity is given by Eq. (38–4), whereas the single-slit intensity is given by Eq. (38–10). Thus their product is

$$I = I_{\text{multi}} I_{\text{single}} = I_{\text{max}} \left[\frac{\sin(N\beta)}{\sin\beta}\right]^2 \left(\frac{\sin\alpha}{\alpha}\right)^2, \tag{38–16}$$

where we recall that

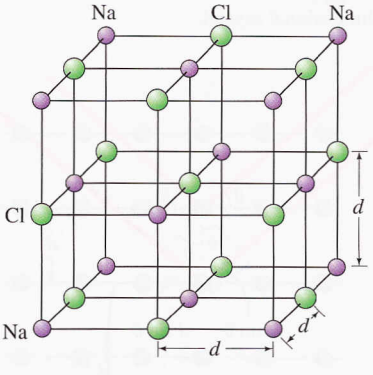
$$\beta = \frac{\pi d \sin\theta}{\lambda} \quad \text{and} \quad \alpha = \frac{\pi a \sin\theta}{\lambda}.$$

In the equation for the intensity, we have combined the maximum intensity factors into a single maximum intensity I_{max}.

The fact that the intensity patterns are multiplied means that the broader pattern (usually due to the single slit) acts as an envelope for the narrower pattern. For example, suppose that $d = 3a$ for a double slit ($N = 2$). In this case, the individual slit pattern is much broader than the multiple-slit pattern. At the same time, let $a = 4\lambda$, so that the single-slit pattern is easily distinguishable. Figure 38–18 shows the single-slit pattern, double-slit pattern, and combined pattern. Note that certain maxima of the double-slit pattern are absent from the combined pattern because they fall where the minima of the single-slit diffraction pattern occur. These missing maxima are called *missing orders*. The locations of missing orders are independent of λ, as Problem 43 illustrates. A measurement of the pattern described here, but with $d = 10a$, is shown in Fig. 38–19.

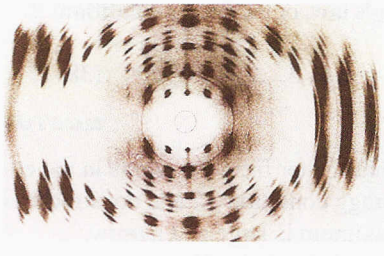
*38–6 X-Ray Diffraction

We have been emphasizing the use of gratings as a tool for the exploration of diffracted light. Light is just one form of electromagnetic radiation, and other electromagnetic waves can also be diffracted. Let's take a look at the diffraction of X rays, an important tool in the understanding of crystalline solids. Diffraction gratings work because the

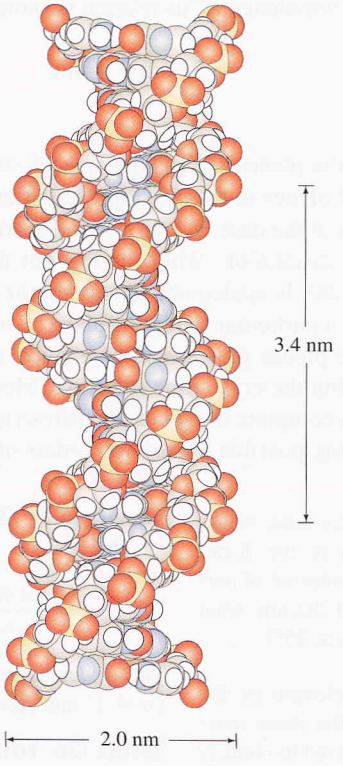


apertures or obstacles serve as rescatterers. A powerful constructive interference occurs among rescattered light from *all* the apertures or obstacles because the sources of wavelets are in a *regular* pattern. A crystalline solid contains a regular array of obstacles and therefore forms a natural diffraction grating. In a crystalline solid the array is spread over three dimensions rather than two, but the effect works in just the same way. If the electromagnetic waves can penetrate the material, each atom in the array can serve as a rescatterer, and the diffraction pattern will be characteristic of the particular way in which the rescatterers are arranged.

In 1895, Wilhelm Roentgen discovered that radiation was produced when he bombarded metal with high-energy *cathode rays* (now called electrons). This radiation was unlike any seen previously, and Roentgen called it *X rays*. Shortly thereafter, he produced the first X-ray picture, a human hand (Fig. 38–20). We know now that X rays are just electromagnetic radiation with wavelengths in the range of about 0.01 nm to 10 nm. This radiation is produced when atomic electrons change states within atoms, or when electrons are accelerated (or decelerated).

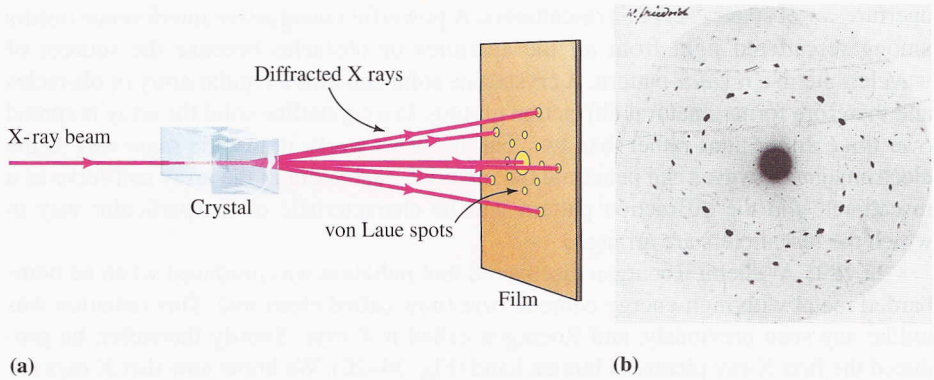


In the early 1900s, it was suspected that X rays might be some form of electromagnetic radiation. A diffraction experiment reported in 1899 vaguely suggested that X rays might have wavelengths of about 0.1 nm, much smaller than those of visible light. At the same time, some scientists suspected that solids might be made of atoms arranged in regular arrays. In 1912, Max von Laue had the idea of scattering X rays from solids. If X rays had about the same wavelength as the distance between the arrays of atoms (about 0.1 nm), then diffraction effects would be significant. Von Laue was interested in both a tool for the precise measurement of the wavelengths of X rays and a tool for the exploration of crystals. He convinced two of his colleagues, Friedrich and Knipping, to perform an experiment, and the observation of X-ray diffraction soon followed. Von Laue's idea was a crucial step in the measurement of X-ray spectra and led to a revolution in our ability to study the nature of solids and the molecules that compose them. The precise knowledge that table salt, NaCl, has the three-dimensional structure shown in Fig. 38–21 is a consequence of X-ray diffraction experiments; virtually all of our knowledge of crystalline structure comes from such experiments. It was the use of X-ray diffraction on a crystallized form of DNA that led to the discovery of that molecule's double-helical structure (Fig. 38–22).

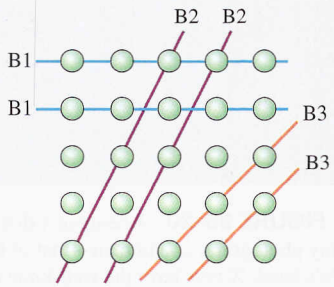


▲ **FIGURE 38–20** Roentgen's first X-ray photograph of a human—that of his wife's hand. X rays have the well-known property of penetrating matter.

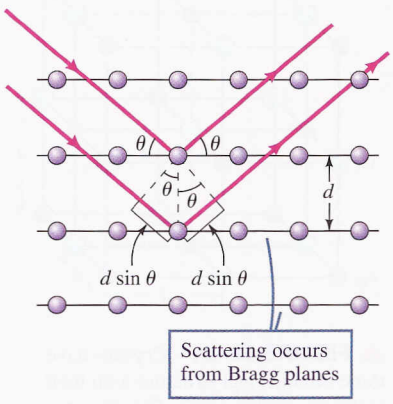
▲ **FIGURE 38–21** Crystals have three-dimensional structure with their atoms in regular arrays. This diagram shows one of the simplest, NaCl (table salt), which has a cubic structure.



(a)



(b)



▲ **FIGURE 38–22** (a) Analysis of thousands of diffraction patterns produced by crystals of the large biological molecule deoxyribonucleic acid (DNA) showed that (b) the molecule has the shape of a double helix.

▶ **FIGURE 38–23** (a) Schematic diagram of the von Laue experiment for the diffraction of X rays. (b) Von Laue spots in one of the first X-ray diffraction patterns. The large spot is undiffracted radiation.

▲ **FIGURE 38–24** Many parallel Bragg planes can be drawn in a three-dimensional crystal.

▲ **FIGURE 38–25** The geometry of X-ray diffraction between adjacent Bragg planes.

Because the rescattering centers (the atoms of a solid) are pointlike and three-dimensional rather than slitlike, the diffraction pattern of a crystalline solid consists of a regular array of spots rather than lines. The von Laue experiment on a crystalline solid, shown schematically in Fig. 38–23a, leads to a set of spots like those shown in Fig. 38–23b. Von Laue's idea was clarified almost immediately by W. L. Bragg in 1912, who proposed a simple and systematic way of showing just how the positions of the spots would be determined by the solid's crystalline structure. Bragg pointed out that in any crystal, many sets of parallel planes (called *Bragg planes*) can be drawn that pass through the positions of the atoms, and that the planes of a set are separated by characteristic distances (*Bragg spacings*). Figure 38–24 shows where some of these planes cut a two-dimensional cross section of a cubic lattice similar to that formed by NaCl. We can think of each family of parallel planes as a slit-type diffraction grating for the X rays. Figure 38–25 shows two rays scattered from two parallel planes within a crystal. These rays scatter from a given plane for which the reflection angle equals the incident angle because, at that reflection angle, the wavelets re-emitted by each atom within that plane add constructively. Now consider the interference between the scattered waves of *different* planes, which occurs because the X rays penetrate the crystal. If the separation between the planes is d, then, from the geometry of Fig. 38–25, the difference in path lengths for the two lines is $2d \sin\theta$. Note that angle θ is measured from the plane surface rather than from the normal to the plane. Constructive interference for scattering from these two adjacent planes occurs when this path-length difference is an integer multiple of the wavelength. This relation is known as **Bragg's law**, or the **Bragg condition**:

$$2d \sin\theta = n\lambda, \qquad \text{where } n = 1, 2, 3, \ldots. \tag{38–17}$$

BRAGG'S LAW

Because the planes are equally spaced, the waves that scatter from the atoms in the entire set of planes in the direction specified by the Bragg condition *all* add constructively and, as in the case of a diffraction grating, the maximum is large and narrow.

This discussion, while laying out the principles behind the X-ray spectrometer (Fig. 38–26), is inadequate to explain the *intensities* of the spots. We may state generally that, if a particular family of planes contains more atoms than another does, the maxima those planes give are more intense, and intensity information is very important in determining the crystalline structure. More advanced mathematical methods are necessary for a complete model of the diffraction pattern, which is quite complicated because of the many possible planes and orders of scattering.

EXAMPLE 38–7 Figure 38–26 shows an X-ray tube, which produces a continuous distribution of wavelengths in the X-ray range. If these wavelengths are scattered from a particular set of parallel planes of rock salt (NaCl) with a spacing $d = 0.282$ nm, what wavelengths will appear in the first and second orders at 25°?

Strategy To use Bragg's law, either the wavelength or the atomic-plane spacing must be known. In this case, the plane spacing is known, and Bragg's law, Eq. (38–17), can be used to identify unknown wavelengths.

Working It Out We use Eq. (38–17) to determine the wavelengths:

$$\lambda = \frac{2d \sin\theta}{n} = \frac{2(0.282 \text{ nm})(\sin 25°)}{n} = \frac{0.238 \text{ nm}}{n}.$$

The wavelengths at 25° are 0.238 nm and 0.119 nm for the first ($n = 1$) and second ($n = 2$) orders, respectively.

What Do You Think? If $\theta = 25°$, what is the actual overall deflection from the original beam?

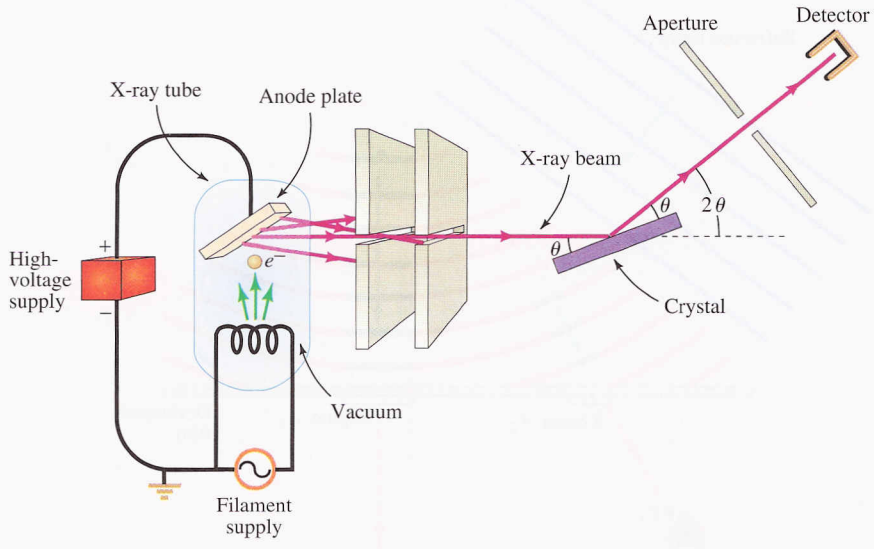


FIGURE 38–26 Schematic diagram of an X-ray spectrometer used to study properties of crystals. Electrons bombard the anode plate, producing X rays that are collimated before being scattered by the crystal. A movable detector records X-ray intensity as a function of θ to determine where constructive interference occurs.

*38–7 Holography

In 1947, Dennis Gabor proposed that interference effects between light emitted by an object (a source) and a second coherent beam can be recorded on film, which effectively becomes a diffraction grating. When light is passed through this diffraction grating, it is diffracted and forms a fully three-dimensional image of the object, an image that can be viewed from different positions and angles, just like the original object. This process is **holography**, and the film on which the interference pattern is stored is a *hologram*.

In order to understand the principles, let's start with a distant point source that sends plane waves directly toward a piece of film (Fig. 38–27). At the same time, we send a second beam—*coherent with the light from the source*—toward the film from an angle θ_r. This second beam is known as the *reference beam*. The reference beam interferes with the light from the source. Suppose that the wave in the reference beam interferes constructively with the source wave at point P_1. There will also be constructive interference at P_2, a distance d from P_1, if the wave path along line ℓ_2 differs from the path along line ℓ_1 by λ (or an integer m times λ; we consider only the case $m = 1$). When there is constructive interference at both P_1 and P_2, the relation between θ_r, the wavelength of the light, λ, and the separation d is

$$d \sin \theta_r = \lambda. \tag{38–18}$$

On the slice of film shown in Fig. 38–27, constructive interference will occur at a series of equally spaced points, which will be recorded as dark spots on the film. (Recall that the film makes a negative.) These points are parts of continuous lines into or out of the page. The full interference pattern on the film thus consists of a set of curving lines that represent all the places where there is constructive interference. The film can record with shadings of gray places where the interference is not totally destructive.

Let's now turn to the question of how the image is viewed (or *reconstructed*). Suppose that we project a beam just like the reference beam, and at the same angle, onto the back of the film (Fig. 38–28). The dark areas on the film act as obstacles that rescatter the light. The direction indicated, *that of the original light from the source*, is a direction for which the diffracted light is a maximum as the geometry in Fig. 38–28 shows. Thus a viewer placed at point E will see light as though it comes from a distant point I, which we may think of as an image of the original source. Note that there is no requirement that the beam that produces the image be identical to the original reference beam, as long as it is coherent across the film. If the angle of the new beam is different, the only effect is to shift the angle of the viewed image.

Suppose now that the point source is closer to the film when the image is made. In this case, the spots of constructive interference will not be spaced equally across the screen (Fig. 38–29). At region A_1, the situation we have described is reproduced, but at

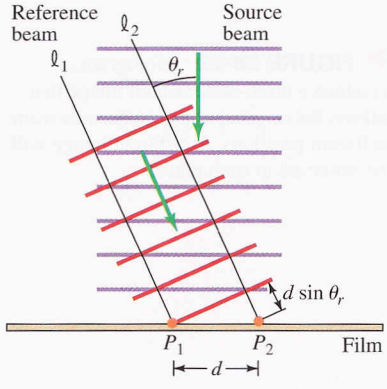

FIGURE 38–27 Coherent light from a distant source beam and from a reference beam interfere on film, producing a hologram.

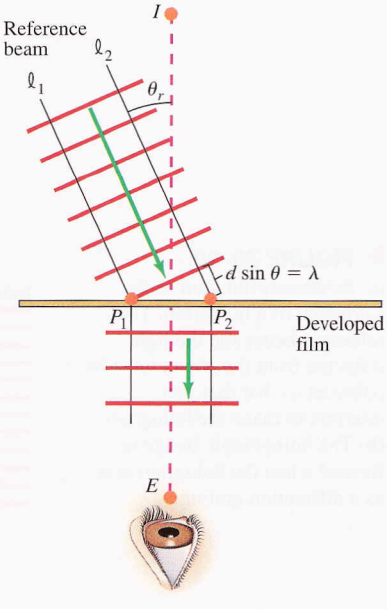

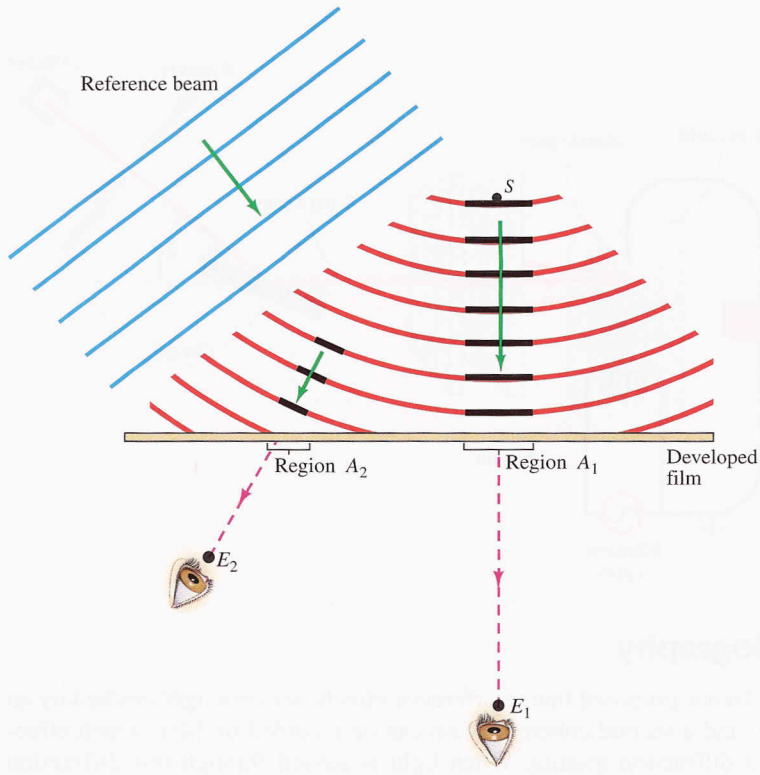

FIGURE 38–28 When a reference beam shines on holographic film, the image of the original object is reconstructed.

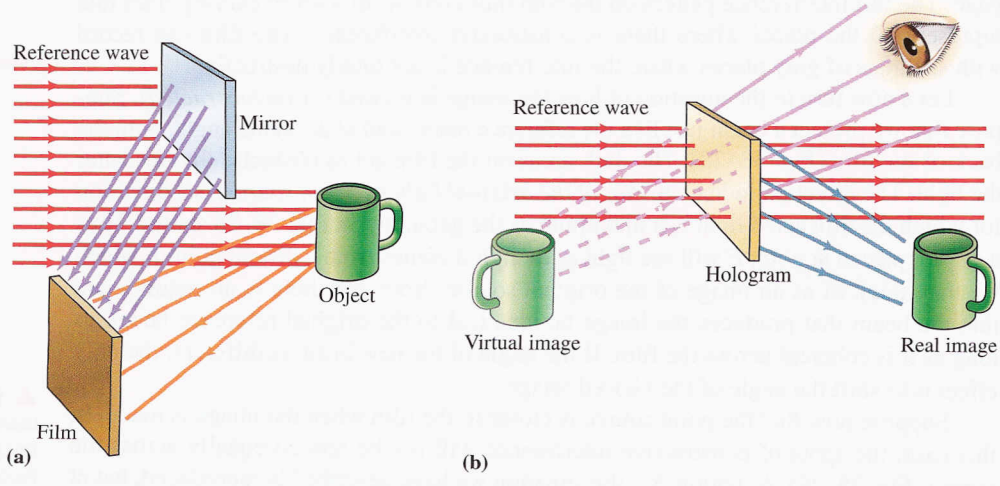


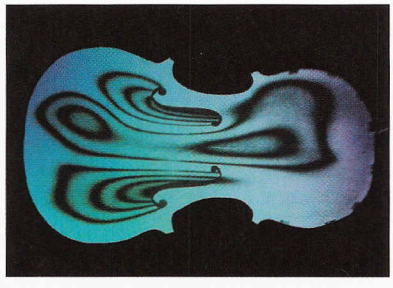
▶ **FIGURE 38–29** Holograms produce a three-dimensional image that allows the original object to be seen from different positions. A different image will be observed in each place.

region A_2, the points where there is constructive interference between the beams are different. When the exposed film is illuminated by a reference beam, a viewer at E_1 will see a plane wave along the direction from E_1 back to region A_1; that is, the observer will be looking back at the source from one angle. However, when the viewer is at E_2, the maximum of the diffraction pattern will indicate an image back along the direction from E_2 to A_2. *The viewer will be looking at the source from another angle*. There is a true three-dimensional image, which can be viewed from different angles.

When the object is more complicated than a point source, light arrives at any given point on the film from many points of the object. The interference pattern that this light makes with the reference beam is far more complicated and irregular, but it is nevertheless unique to the object. Once this pattern is recorded, it serves as a diffraction grating for light from a reference beam to make a unique pattern that reproduces the light emitted by the original object, and from many angles. Although we have treated the film as a transmission grating, if the interference pattern can be recorded as scratches on a shiny surface, then it will act as a reflection grating, such as that in a hologram on a credit card.

How is the reference beam made coherent with the light from the source? We can take a laser beam and split it in two. One part illuminates the object while the other is routed to serve as a reference (Fig. 38–30). Figure 38–31 shows one of the many uses of holograms.

▶ **FIGURE 38–30**
(a) Schematic diagram of the formation of a hologram. The reference beam and the light reflected from the object must be coherent so that they can interfere to make the hologram. (b) The holographic image is formed when the hologram acts as a diffraction grating.



◀ **FIGURE 38–31** You can observe a hologram like those visible on these visa documents by looking at a credit card. Holograms such as these are difficult to counterfeit.

THINK ABOUT THIS. . .

WHAT ARE THE USES OF HOLOGRAPHY?

The uses of holograms go beyond the simple beauty of the image. Holography has the potential to provide an extremely compact system of information storage. Because the light from every point on a printed page reaches every point of a hologram, every region of the film larger than several wavelengths across can reproduce the entire page, albeit with less detail. Moreover, successive holograms of successive pages can be made within thick photographic emulsions. If the exposure of each page is made with a reference beam oriented at a slightly different angle, then, by illuminating the resulting hologram with a light beam of that particular angle, only the corresponding page appears from a particular vantage point. For example, all the paintings in a museum could be so recorded with great accuracy in a very small space indeed.

Another important use of holography involves making two holograms of the same object on the same film at successive times. If the object has moved slightly between the moments when the holograms are made, then the two images interfere with each other like the light from two surfaces of a soap film does. Figure 38–32 shows an interference hologram of a violin in motion under the influence of a vibrating string. This interference pattern, not to be confused with the interference that makes the hologram itself, reveals detail about the motion not otherwise visible. Similarly, density variations in air are visible as the interference between two successive images of the air made on the same hologram. In this way, the mechanisms by which a candle heats the air above it or an airplane produces shock waves can be studied.

▲ **FIGURE 38–32** Interference and diffraction were crucial in producing this image of a violin. The lines indicate the motion of the vibrating instrument and are associated with the interference of two holographic images.

Summary

Diffraction is a manifestation of interference among waves. Examples include the pattern produced by screens with evenly spaced multiple slits (diffraction gratings) and the patterns made by light that passes through single apertures or around obstacles.

If d is the distance between slits in a diffraction grating and θ is the angle of observation from the direction of incident light, principal maxima are observed for the condition

$$d \sin\theta = m\lambda, \qquad \text{where } m = 0, \pm 1, \pm 2, \ldots. \tag{38–1}$$

Here, m is the order of the principal maxima. If the average intensity reaching the screen from any one slit is I_0, then the intensity of the light from the grating at the principal maxima is $N^2 I_0$, where N is the number of slits. In addition, the width of the principal maxima depends on N as $1/N$, so the diffraction peaks become sharper as N increases. This dependence on the parameters of the grating is contained in the expression for the intensity pattern:

$$I = I_0\left[\frac{\sin(N\beta)}{\sin\beta}\right]^2, \tag{38–4a}$$

where

$$\beta = \frac{\pi d \sin\theta}{\lambda}. \tag{38–4b}$$

Angular dispersion represents the change in observation angle θ as a function of a change in wavelength and is given by

$$\frac{\Delta\theta}{\Delta\lambda} = \frac{m}{d\cos\theta}. \tag{38–5}$$

The resolving power, R, is the ability of a grating to separate closely spaced lines:

$$R = \frac{\lambda}{\Delta\lambda} = mN. \tag{38–6, 38–7}$$

A single slit produces a diffraction pattern that can be derived by considering the slit to be composed of a large number of very thin slits. The criterion for destructive interference is

$$\sin\theta = \frac{m\lambda}{a}, \qquad \text{where } m = \pm 1, \pm 2, \pm 3, \ldots \tag{38–8}$$

and a is the width of the slit. The intensity pattern of a single slit is

$$I = I_{\max}\frac{\sin^2\alpha}{\alpha^2}, \tag{38–10}$$

where the angle α is given by

$$\alpha = \frac{\pi a \sin\theta}{\lambda}. \tag{38–12}$$

The minima are given in terms of α by

$$\alpha = n\pi, \qquad \text{where } n = \pm 1, \pm 2, \pm 3, \ldots. \tag{38–12}$$

Most of the light from the single slit is contained in the central peak; the secondary peaks are much less intense. The narrower the slit, the broader the diffraction pattern.

The Rayleigh criterion specifies that two point sources are just resolved if the peak of the diffraction image of the first source falls on the first minimum of the diffraction image of the second source. The minimum separation angle of two closely spaced sources obtained by a circular aperture of diameter D is approximated by

$$\theta_{\min} \cong \frac{\lambda}{D}. \tag{38–14}$$

The minimum separation $S_{\min}$ of two closely spaced objects a distance L from a lens of diameter D is given by

$$S_{\min} \cong \frac{L\lambda}{D}. \tag{38–15}$$

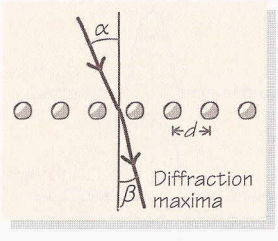
The practical limitation of Earth-based telescopes is due to air turbulence and not to diffraction limits.

X rays are diffracted by the atom centers of regularly spaced Bragg planes—planes formed by the regular array of atoms in a crystal. The technique is important for studies of crystalline structure. Bragg's law gives the observation angles θ (as measured from a plane surface in a crystal lattice) for which constructive interference is obtained from planes of spacing d:

$$2d\sin\theta = n\lambda, \qquad \text{where } n = 1, 2, 3, \ldots. \tag{38–17}$$

Holography represents a special process by which three-dimensional images are captured. A hologram is a kind of diffraction grating formed on film by scattering coherent light from an object; the three-dimensional image of the object can be reconstructed from the film when an appropriate light beam passes through it.

Understanding the Concepts

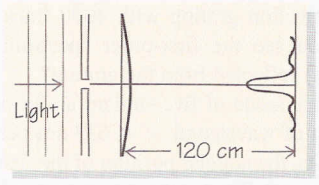


1. Describe what happens to the pattern you observe for single-slit diffraction as the width of the slit is slowly reduced.
2. Would the diffraction of water waves around the timbers of a pier be reduced by decreasing the diameter of the support poles? By increasing their diameter?
3. There are tentative plans to build telescopes for waves of various wavelengths, including visible light, on the Moon. What would the advantages of such facilities be?
4. Discuss how a Poisson spot might be obtained from a bowling ball. Would you want the source and screen to be close to or far away from the bowling ball? Explain.
5. A CD is "burned" with a laser—information is inscribed with the beam on the disk. If you had to maximize the information the CD contained, should you use a short or a long wavelength laser?
6. Is it possible to obtain better resolution with a microscope with blue light than with red light? Why or why not?
7. Two waves are linearly polarized. The electric field of one wave is aligned with the x-axis and the other is aligned with the y-axis. In the absence of matter that might change the polarization, can these waves interfere with each other?
8. In a demonstration of diffraction peaks that involves the reflection of laser light from an ordinary ruler, does the light have to be at a glancing angle?
9. The spreading of light due to diffraction in an optical instrument is greater when the instrument uses red as opposed to blue light. Why?
10. A hologram contains information about an entire object, even in just a small portion of the film. Would you expect the image made by a small portion of the hologram to be as sharp as the image made by the entire hologram?
11. For diffraction by two slits whose centers are a distance a apart, the condition for maximum intensity is $n\lambda = a\sin\theta$. When the center between the slits is removed, so that we now have a single slit of width b, the same formula with a replaced by b describes minima. What is the role of the centerpiece in producing opposite effects in the apparently identical formulae?
12. What are the differences between the interference patterns formed on a distant screen by coherent light that passes through a diffraction grating with thousands of rulings at a particular spacing and a double slit separated by the same spacing?

13. A lightbulb emits light with a spectrum characteristic of blackbody radiation (see Chapter 17). What pattern will this light produce when it is observed through a grating?
14. You are standing in the ocean, and a wave passes around you. Is this an example of diffraction?
15. How do the X rays used in X-ray diffraction "know" that there is a given set of planes of atoms for which a diffraction pattern appears?
16. Does the fact that light bends around corners mean that, with a sensitive camera, you could read a newspaper from around a corner? (This is a serious question: Try to estimate the amount of bending that the smallest obstacle would give for light, and how much information that light could contain.)
17. In the so-called 3-D movies introduced in the 1950s, a three-dimensional effect is achieved when different images are sent to each of your two eyes. How could you tell that they are not holographic images?
18. When monochromatic light falls with normal incidence on a screen with a circular hole, and we look at the transmitted light falling on a second parallel screen, there is a diffraction pattern on the second screen. At a given distance between the two screens the intensity at the center of the diffraction pattern is zero. As the second screen is moved away, the center of the pattern brightens, darkens again and then brightens, remaining the brightest part of the pattern at all greater distances. Explain these observations.

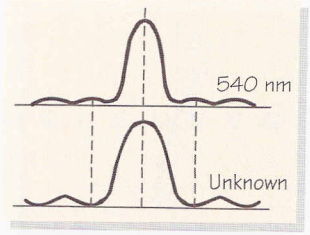
Problems

38–2 Diffraction Gratings



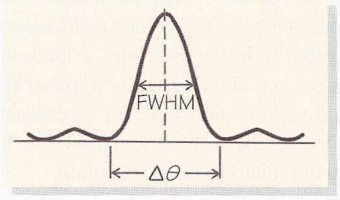
1. (I) Laser light is diffracted from a grating with 400 lines/cm. The central peak and the fourth peak are 10.34 cm apart on a screen 1.44 m away. The screen is perpendicular to the ray that makes the central peak. What is the wavelength of the light?
2. (I) A grating has a line density of 1200/cm, and a screen perpendicular to the ray that makes the central peak of the diffraction pattern is 1.5 m from the grating. If light of two wavelengths, 620 nm and 635 nm, passes through the grating, what is the separation on the screen between the second-order maxima for the two wavelengths?
3. (I) A student finds a diffraction grating but does not know the spacing of the ruled lines. She shines light from a laser with $\lambda = 680$ nm through the grating and examines the maxima on a screen 265 cm away. If the distance between the tenth maxima on either side of the central peak is 14.3 cm, what is the rule spacing of the grating?
4. (I) A spectrum is formed with a diffraction grating, which has 4500 lines per cm. Sodium light has two nearby lines with $\lambda = 589.0$ nm and $\lambda = 589.6$ nm. What is the resolution in the second-order spectrum for this grating? What is the angular separation for the sodium lines in the second-order spectrum?
5. (II) Mercury has visible optical spectral lines of wavelengths 422.729 and 422.787 nm. You have an apparatus that allows the light to fall on only 0.800 cm of a transmission diffraction grating. How many lines per centimeter does your diffraction grating need in order to resolve the third-order maxima of the two mercury lines?
6. (II) A grating with 2.0×10^4 rulings spaced uniformly over 3.0 cm is illuminated at normal incidence by light of wavelength 530 nm. (a) What is the dispersion of the grating in the second order? (b) What is the smallest wavelength interval that can be resolved in the second order near $\lambda = 530$ nm?
7. (II) What is the resolving power of a 3.0-cm-wide diffraction grating with 5000 lines/cm, for the first three orders? If light consisting of a series of discrete wavelengths around 420 nm is incident on the grating, what is the minimum wavelength separation that can be resolved in these three orders?
8. (II) Estimate the line spacing between two closely spaced lines near 530 nm if they are barely resolved in the third order by a grating with $N = 11{,}000$.
9. (II) A grating is to be inscribed on a 4.00-cm-wide glass plate so as to resolve two spectral lines with wavelengths 618.32 nm and 618.34 nm, respectively, in the first order. What is the minimum number of lines that must be ruled on the plate? What is the dispersion of the grating with this number of lines?
10. (II) Argon has wavelengths of 454.6 and 457.9 nm. (a) What resolving power does a transmission diffraction grating need to resolve the two wavelengths? (b) If the diffraction grating has 450 lines/mm, how wide does the grating have to be in order to resolve the second-order maxima?
11. (II) Parallel light falls at an angle of 30° from the vertical on a horizontal reflection grating with 4000 lines per cm. At what angle will you see the first-order spectrum of sodium light ($\lambda = 589$ nm) reflected from the grating?
12. (II) A grating is made of five similar, uniformly spaced, narrow slits. For light of wavelength $\lambda = 633$ nm perpendicularly incident on the slits, the angular position of the first principal order is 0.18° to the normal. What is the slit separation? What is the angular position of the first principal order when the first and fifth slits are covered? When the second and fourth slits are covered?
13. (II) The resolving power of a certain grating for the first-order spectrum is 10^4. If the grating is 2 cm long, what angle separates the first- and second-order images for light with $\lambda = 580$ nm at normal incidence?
14. (II) White light shines on a diffraction grating with 3600 lines/cm. The diffracted light is observed on a screen 0.90 m away. Find the second- and third-order positions for blue light (440 nm), green light (560 nm), and red light (720 nm). Sketch a view of the screen.
15. (II) Visible light extends from wavelengths of 430 nm to 680 nm. If blackbody radiation, which contains all these wavelengths, is incident on a 5.0-cm-wide grating with 2500 slits/cm, what range of angles is covered for these wavelengths in the first-order maximum? In the second-order maximum?
16. (II) An atomic source emits two strong spectral lines, a red one of wavelength 615 nm and a blue one of wavelength 475 nm. The light falls on a diffraction grating with 5000 lines/cm that is 1.2 cm across, and passes to a screen 2.00 m away. On the screen, how far from the central maximum are the second-order maxima ($m = 2$) of the spectral lines? What is the width of these maxima?
17. (II) Light of wavelength λ is incident at an angle α to the normal of a transmission grating with spacing d between each slit (Fig. 38–33). At what angles β to the normal will diffraction maxima be located?

▲ **FIGURE 38–33** Problem 17.



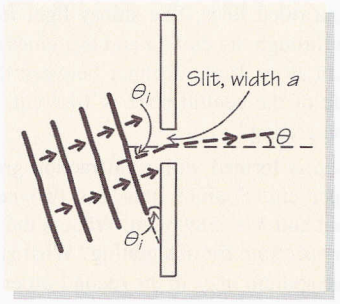
38–3 Single-Slit Diffraction

18. (I) Light of wavelength $\lambda = 535.0$ nm falls on a slit of width $a = 0.35$ mm. At what angle θ from the normal to the wall in which the slit is cut does the second dark fringe occur?
19. (I) A single slit of width 2.8×10^{-5} m diffracts light of wavelength 495 nm to a screen. The distance between the minima on either side of the central maximum is 1.8 cm. How far away is the screen?
20. (I) A single slit diffracts laser light of wavelength 635 nm onto a screen 2.5 m away. The distance between the first-order maxima on either side of the central peak is 6.0 mm. How wide is the slit?
21. (I) Microwaves of wavelength 2.6 cm are perpendicularly incident on a single slit of width 4.2 cm, and then onto a screen. (a) At what angles are maxima and minima found on the screen? (b) If the screen is 0.8 m away from the slit, what is the distance of the secondary maximum from the central maximum?
22. (II) Plane waves of light of wavelength 610 nm are incident on a single slit of width 75 μm. A lens focuses the plane waves on a screen 120 cm away (Fig. 38–34). (a) What is the width of the central maximum on the screen? (b) What is the intensity ratio between the central maximum and the first-order maximum?



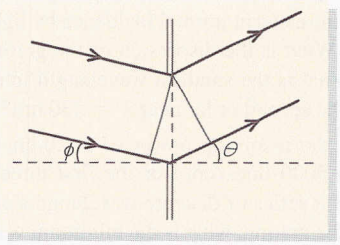
▲ FIGURE 38–34 Problem 22.

23. (II) Blue light ($\lambda = 470$ nm) passes through a slit 10 μm wide. What is the ratio between the maximum intensity of the central peak and the maximum intensity of the next adjacent peak? At what angle θ from the horizontal will the intensity of the central peak be half its maximum value? Would θ increase or decrease if red light ($\lambda = 670$ nm) were used instead?
24. (II) A diffraction pattern is formed by an adjustable slit. If the width of the slit is doubled, how do the following quantities change? (a) The distance of the first minima on the two sides of the central maximum; (b) the intensity at the central maximum; (c) the total power reaching the screen.
25. (II) A single slit produces a diffraction pattern on a distant screen. Show that the separation distance between the two minima on either side of the central maximum is twice as large as the separation distance between all the other neighboring minima. Compare your result to the corresponding case for a double-slit pattern with very narrow slits.
26. (II) When light of wavelength 540 nm passes through a single slit of unknown width, the diffraction pattern displays a second maximum where the first minimum of light of an unknown wavelength had been observed to fall (Fig. 38–35). What is the unknown wavelength?



▲ FIGURE 38–35 Problem 26.

27. (II) The width of the central peak of a single-slit diffraction pattern can be characterized by the distance of the first-order minima on both sides of the maximum or the full width at half maximum, the latter defined by the points where the intensity decreases to 50 percent (Fig. 38–36). Compare the values of these widths.



▲ FIGURE 38–36 Problem 27.

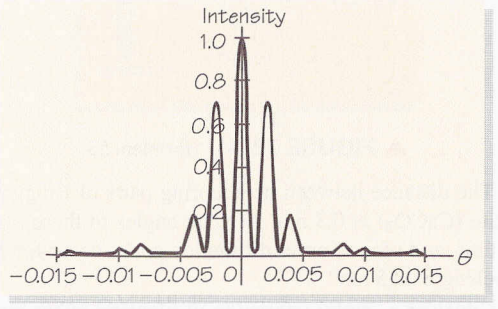
28. (II) Monochromatic light falls with normal incidence on a screen with a circular hole of diameter 2.2 mm. When a second screen is placed 0.60 m away, the intensity at the center of the diffraction pattern is zero (first minimum). As this screen is moved away, the center of the pattern brightens, darkens again and then brightens, remaining the brightest part of the pattern at all greater distances. What is the wavelength of the light? What was the distance between the screens at the second minimum?
29. (II) Light of wavelength λ arrives at a single slit of width a; the plane wave fronts arrive at the slit at an angle θ_i (Fig. 38–37). Find the angles θ for which minima appear on a very distant screen. Is there a "central maximum" in the direction defined by the incoming wave; that is, at $\theta = \theta_i$?

▲ FIGURE 38–37 Problem 29.

30. (II) Suppose that light falls on a single slit at an angle ϕ with the normal to the wall that contains the slit (Fig. 38–38). Show that Eq. (38–10) still holds, but $\sin\theta$ must be replaced by $(\sin\theta + \sin\phi)$ in the expression for α [Eq. (38–11)].

▲ FIGURE 38–38 Problem 30.

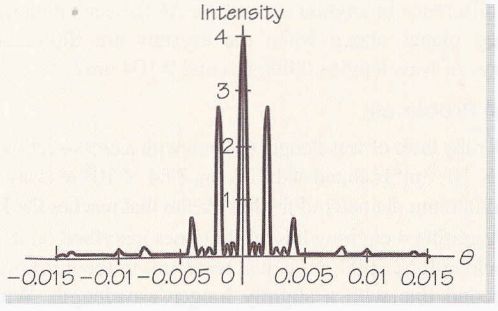
31. (III) When we determined the position of the minima of the Fraunhofer diffraction pattern for a single slit, we argued that the maxima are located midway between the minima. To look at the accuracy of this assumption, (a) show that the maxima of the intensity pattern $(\sin^2\alpha)/\alpha^2$ are determined by the solutions of the transcendental equation $\alpha = \tan\alpha$. (b) Compare a numerical solution of this equation for the first and second maxima with



angles that are midway between the first and second, and second and third, minima (you will need a calculator for the trigonometric values). (c) By plotting the intersection points of $y = \tan\alpha$ and $y = \alpha$, show that the approximation improves as the order of the maximum increases.

38–4 Resolution of Optical Instruments

32. (I) A plane wave of microwave radiation, $\lambda = 2.3$ cm, passes through a circular aperture of diameter 4.7 cm. What is the angular position of the first minimum of the resulting Fraunhofer diffraction pattern?
33. (I) Astronauts leave two lunar rovers 5.00 km apart on the Moon. An Earth-based telescope of what minimum diameter is required to resolve laser beams ($\lambda = 650$ nm) emitted by the rovers toward the telescope? The rovers are 3.0 m long. A telescope of what diameter is required for the rovers themselves to be detected? Ignore air turbulence. (The Earth–Moon distance is 3.83×10^8 m.)
34. (I) An amateur astronomer uses a reflecting telescope of diameter 20 cm and focal length 200 cm to observe light of $\lambda \cong 600$ nm from a star. (a) What minimum angular resolution can the astronomer obtain? (b) What is the diameter of the Airy disk? (c) What is the minimum separation distance of two objects on the Moon that the telescope can resolve?
35. (II) An astronaut in a satellite can barely resolve two point sources on Earth 220 km below. What is the separation distance between the sources, assuming ideal conditions, $\lambda = 480$ nm, and a pupil diameter of 1.5 mm?
36. (II) The two stars of a binary star system are just resolvable when observed by a telescope with a resolution of 18 seconds of arc and are 125 ly from Earth. Estimate their separation.
37. (II) A spy satellite is announced to be capable of distinguishing detail 10 inches across. If the satellite orbits at a height of 220 mi, what must be the minimum size of the lens aperture, assuming maximum sensitivity at $\lambda = 525$ nm? Would it be better if the film (or other sensor) were sensitive to shorter or to longer wavelengths?
38. (II) What must be the lateral separation between two objects located 1.0 km from a camera that must resolve them? The camera lens's aperture is 5.0 mm in diameter, and the film is sensitive to light of wavelength 550 nm.
39. (II) The lens of a 35-mm camera is set in such a way that the image of a very distant object is ideally sharp on the film. The focal length of the objective is 50 mm. At what setting of the camera's aperture will the sharpest possible image of an object 5.0 m away form? [*Hint*: The image will be blurred both because it is off focus and because of diffraction. Find the aperture at which these two sources give equal contributions.]
40. (II) Use the Rayleigh criterion and make assumptions to estimate the distance at which the human eye should be able to resolve the headlines in a newspaper. Carry out an experiment to see how good your estimate is!
41. (II) The SR-71 Blackbird reconnaissance airplane could fly at over 70,000 ft. If the pilot's pupil has a diameter of 1.5 mm on a bright day, what is the distance between two objects on Earth that the pilot could just resolve from 60,000 ft? Take the wavelength of light to be 520 nm.
42. (II) The headlights of a car are 1.8 m apart. At night, the pupils of an oncoming driver have expanded to 4.2 mm. How close must the two cars approach before the headlights can be resolved? Take the wavelength of the light to be 510 nm.

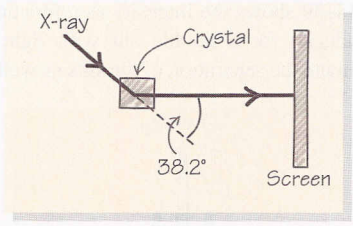


38–5 Slit Width and Grating Patterns

43. (II) Calculate the lowest missing order of a double-slit interference pattern if the separation of the two slits is three times their individual widths, $d = 3a$.
44. (II) The separation distance between two narrow slits is ten times the width of either slit. What is the intensity of the tenth interference maximum, taking the center as the first, when monochromatic light passes through the two slits and falls on a distant screen?
45. (II) Light of wavelength 690 nm from a ruby laser impinges on two slits 1.1 mm apart. Each slit is 0.20 mm wide. Find the intensity ratio I/I_0 on a screen 3.0 m away at the following distances from the central maximum: 0.050 mm, 0.50 mm, 1.5 mm, and 3.0 mm.
46. (II) Figure 38–39 shows the intensity as a function of diffraction angle (in radians) for a double slit with light of wavelength 550 nm. Estimate the separation of the slits as well as their widths.

▲ **FIGURE 38–39** Problem 46.

47. (II) Figure 38–40 shows the intensity as a function of diffraction angle (in radians) for a multiple slit with light of wavelength 600 nm. Compare the pattern with the double-slit pattern shown in Fig. 38–39 of the previous problem and determine the number of slits, their separation, and their width. [*Hint*: Look at Fig. 38–8.]



▲ **FIGURE 38–40** Problem 47.

48. (II) Light of wavelength 600 nm is perpendicularly incident on a diffraction grating. Two adjacent maxima occur at $\sin\theta = 0.30$ and $\sin\theta = 0.36$, respectively. The fourth order is missing. (a) What is the separation distance between adjacent slits? (b) What is the smallest possible individual slit width? (c) Name all orders that appear on the screen, consistent with the answers to parts (a) and (b).
49. (II) The centers of a double slit are separated by 1.2 mm; each slit is 0.4 mm wide. Are there missing orders? If so, at what angles are they missing on a distant screen if $\lambda = 589$ nm?
50. (II) The slit widths of a grating with 900 slits/cm are one-third the slit spacing. What is the ratio of the intensities of the second-order and first-order principal maxima of the grating?
51. (II) Light of wavelength 625 nm is perpendicularly incident on a screen in which double slits of width $a = 0.25$ mm have been cut. The slits are a distance $d = 0.30$ mm apart. Find the first angle away from the central axis for which the intensity on a distant screen is exactly one-half the maximum intensity.

52. (II) A grating consists of slits of width a whose centers are separated by a distance d. Sketch the diffraction pattern for (a) $d \gg a$ and (b) $d - a \ll a$ (the slits are wide compared to the strips between them).

*38–6 X-Ray Diffraction

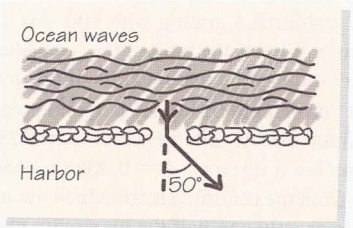
53. (I) X rays of wavelength 0.14 nm are aimed at an unknown crystal in a diffractometer. A first-order peak occurs at 38.2° (Fig. 38–41). What is the corresponding Bragg-plane spacing for the crystal?

▲ FIGURE 38–41 Problem 53.

54. (II) The distance between neighboring pairs of Bragg planes in calcite ($CaCO_3$) is 0.3 nm. At what angles to these planes will the first- and second-order diffraction peaks occur for X rays of wavelength 0.55 nm?

55. (II) Consider a crystal consisting of identical cubes with atoms at the vertices. The spacing between adjacent atoms is 0.28 nm. X rays of wavelength 0.14 nm scatter elastically from a set of planes parallel to the face of the cubes. At what angles will first-order Bragg diffraction be observed?

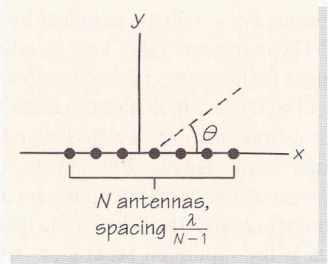
56. (II) Mica has a set of Bragg planes with spacing of 1.0 nm, whereas a set of planes in rock salt has a spacing of 0.28 nm. For an X ray of wavelength 0.10 nm, which material produces a diffraction pattern with the greater angular separation? What is the difference in angular separation $\Delta\theta$ for each material for the Bragg planes above when the crystals are illuminated with X rays of wavelengths 0.096 nm and 0.104 nm?



General Problems

57. (I) A ruby laser of wavelength 690 nm with a cross-sectional area of 1.0×10^{-3} m^2 is aimed at the Moon, 3.84×10^8 m away. Estimate the minimum diameter of the light beam that reaches the Moon.

58. (I) A grating 4 cm long has 16,000 lines inscribed on it. A line of wavelength 623.000 nm is just resolved, in the third order, from a second line with a slightly longer wavelength. What is the wavelength of the second line?



59. (II) Radar is used to study the shapes of airplanes from as far away as 100 km. (a) Assuming that the distance scale determining a plane's shape (the size of the curves that distinguish one plane from another) is 1 m, what angular resolution is needed in the radar system? (b) Estimate the wavelength of the radar waves if the reflected radar signals are gathered in a dish of diameter 2.5 m.

60. (II) Deep-ocean waves move in linear fronts directly toward a harbor opening of width 50 m (Fig. 38–42). For what wavelength will there be a minimum within the harbor at an angle of 50° from the axial line of the opening?

▲ FIGURE 38–42 Problem 60.

61. (II) By varying the spacing between two vertical dipole antennas as well as the phase of the signal generated by each antenna, the antennas can give signals that are stronger in some directions than in others (see Chapter 37). Suppose that N antennas are lined up along the x-axis (Fig. 38–43). The total distance between the first and last antennas is λ, so the spacing between the antennas is $\lambda/(N - 1)$. Any one antenna would radiate its signal with the same intensity I_0 for any angle θ. (a) Find the intensity radiated very far from the array by the system of antennas as a function of angle θ in terms of I_0, assuming that the signals of all the antennas are in phase. (b) Describe the signal for all values of θ from 0° to 360°.

▲ FIGURE 38–43 Problem 61.

62. (II) A grating with alternate perfectly clear and perfectly opaque spaces gives a spectrum in which all the even orders are missing. What is the ratio of the width of the clear and opaque spaces?

63. (II) A researcher embeds a single slit of width 5×10^{-4} m in a piece of glass of index of refraction n. He then shines laser light of wavelength 560 nm through one surface of the glass, which is diffracted through the slit and passes through another surface of the glass and on to a distant screen. The screen in which the slit is cut, the second surface of the glass, and the distant screen are all parallel to one another and perpendicular to the incoming laser beam. He hopes to measure the index of refraction n of the glass by seeing how the position of the first diffraction minimum differs from the position of the same minimum when the slit is in air. Can the researcher measure n this way?

64. (II) In Chapter 40, we shall see that an electron behaves like a wave whose wavelength, λ, is related to its momentum p by $\lambda = h/p$. Here, h is Planck's constant, $h = 6.63 \times 10^{-34}$ J·s. Electrons used in an electron microscope can be diffracted, and electron microscopes have a diffraction limit. If the energy of the electrons used in an electron microscope is 8.0 keV and if the aperture through which the electrons are channeled has a diameter of 0.06 mm, what, approximately, is the smallest angular separation the microscope can distinguish in an object?

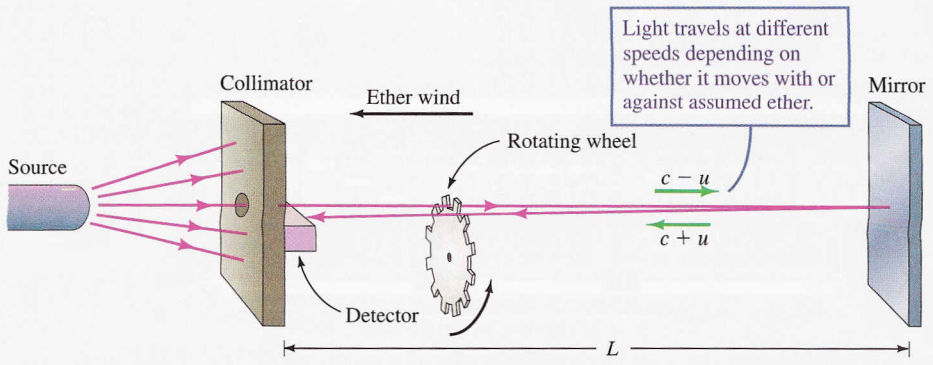
65. (III) *Babinet's principle* is useful for the treatment of the diffraction of light by obstacles. It states that if light is incident on an opaque screen in which a hole (of any shape) is cut, then the diffraction pattern produced is the same (except at $\theta = 0$) as that obtained if the screen were removed and the hole were replaced by an obstacle. Use Babinet's principle to estimate the size of an opaque obstruction on a glass slide if a narrow laser beam (with $\lambda = 633$ nm) perpendicularly incident on the slide spreads to a spot of diameter 0.70 cm on a screen 2.5 m from the slide.

66. (III) What diffraction pattern is produced on a distant screen when light of wavelength λ is perpendicularly incident on a plane that contains N very thin hairs, each spaced a distance d apart from the next hair. [*Hint*: See Problem 65.]

67. (III) Electromagnetic radiation of frequency 1.25×10^{23} Hz is scattered by a nucleus of radius 3.2×10^{-15} m. The nucleus is totally radiation-absorbent and thus is a perfect obstacle. At what angle will the first diffraction minimum lie? [*Hint*: Use Babinet's principle (Problem 65).]

Chapter 39

◀ The fact that the speed of light is the same in all frames has deep implications for how we see the world when it involves objects moving with speeds comparable to that of light. The trolley car in the top image is at rest with respect to an observer standing in the street. In the bottom image, the same trolley car is moving to the left at a speed that is a significant fraction of the speed of light, here 0.866 of the speed of light, and the same observer sees it in a very different way.



Special Relativity

There appears to be an important difference between electromagnetism and mechanics, at least superficially. The laws of mechanics look the same in all inertial frames—all reference frames that move with uniform velocity with respect to some standard inertial frame (for example, a frame at rest relative to distant stars). Electromagnetism, however, appears to violate this general law. According to Maxwell's equations, electromagnetic waves propagate at the speed c, with no restrictions on the state of motion of the source or detector. This suggests the existence of an absolute frame for electromagnetism.

The special theory of relativity, proposed by Albert Einstein in 1905, extended to electromagnetism the principle that *the fundamental laws of physics look the same in all inertial frames*. This was accomplished by modifying certain assumptions about our notions of space and time, assumptions that had gone unquestioned until 1905. Here we explore these ideas of space and time as well as the physical consequences of Einstein's theory.

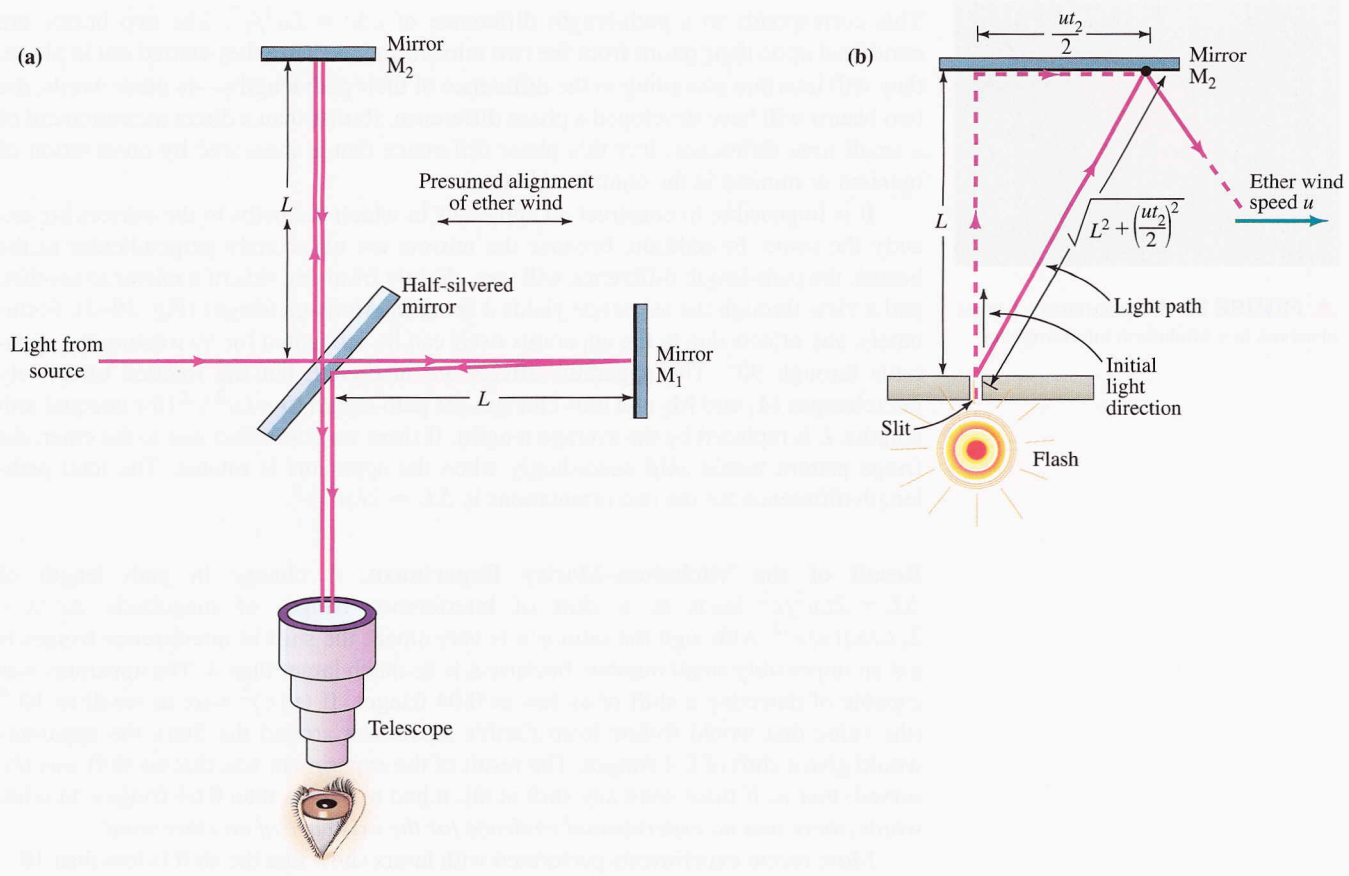
39–1 Is an Ether Necessary?

In the years following Maxwell's mid-nineteenth-century discovery of the nature of light, the absolute value of the speed of propagation of electromagnetic waves caused little concern. In an age of mechanical models, it was believed that electromagnetic waves need a medium to support them (just as sound waves need air). This presumed medium was thought to fill the universe and was called the **ether**. The ether was assumed to be at rest relative to the fixed stars. Maxwell's theory was assumed to give c

▶ **FIGURE 39–1** A "standard" measurement of the speed of light, which measures the time for a light beam to travel in a round trip over a known distance. While such methods can be used to measure the speed, they are by no means sufficiently precise to find the effect of any motion through the ether.

for the speed of propagation of electromagnetic waves *relative to the ether's rest frame*, just as the speed of sound is given as 330 m/s relative to stationary air. This assumption was accepted even though the derivation of the speed of light in Maxwell's equations contains no reference to a frame and no reference to a medium of any kind.

The existence of the ether means that in a reference frame moving at speed u relative to the ether, the speed of light emitted by a source at rest relative to the ether would be $c + u$ if the frame were moving toward the source, and $c - u$ if the frame were moving away from the source. Earth represents such a moving frame because it travels at a speed of approximately 30 km/s relative to the fixed stars in its motion around the Sun. From the point of view of a frame fixed to Earth, the ether moves past at a speed of 30 km/s. Detecting the *ether wind*, though, was likely to be very difficult.



We can see why detection of the ether wind might be hard by considering the following. A standard speed-of-light measurement is set up with the light beam propagating along an axis that lies in the direction of the supposed ether wind. If the distance from the source (and detector) to a mirror is L, then in the absence of ether wind, the time for a single traversal of light from source to mirror and back is $t_0 = 2L/c$ (Fig. 39–1). If the ether wind is blowing against the source, the speed of light that travels toward the mirror is $c - u$, and the speed of light that returns is $c + u$. Thus the time for a single traversal is

$$t_1 = \frac{L}{c-u} + \frac{L}{c+u} = \frac{2Lc}{c^2-u^2} = \frac{2L/c}{1-(u^2/c^2)}. \qquad (39\text{–}1)$$

For $u = 30$ km/s and $c = 3 \times 10^5$ km/s, the factor $u^2/c^2 = 10^{-8}$. Thus from the denominator alone, a time sensitivity of better than one part in 10^8 is necessary. The problem is compounded by the fact that the time factor L/c is also very small—if, for example, $L = 1$ m, then $2L/c$ is of the order of 10^{-8} s. The detection of the ether wind by this method would require a sensitivity of one part in 100 million in a measurement of one one-hundredth of a microsecond!

The Michelson–Morley Experiment

In 1887 Albert A. Michelson and Edward W. Morley carried out a high-precision experiment to measure the possible effect of an ether wind. They used an interferometer designed by Michelson (see Section 37–4 for a general discussion of such devices). Let's suppose that the ether wind were aligned in the direction shown in Fig. 39–2a. The distance from the half-silvered mirror to mirror M_1 in the direction aligned with the ether wind is L. The time that it takes for light to travel to mirror M_1 and back is t_1, given by Eq. (39–1). Let's next find t_2, the time it takes for the light to travel to mirror M_2 and back in the direction perpendicular to the presumed ether wind. Mirror M_2 is also a distance L away from the half-silvered mirror. (The assumption that the arms of the interferometer are equal in length is not essential, as we shall see later.) Because the second beam is perpendicular to the presumed ether wind, the light would have to travel a distance larger than $2L$. The beam would be blown "off course" by the ether wind, like the boat crossing the river in Section 3–6. As Fig. 39–2b shows, it travels a distance given by the hypotenuse of a triangle in which one leg has length L and the

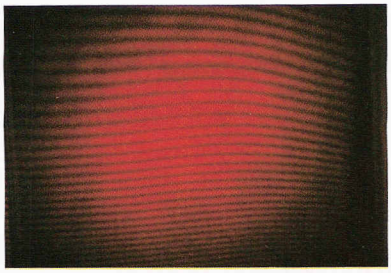
▲ **FIGURE 39–2** (a) Schematic diagram of the Michelson–Morley experiment. Light is split into two beams by a half-silvered mirror. The beams reflected by mirrors M_1 and M_2 recombine before they enter the telescope, where interference fringes are produced. (b) The beam that is perpendicular to the supposed ether wind is carried off course. Because the distance covered is larger than the direct line L, the time for a round trip to the mirror and back is longer than it would be if the distance were $2L$.

other leg is the transverse distance the beam is blown in time $t_2/2$; that is, $ut_2/2$. The distance is $\sqrt{L^2 + (ut_2/2)^2}$. Because the speed of light is c, we find

$$\sqrt{L^2 + \left(\frac{ut_2}{2}\right)^2} = \frac{ct_2}{2}.$$

We square both sides to find

$$L^2 + \left(\frac{u^2}{4}\right)t_2^2 = \left(\frac{c^2}{4}\right)t_2^2.$$



From this equation, it follows that

$$t_2^2 = \frac{4L^2}{c^2 - u^2};$$

$$t_2 = \frac{2L/c}{\sqrt{1 - (u^2/c^2)}}.$$

We now use the fact that for small x, $(1 - x)^{-1} \cong 1 + x$ and $(1 - x)^{-1/2} \cong 1 + \frac{1}{2}x$ and apply these formulas for $x = u^2/c^2$. We find that the time difference between the arrivals of two parts of a wave pulse is

$$\Delta t \equiv t_1 - t_2 = \frac{2L}{c}\frac{u^2}{2c^2}. \qquad (39\text{–}2)$$

▲ **FIGURE 39–3** Interference fringes observed in a Michelson interferometer.

This corresponds to a path-length difference of $c\Delta t = Lu^2/c^2$. The two beams are combined upon their return from the two mirrors and, because they started out in phase, they will interfere according to the difference of their path lengths—in other words, the two beams will have developed a phase difference. Rather than a direct measurement of a small time difference, it is this phase difference that is measured by observation of maxima or minima in the combined beams.

It is impossible to construct an apparatus in which the paths to the mirrors are exactly the same. In addition, because the mirrors are not exactly perpendicular to the beams, the path-length difference will vary slightly from one side of a mirror to another, and a view through the telescope yields a set of interference fringes (Fig. 39–3). Fortunately, any effects due to the apparatus itself can be accounted for by rotating the apparatus through 90°. The apparatus effects are unaltered, but the rotation effectively interchanges M_1 and M_2 and thus changes the path length to $-Lu^2/c^2$ (for unequal arm lengths, L is replaced by the average length). If there were an effect due to the ether, the fringe pattern would *shift* accordingly when the apparatus is rotated. The total path-length difference for the two orientations is $\Delta L = 2Lu^2/c^2$.

Result of the Michelson–Morley Experiment: A change in path length of $\Delta L = 2Lu^2/c^2$ leads to a shift of interference fringes of magnitude $\Delta L/\lambda = 2(L/\lambda)(u/c)^2$. Although the ratio u/c is very small, the shift in interference fringes is not an impossibly small number, because L is so much larger than λ. The apparatus was capable of detecting a shift of as few as 0.04 fringes. If $(u/c)^2$ were as small as 10^{-8} (the value that would follow from Earth's movement around the Sun), the apparatus would give a shift of 0.4 fringes. The result of the experiment was that no shift was observed; that is, if there were any shift at all, it had to be less than 0.04 fringes. In other words, *there was no experimental evidence for the existence of an ether wind.*

More recent experiments performed with lasers show that the shift is less than 10^{-3} of the result that would be "expected" for Earth's movement through the ether. The Michelson–Morley experiment sharpened the difference between mechanics and electromagnetism. Maxwell's equations predict a definite speed of light, and all previous experience with mechanical waves had suggested that any wave speed refers to a definite reference frame. This frame would have been the "preferred" frame of electromagnetism, yet the Michelson–Morley experiment showed that motion through this preferred frame cannot be detected.

39–2 The Einstein Postulates

Albert Einstein was unaware of the Michelson–Morley experiment when he formulated the laws that explain its result. He conjectured that the laws of electricity and magnetism (electrodynamics), like those of mechanics, are the same in all inertial reference frames—frames that move with constant velocity with respect to one another, and in which Newton's laws held. The **special theory of relativity** is the result of this conjecture. Einstein himself referred to the following two postulates:

1. The laws of physics are the same in all inertial reference frames. In other words, no experiment can be performed to decide who in a set of inertial frames is moving and who, in any absolute sense, is standing still.
2. The speed of light in empty space is the same in all inertial frames.

Strictly speaking, the second postulate is part of the first because Maxwell's equations do not specify a frame when they predict the speed of light. But as we have seen in Section 39–1, the second postulate might appear to be incompatible with the first. The combination of these apparently irreconcilable assertions led to the revolutionary insights into space and time that underlie the special theory of relativity.

The first postulate as applied to mechanics was introduced in Chapter 4, where we noted, for example, that an observer in a steadily moving train could not tell by observing the motion of a ball that he tosses that he is moving in any absolute sense. We also

saw in Chapter 4 that one way of characterizing this fact is to say that the laws of mechanics are unchanged under the transformation

$$\vec{r}' = \vec{r} - \vec{u}t. \tag{39–3}$$

Figure 39–4 shows the two frames to which these equations apply. The primed variables are the coordinates in a coordinate system (or reference frame) F′. Unprimed variables are the coordinates in frame F. Frames F and F′ move relative to one another.

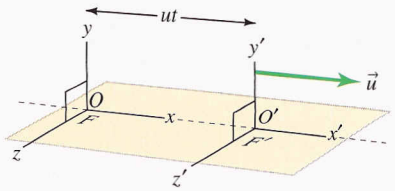
The transformation in Eq. (39–3) has no reference to time in the primed frame. Newton realized that this implied that time is the same in all frames. This may seem quite obvious to you; it certainly is in accord with our everyday experience. Formally this statement reads

$$t' = t. \tag{39–4}$$

This transformation law is a second one to be added to Eq. (39–3). Together these equations form the *Galilean transformations*.

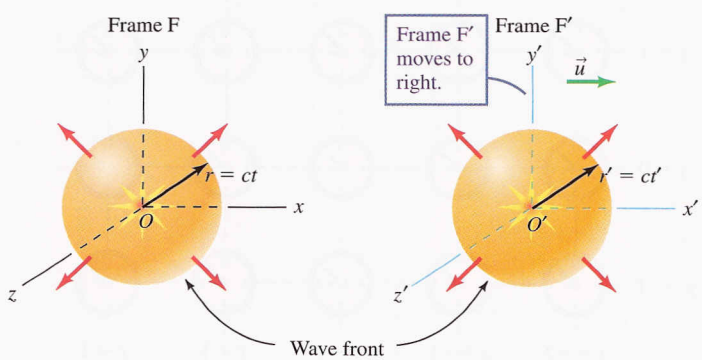
At this point we can see that *the Galilean transformation laws, Eqs. (39–3) and (39–4), are incompatible with Einstein's second postulate*. To see why, suppose that we have a light source at rest at the origin of a frame F that emits a flash of light at time $t = 0$. The flash spreads in the form of a spherical wave that expands at the speed of light; the front's location is given by (see Fig. 39–5)

$$x^2 + y^2 + z^2 = \vec{r}^2 = c^2t^2. \tag{39–5}$$



Now let's consider how the light behaves according to an observer in a second frame, F′, that moves with respect to F, as in Fig. 39–4. Suppose that origin O' of F′ coincides with origin O of F at $t = t' = 0$, when the light flashes. The second postulate implies that *in* F′, *the pulse also forms a spherical wave front* because the speed of light is the same in F′ as it is in F, whatever the direction. Thus

$$x'^2 + y'^2 + z'^2 = \vec{r}'^2 = c^2t'^2. \tag{39–6}$$



If we set $t' = t$, Eq. (39–6) would imply that $\vec{r}'^2 = \vec{r}^2$. But this cannot be; suppose, for example, that $\vec{u}$ points in the x direction. Then we would require

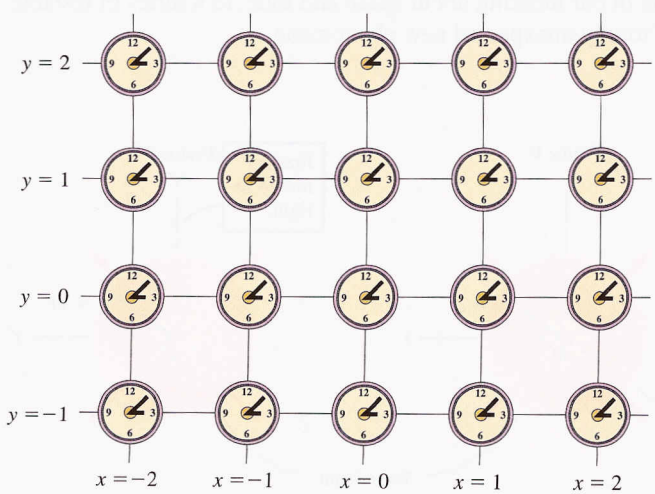
$$(x - ut)^2 + y^2 + z^2 = x^2 + y^2 + z^2,$$

a relation that is patently wrong. There appears to be an irreconcilable conflict between the invariance under the transformation in Eq. (39–3), the statement in Eq. (39–4), and the frame-independence of the speed of light. In a beautiful paper in 1905, Einstein set out to investigate this conflict. He found it necessary to examine what we *really* mean when we talk about measurements of space and time. Einstein did not give up either on invariance or on Maxwell's equations, but he did find that *both* transformation equations, including the frame-independence of time measurement, needed modification. His work led to a revolution in our thinking about space and time, to a series of testable predictions, and to a set of totally unexpected new phenomena.

▲ **FIGURE 39–4** Reference frame F′ moves at velocity $\vec{u}$ with respect to frame F. An observer is in a particular frame when he or she measures the position and time of events in terms of the coordinate system and clocks of that frame.

◀ **FIGURE 39–5** A spherical burst of light is emitted at the origin of frame F. To an observer in that frame, the light makes a spherical wave front centered at origin O. If origin O' of frame F′, moving with respect to frame F, is coincident with O when the light burst occurs, then an observer at O' moving with frame F′ will claim that the light makes a spherical wave front in frame F′ centered at O'.

39–3 Space, Time, and Simultaneity



What do we mean by a measurement of time or a measurement of space? Let us start with the idea of time and hence with the concept of a clock. Our basic requirement is that our clock be periodic: Time intervals between "ticks" are the same. We can put our clock and a light source at the origin of a coordinate system and then shine light along the x-axis. We place a mirror at some point x_1 and measure the time that it takes for the light to reach x_1 and return after reflection. If that time interval is two "ticks," we say that x_1 is one unit of length away from $x = 0$. Specifically, if the length of a tick is τ, then the distance to x_1 is $c\tau$. We now move the mirror farther away until the time for the light to reach there and back is four ticks. That point will be two length units $(2c\tau)$ away from $x = 0$ along the x-axis. Proceeding in this way, we can in principle assign a coordinate (x, y, z) to every point in space.

To be able to discuss time at each point in the coordinate system, we put a clock at every point for which x, y, and z are integer multiples of the unit of distance $c\tau$. We can synchronize all these clocks—set them all to the same time—as follows: At the origin at noon, a light signal is sent out to the point $x = 1$, $y = z = 0$. When the light ray arrives there, the clock operator at that point sets the clock to "one tick after noon," which corresponds to the point $x = 1$, $y = z = 0$. The operator at $x = 2$, $y = z = 0$ will set the clock there to "two ticks after noon" when the wave front reaches that point, and so on. In this way, all the times are synchronized and we have a reference frame in which space and time are well defined (Fig. 39–6). We have transmitted our signals in an unambiguous way because the speed of light is, by postulate (and experiment!), independent of any motion. The determination of the coordinate system and of the notion of synchronization depends on the use of light.

Although time intervals and distances within our given frame F (or another frame F′) are well defined by our setup, we must be careful about how we specify times and distances as seen from a moving frame. Let's reconsider frames F and F′ of Fig. 39–4. An observer at O' in frame F′ who wishes to see how fast a clock ticks in frame F must receive signals from the clock attached to O every time the clock in frame F ticks. Because O' is moving away from O in Fig. 39–4, the signals will be delayed. We'll see that this affects what we mean by simultaneity.

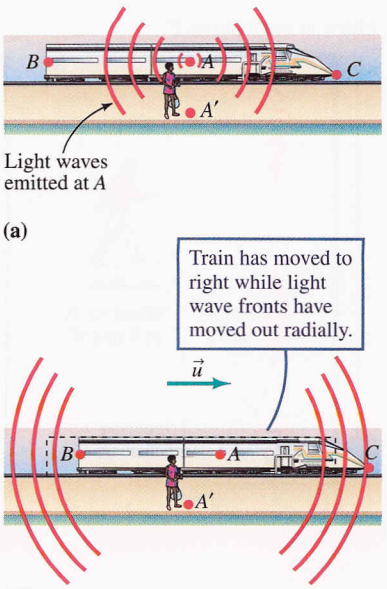
Simultaneity

We define two events at different points in a given reference frame to be *simultaneous* when they occur at the same time in that frame. *This is what we mean when we say that two events are simultaneous in a given inertial frame*. The concept of simultaneity is crucial because it enters subtly into many kinds of measurements. As an example, suppose that an observer in the F′ frame wants to measure the length of a train at rest in the F frame (the observer sees the train move). To measure the length, the observer in F′

▶ **FIGURE 39–6** Clocks attached to lattice points that represent space coordinates separated by fixed distances. The location and the clock reading define the space–time coordinates of an event. Note that all the clocks show the same time as they have been synchronized by means of light signals.

must take care that the locations x'_1 and x'_2, corresponding to the front and rear ends of the train, are marked off *at the same time*—simultaneously. Marking the position of the rear end of a moving train at midnight and the front end at 2 min past midnight and taking the difference between these two positions will not give a correct reading of the length of the train. Thus the notion of simultaneity enters into the length measurement. But as Einstein pointed out, our ordinary notion of simultaneity is strongly affected by the existence of a maximum speed for signals, the speed of light.

Let's take a more careful look at the problem of measuring a train's length. Figure 39–7a shows a train of length L initially at rest with respect to a platform. L is measured while the train is at rest, so there is no difficulty in making the measurement; we merely lay meter sticks down and count them. The rear and front of the train are labeled B and C, respectively; two persons, A and A', are stationed at the exact midpoint of the train. Person A is *inside* the train, and person A' is *outside* on the platform. For the moment, everything is measured with respect to a single inertial reference frame F. As we have already described, there is a set of synchronized clocks in this frame. We label all times in frame F as t. If A sends out a spherical light pulse at $t = 0$, light reaches B and C simultaneously, at $t = L/2c$.

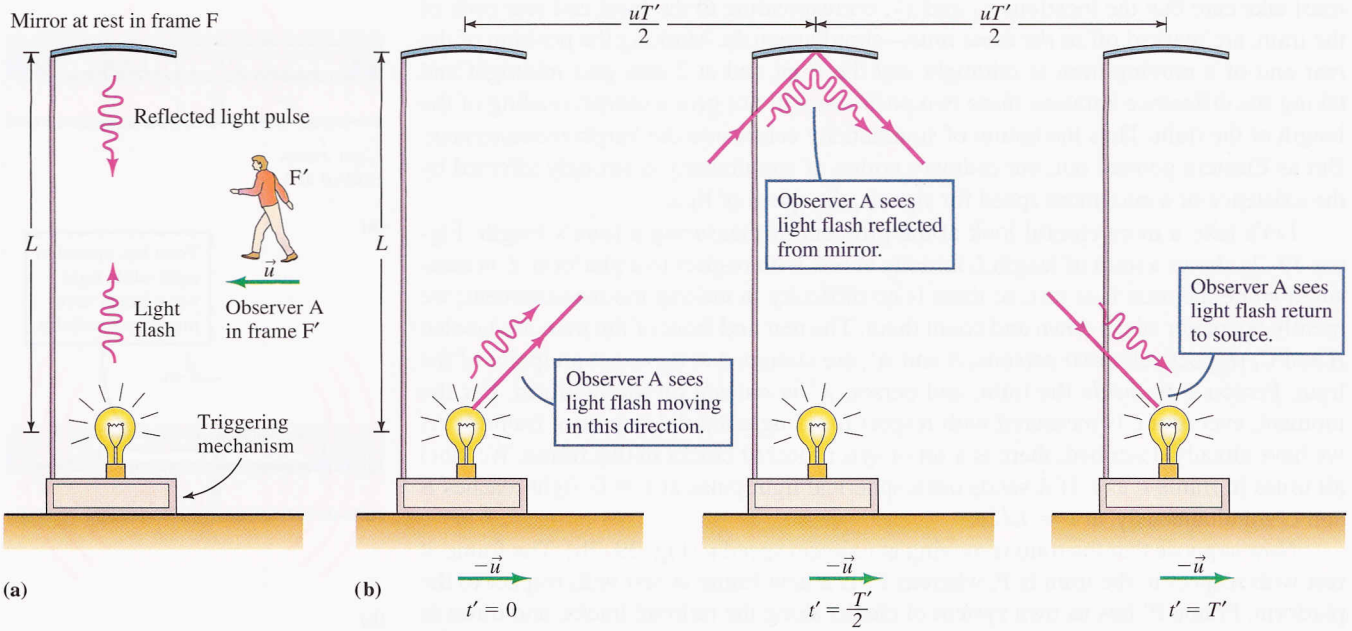


Now suppose that the train is moving at uniform speed u (Fig. 39–7b). The frame at rest with respect to the train is F, whereas F′ is a new frame at rest with respect to the platform. Frame F′ has its own system of clocks along the railroad tracks, and times in that frame are labeled t'. At the moment person A is adjacent to person A', person A fires a light pulse, and we can set the clocks to $t = 0 = t'$. From the point of view of frame F, all is as it was in the original situation: The light pulse reaches both points B and C at $t = L/2c$. *But this cannot be true from the point of view of frame* F′ *if the speed of light is the same for both frames*. Person A' sees point B approach even as the light pulse moves toward B at the (fixed) speed of light, and the light pulse reaches B at a time $t' = t'_B$ somewhat earlier. Similarly, the light pulse arrives at point C at a time $t' = t'_C$ somewhat later. In fact, if the train moves a distance ut'_B during the time point B moves toward the pulse, then the distance the beam moving toward B covers is $(L/2) - ut'_B$; according to Einstein's second postulate, this distance is ct'_B. Thus $(L/2) - ut'_B = ct'_B$, an equation that we can solve for t'_B:

$$t'_B = \frac{L/2}{c + u}. \tag{39–7}$$

Similarly, according to an observer in F′, the light beam must travel an additional distance ut'_C to reach C. By the same argument,

$$t'_C = \frac{L/2}{c - u}. \tag{39–8}$$



Time t'_B is different from time t'_C so *events that are simultaneous in* F *are not simultaneous in* F′! This rather counterintuitive idea that the concept of simultaneity is not absolute will play an important role in much of what is to follow. Note that the time difference between t'_B and t'_C is very small for $u \ll c$, and we do not see these time differences in everyday experience; this fact explains the origin of our nonrelativistic intuition. If we lived in a world where ordinary speeds were comparable to the speed of light, we would have developed a different intuition.

▲ **FIGURE 39–7** (a) Light emitted at point A, located midway between points B and C, reaches points B and C at the same time. (b) When B is moving toward A' and C away from A', the light reaches B before it reaches C.

39–4 Time Dilation and Length Contraction

The Einstein postulates, or the fact that events that are simultaneous in one reference frame are not simultaneous in a frame that is moving with respect to the first, have two dramatic consequences. These are the slowing down of moving clocks—time dilation—and the shortening of moving rods aligned with the direction of motion—length contraction. Let's examine both consequences.

▲ **FIGURE 39–8** (a) Schematic diagram of a clock. The lightbulb at one end of the rod flashes whenever it receives a light flash reflected off the mirror a distance L away from the bulb. The time interval between flashes in the frame of the clock ("ticks") is $2L/c$. (b) The path that the light ray must take according to an observer for whom the clock is moving.

Time Dilation

To clarify our discussion,[†] consider a very simple clock (Fig. 39–8a). It consists of a rod with a lightbulb at one end and a mirror at the other end, a distance L apart. A mechanism is attached to the lightbulb that makes the bulb flash instantaneously whenever a previous flash returns after reflecting off the mirror. According to an observer at rest relative to the clock, the bulb flashes with a period $T = 2L/c$.

A moving observer sees this clock behaving rather differently. Suppose that this observer is in an inertial frame F′ that moves at speed u to the left (Fig. 39–8a). An observer in F′ will see the clock receding to the right (Fig. 39–8b). In F′, the light still travels at speed c to the mirror, but it now has farther to go: The mirror moves during the time that the light travels to it from the lightbulb. As in our discussion of the transverse light beam in the Michelson–Morley experiment, the time that it takes for the light to travel to the mirror and back is such that

$$\frac{cT'}{2} = \sqrt{L^2 + \left(\frac{uT'}{2}\right)^2};$$

that is, $T' = (2L/c)/\sqrt{1 - (u^2/c^2)}$, or

$$T' = \frac{T}{\sqrt{1 - (u^2/c^2)}}. \qquad (39\text{–}9)$$

TIME DILATION

[†]Here we follow N. D. Mermin in *Space and Time in Relativity*, New York: McGraw-Hill, 1968.

Time T' is greater than time T by a factor of $1/\sqrt{1 - (u^2/c^2)}$. The observer in frame F′ sees longer "ticks" for the clock; in other words, *the moving clock is slower by a factor of* $\sqrt{1 - (u^2/c^2)}$. This effect is known as **time dilation**: *Moving clocks are observed to run more slowly than clocks at rest do.* It is not that the clocks are physically altered; rather, time intervals that are observed in different inertial frames differ.

CONCEPTUAL EXAMPLE 39–1 Suppose there were a clock at rest in frame F' identical to the clock at rest in F. Would the observer in F see the clock in F' run faster or slower, and by what amount?

Answer We can go through a calculation similar to the one we just carried out, or we can appeal to the first postulate, which can be rephrased as follows: There is no experiment that tells us exactly which inertial frame is moving or which is not. The postulate itself demands that the observer in F sees the clock in F' run slower, and by exactly the same amount as the observer in F' sees the clock in F run slow.

There are two important features of the time-dilation effect. First, it is a symmetric effect, as Conceptual Example 39–1 makes clear. Second, although the particular clock we have considered (the "light clock") is an odd one, it is universal in the sense that *every* clock imaginable must behave like it. An additional clock in F of any type can be synchronized with the light clock so that its ticks are directly tied to the light clock's ticks. The ticks of a clock can take diverse forms from the periodic vibrations of an atomic system to the frequency of a light wave to the beating of a heart. *All* these clocks run slow according to an observer who is moving with respect to them.

THINK ABOUT THIS. . .

ARE EXPERIMENTAL TESTS OF TIME DILATION POSSIBLE?

The time-dilation effect is real. We can produce experimental evidence with measurements of the half-lives of radioactive nuclei or unstable particles in motion. We shall learn in subsequent chapters that there exist radioactive nuclei and unstable particles; starting with a collection of such objects, a well-defined and accurately measurable fraction of them decay every "tick" of the clock. This fraction is characteristic of the unstable species. Note this doesn't mean that every last one of such particles lasts exactly the same amount of time. It means, rather, that half of them (say) decay in a fixed time interval. In particular, the decays of a specific species are described by a parameter, the *lifetime*, which is the time after which the fraction remaining undecayed is $1/e = 0.3679$; i.e., about 63 percent of the original number will have decayed in one lifetime. For example, a collection of the unstable fundamental particle called the *muon* has a lifetime of 2.197×10^{-6} s when the muons are at rest. We can regard the length of time it takes for 63 percent of a given large sample of at-rest muons to decay as the tick of a clock. These decays are thus a visible measure of the tick of the "clock."

With this "clock" we can test time dilation. Muons can be produced in a particle accelerator and will then travel at a speed u determined by the characteristics of the accelerator and which is a sizable fraction of the speed of light. Then in the laboratory frame of the accelerator, one finds that 63 percent of the moving muons decay after a time $t = \left[2.197/\sqrt{1 - (u^2/c^2)}\right] \mu s$, *not* after a time 2.197 μs. In modern high-energy accelerators, it is possible to accelerate the muons to such a high velocity that the time-dilation factor $1/\sqrt{1 - (u^2/c^2)}$ can be as large as 10^6, and 63 percent of these muons decay in a period $10^6 \times (2.197\ \mu s) = 2.197$ s.

The time-dilation effect was also checked in a much more pedestrian way in 1972 (Fig. 39–9). A very accurate cesium clock was flown in a commercial airplane around the world and used to confirm time dilation to an accuracy of about 10 percent. This test contains some extra elements due to accelerations associated with Earth's rotation and the presence of gravity, and these lead to some additional corrections. To eliminate these effects the experiment was carried out twice, once with the clock traveling in the easterly direction and once with the clock traveling in the westerly direction.

The time-dilation effect has been confirmed so often that there is no doubt as to its reality nor of the accuracy of Eq. (39–9). Indeed, it is now an essential element of technology; for example, the Global Positioning System must include the effect to operate properly.

▲ **FIGURE 39–9** The clock used to test time dilation on an around-the-world flight took up a good number of seats.

EXAMPLE 39–2 Consider a clock taken on an airplane that travels at 1.0×10^3 km/h around the world along the equator. If the clock is synchronized with a stationary clock on departure, by how much will the two clocks differ after one round trip? (Take into account only the time-dilation effect of special relativity.)

Setting It Up We will need to calculate the number of seconds it takes to go around the world, and for that we need Earth's circumference, approximately 4.0×10^4 km.

Strategy The stationary observer sees the traveling clock tick slower by a factor of $\sqrt{1 - (u/c)^2}$, where u is the airplane's speed relative to the surface. This factor must be applied to the total time T for which the motion occurs, which is T = (distance traveled in km)/(speed in km/s).

Working It Out The speed of the plane in km/s is $u = (1.0 \times 10^3 \text{ km/h})/(3600 \text{ s/h}) = 0.28$ km/s. Thus

$$T = \frac{40 \times 10^3 \text{ km}}{0.28 \text{ km}} = 1.4 \times 10^5 \text{ s}.$$

Also, $\frac{u}{c} = \frac{0.28 \text{ km/s}}{3.0 \times 10^8 \text{ m/s}} \times \frac{10^3 \text{ m}}{\text{km}} = 9.3 \times 10^{-7}$, or $(u/c)^2 = 8.6 \times 10^{-13}$. This is quite small, and we can use the small-x approximation $\sqrt{1 - x} \approx 1 - x/2$ for our dilation factor. The number of seconds lost is the difference between T and the dilated value of T, i.e.,

$$T - T\sqrt{1 - (u/c)^2} \cong T - T\left(1 - \frac{u^2}{2c^2}\right) = T\frac{u^2}{2c^2}.$$

The numerical value of this loss is quite small, $(1.4 \times 10^5 \text{ s}) \times (0.5 \times 8.6 \times 10^{-13}) = 6.0 \times 10^{-8}$ s.

The Twin Paradox

Time dilation applies to clocks that move with uniform velocities. If you don't pay enough attention to this restriction, you may be led to the *twin paradox*. Consider a set of identical twins. One of them takes off on a long journey. After traveling outward for a long time at a high speed v, that twin turns around and retraces her steps back home. When the traveling twin finally arrives at home after years of travel, the stay-at-home twin will observe that the traveling twin is now the younger of the two—no wrinkles, gray hair, or other signs of age. The twins are no longer identical. The stay-at-home twin reasons that this is to be expected because, relative to herself, the traveling twin was moving with uniform velocity: The traveling twin's clock slowed by a factor of $\sqrt{1 - (v^2/c^2)}$, and it is not just the mechanical clock but all types of clocks, including the twin's metabolism, heart rate, and so on that are slowed down. She decides that the deceleration and acceleration at the turning point occur in such a short time that they do not affect this conclusion.

The paradox appears if the traveling twin considers herself to be at rest while the stay-at-home twin was traveling at speed v in the opposite direction. The traveling twin would expect the stay-at-home twin to be younger. Surely both cannot be right! But there is no paradox: The traveling twin is not always in an inertial frame. She moves at uniform speed most of the time, but she does experience a deceleration and then an acceleration for the return. These are very real to her, and she knows that she has not been in the same inertial frame all the time. Thus she cannot make the same statements about the slowing down of clocks as her sister can. From the point of view of special relativity, only the stay-at-home twin, who is always in an inertial frame, can apply the theory to herself. In fact, a careful use of special relativity can show just how much older the stay-at-home twin is at the end of the journey.

The paradox may already have occurred to you in our discussion of the clock that traveled around the world in an airplane. An observer on Earth sees that clock running more slowly and arriving having lost time. A naïve symmetry argument would say there was a paradox, because an observer on the airplane might claim that he is not moving and it should be an Earth-based clock that runs more slowly. But the airplane is in a noninertial frame—it travels in a circle. There is no symmetry here, and therefore no reason to invoke a paradox. The clock on the airplane was indeed the moving clock.

Length Contraction

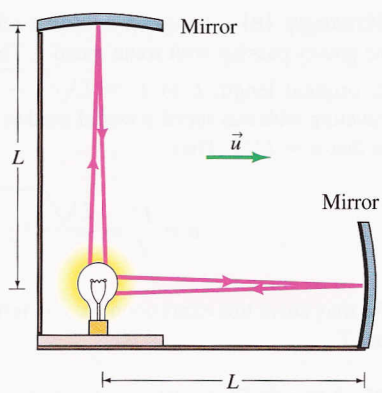
The slowing down of moving clocks is accompanied by the contraction in length of moving objects along their direction of motion. We can begin by giving an argument that uses time dilation. Consider again the muon, an unstable particle with a lifetime of $\tau \cong 2\ \mu$s. Experiments with balloons at the top of the atmosphere measure the number of muons that arrive at that level as well as their speeds. Given those numbers and the

value of τ, one can calculate that without time dilation, the number of muons arriving at sea level would be completely negligible, even if they were traveling at (nearly) the speed of light. But in fact, the number of muons that make it all the way to the surface is quite consistent with a muon lifetime increased by the time-dilation factor. We may state this quantitatively: If the muons all have speed u, the lifetime is $\tau/\sqrt{1 - (u/c)^2}$, meaning that 37 percent of the initially present muons will travel a distance

$$L = \frac{u\tau}{\sqrt{1 - (u/c)^2}} \tag{39–10}$$

without decaying. This length is much greater than it would be if there were no time-dilation effect, because the square-root factor approaches zero as u approaches c. The length could be larger than the height of the atmosphere; in this way, muons could reach the ground before they decay. We'll suppose that the speed of the muons is such that the "average" muon just reaches the ground before decaying, so L in Eq. (39–10) is the height of the atmosphere.

At this point we'll shift our attention to how this looks to an observer who is moving with the muon—an observer to whom the muon is at rest. He will measure the muon's lifetime to be its original value τ. This observer, however, will also detect that the muon reaches the ground if the Earth-based observer does; the collision with the ground is an event no observer could dispute. That means that for him it takes a time τ for the whole atmosphere to move past him at speed u. The only way this can happen is for our observer to measure the atmosphere to have a height L', where $L' = u\tau$, or, from Eq. (39–10),



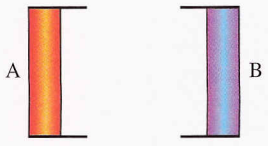
$$L' = L\sqrt{1 - \frac{u^2}{c^2}}. \tag{39–11}$$

LENGTH CONTRACTION

The observer moving with the muon measures the atmosphere to be thinner than an Earth-based observer does. To the moving observer, the atmospheric height, or any length in the direction of his motion, has undergone a **length contraction** by a factor of $\sqrt{1 - (u^2/c^2)}$.

Another way of seeing that there must be a length contraction along the direction of motion is to modify the clock constructed at the beginning of this section. We add an identical rod at right angles (transverse) to the original rod (Fig. 39–10). The mechanism is modified so that the bulb relights only when both reflected beams reach the lightbulb at the same time. This can be achieved by making the length of the rods identical. Each flash of the bulb is an event, and these events are observed from any inertial frame. Suppose now that the clock moves at speed u in the direction of the added rod with respect to an observer in frame F′. According to the observer in frame F′, the round-trip time for the light on the transverse rod is

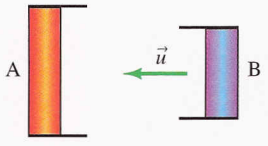
$$T' = \frac{2L}{c}\frac{1}{\sqrt{1 - (u^2/c^2)}}. \tag{39–12}$$



▲ **FIGURE 39–10** Schematic diagram of a two-armed clock used to exhibit length contraction. Note the similarity to the Michelson–Morley apparatus.

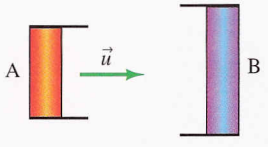
The round-trip time for the light that travels along the horizontal rod is the time t'_1 it takes to get to the mirror added to the time t'_2 it takes to return. The mirror is moving to the right, so the light on its outward trip has an extra distance ut'_1 to travel. If, according to the observer in frame F′, the length of the rod is L' (the quantity we want to find), then

$$ct'_1 = L' + ut'_1.$$



For the return trip, the bulb approaches the mirror at speed u, so the time t'_2 to return is determined by

$$ct'_2 = L' - ut'_2.$$



A and B at rest

(a)

A at rest with respect to B;
B scratches A
(NOT POSSIBLE)

(b)

B at rest with respect to A;
A scratches B
(NOT POSSIBLE)

(c)

We solve these two equations for t'_1 and t'_2, respectively, and add:

$$t'_1 + t'_2 = \frac{L'}{c - u} + \frac{L'}{c + u} = \frac{2L'/c}{1 - (u^2/c^2)}. \tag{39–13}$$

This, however, must equal T'—remember, that is the only way the bulb reflashes—and a comparison of Eqs. (39–12) and (39–13) gives $L' = L\sqrt{1 - (u^2/c^2)}$, which is the length contraction of Eq. (39–11).

Note that length contraction occurs only *along* the direction of motion. We can see that there is no change in directions transverse to the motion by the argument in Fig. 39–11. We made the unspoken assumption that there is no transverse length contraction in our derivation of time dilation; that assumption is justified by the argument in Fig. 39–11.

◀ **FIGURE 39–11** (a) Two rods, A and B, have the same length when they are at rest with respect to one another. (b) Now the rods approach each other. From the viewpoint of rod A, rod B might be shortened in a direction transverse to its direction of motion. Rod B could *simultaneously* scratch marks near the top and bottom of rod A as shown. (c) If the principle of relativity holds, then from the viewpoint of B, A would similarly be shortened. This shortening could be marked by scratches made by A onto B. But now bring the rods to rest and compare: A scratch at the 0.8-m mark of A, say, was made by the 1-m mark of B; a scratch at the 0.8-m mark on B was made by the 1-m mark of A. One "event," as recorded by the scratches, has been seen differently by two observers—an impossibility. The only possible resolution is that there can be no shortening in directions perpendicular to the motion.

EXAMPLE 39–3 The radius of our galaxy is 3.0×10^{20} m. (a) How fast would a spaceship have to travel to cross the entire galaxy in 300 yr as measured from within the spaceship? (b) How much time would elapse on Earth during the traversal?

Strategy (a) An observer at rest relative to the spaceship sees the galaxy passing with some speed v. The galaxy is contracted from its original length L to $L' = L\sqrt{1 - (v/c)^2}$. The whole galaxy traveling with this speed v would need to pass the observer in time T, so that $v = L'/T$. Thus

$$v = \frac{L'}{T} = \frac{L\sqrt{1 - (v/c)^2}}{T}.$$

We may solve this expression for v in terms of the given quantities L and T.

Working It Out We rewrite the last formula by squaring it and cross-multiplying, so that

$$v^2T^2 = L^2\left(1 - \frac{v^2}{c^2}\right) = L^2 - \frac{L^2}{c^2}v^2.$$

Rearranging, $v^2\left(T^2 + \frac{L^2}{c^2}\right) = L^2$, and hence

$$\frac{v^2}{c^2} = \frac{L^2}{L^2 + (cT)^2} = \frac{1}{1 + (cT/L)^2}.$$

Numerically $L = 2 \times (3.0 \times 10^{20}\text{ m})$ and $cT = (3.0 \times 10^8\text{ m/s}) \times (300\text{ y}) \times (3.15 \times 10^7\text{ s/y}) = 2.8 \times 10^{18}$ m, so that $(cT/L)^2 = \left(\frac{2.8 \times 10^{18}}{6 \times 10^{20}}\right)^2 = 2.2 \times 10^{-5}$. Thus $(cT/L)^2$ is a very small number, and we may write

$$\frac{v}{c} = \sqrt{\frac{1}{1 + (cT/L)^2}} \cong 1 - \frac{1}{2}\left(\frac{cT}{L}\right)^2 = 1 - 1.1 \times 10^{-5}.$$

The spaceship must travel almost (but not quite) with the speed of light to cross the entire galaxy in 300 years.

Strategy (b) and Working it out The observer on Earth does not see the galaxy contracted, and sees the spaceship move with speed v, so that the time is $t = L/v$. To a very good approximation $v = c$, so that

$$t \cong \frac{L}{c} = \frac{6.0 \times 10^{20}\text{ m}}{3.0 \times 10^8\text{ m/s}} = 2.0 \times 10^{12}\text{ s}$$

$$t = (2.0 \times 10^{12}\text{ s}) \times \frac{1}{3.15 \times 10^7\text{ s/y}} = 6.3 \times 10^4\text{ y}.$$

What Do You Think? If the Earth-based observer could read the spaceship clock, what would he read on the face of this clock when the passage is complete? *Answers to **What Do You Think?** questions are given in the back of the book.*

39–5 The Relativistic Doppler Shift

The Doppler shift for sound describes the changes in pitch of a train whistle as the train approaches, passes, and recedes from an observer. When a moving source that emits sound waves with frequency f travels toward an observer at rest relative to the air, the observed frequency f' is shifted from the source frequency according to Eq. (14–49).

$$f' = \frac{f}{1 - (u/c)} \tag{39–49}$$

We have changed the notation slightly, representing the source speed by u (instead of v_s) and the speed of sound by c (instead of v). If the source is at rest relative to the air and the observer is moving toward the source, then the frequency heard by the observer is Eq. (14–53), with a similar change of notation,

$$f' = f\left(1 + \frac{u}{c}\right) \tag{39–53}$$

The frequencies f' are not the same in the two cases, so it is possible—by an accurate measurement of the frequency shift and a knowledge of the relative speed—to determine whether it is the source or the receiver that is moving relative to the medium (the air). The reason for the difference between the two shifts is that, for sound, there *is* a preferred frame, namely, the frame at rest relative to the air. The Doppler shift for electromagnetic radiation (including light) cannot distinguish between the two situations and therefore has a different, more symmetric, form.

To find the Doppler shift for light, let's consider a periodically flashing light that moves at speed u toward an observer. The source is placed at the origin of frame F′. Suppose that one pulse of light is emitted for every time interval τ_0, so the frequency of emission seen by someone moving with the source is $f_0 = 1/\tau_0$. The stationary observer sees frame F′ moving toward him at speed u. Let's calculate the frequency of the flashes that he observes. First, the flashing is time dilated; the moving clock runs slow according to the stationary observer, with period

$$\frac{\tau_0}{\sqrt{1 - (u^2/c^2)}}.$$

But there is a second effect. The time between two successive pulses is reduced because the flashing clock has moved toward the stationary observer between a first and a second pulse. If he—the stationary observer—says that the light is a distance L from him when the first pulse is sent, then he measures the light to be at a reduced distance

$$L - \frac{u\tau_0}{\sqrt{1 - (u/c^2)}}$$

when the second pulse is sent. This reduces the time between pulses because the second pulse has a shorter distance to travel. If the first pulse arrives at a time $t_1 = L/c$, then the second pulse arrives at a time t_2 given by $\tau_0/\sqrt{1 - (u/c)^2}$ plus the reduced distance divided by c:

$$t_2 = \frac{\tau_0}{\sqrt{1 - (u/c)^2}} + \frac{1}{c}\left[L - \frac{u\tau_0}{\sqrt{1 - (u/c)^2}}\right].$$

The stationary observer measures the period of the pulses to be $\tau = t_2 - t_1$; that is,

$$\tau = t_2 - t_1 = \frac{\tau_0}{\sqrt{1 - (u/c)^2}} + \frac{1}{c}\left[L - \frac{u\tau_0}{\sqrt{1 - (u/c)^2}}\right] - \frac{L}{c} = \frac{\tau_0}{\sqrt{1 - (u/c)^2}}\left(1 - \frac{u}{c}\right).$$

If we use $1 - x^2 = (1 - x)(1 + x)$, we can write this result as

$$\tau = \tau_0 \sqrt{\frac{1 - u/c}{1 + u/c}}. \tag{39–14}$$

Recognizing that the frequency is the inverse of the period, we have

$$f_1 = f_0 \sqrt{\frac{1 + (u/c)}{1 - (u/c)}}, \tag{39–15a}$$

DOPPLER SHIFT FOR LIGHT

where f_0 is the frequency of the source in its rest frame and f_1 is the frequency observed from a frame that moves at speed u relative to the source. The two frames are moving toward each other at relative speed u, and the frequency of flashes is increased. Instead of the frequency, we can use $\lambda = c/f$ to express the wavelength λ_1 seen by the observer in terms of the wavelength λ_0 at the source:

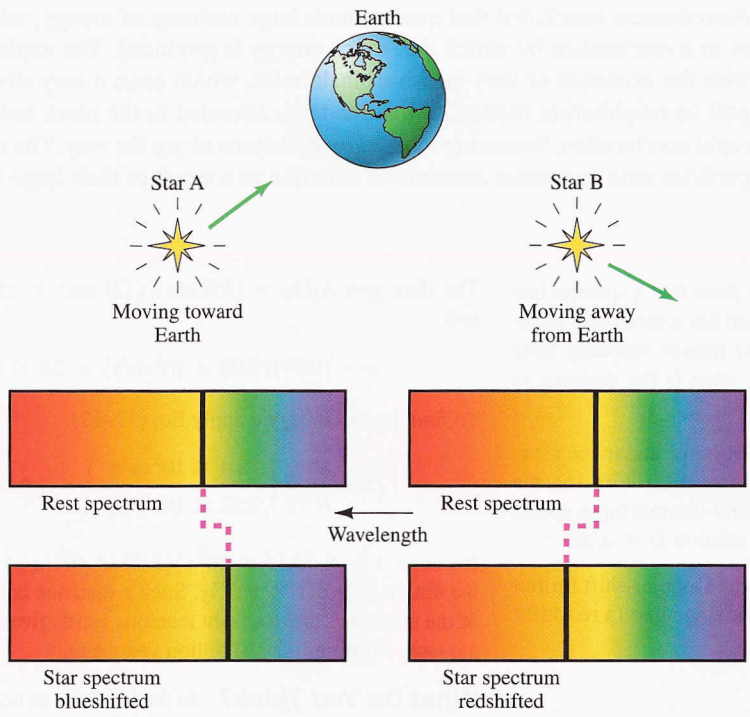
$$\lambda_1 = \lambda_0 \sqrt{\frac{1 - (u/c)}{1 + (u/c)}}. \tag{39–15b}$$

We call this situation—in which the source moves toward the observer and the observed wavelength decreases—a *blueshift*. The speed u can be interpreted either as the speed of the source toward a stationary receiver or as the speed of the receiver toward a stationary source. According to the principles of special relativity, these two possibilities are not distinguishable. If the source is moving away from the observer, then we must change the sign of u in our results, and

$$f_1 = f_0 \sqrt{\frac{1 - (u/c)}{1 + (u/c)}}. \tag{39–16a}$$

Equivalently, the observed wavelength is

$$\lambda_1 = \lambda_0 \sqrt{\frac{1 + (u/c)}{1 - (u/c)}}. \tag{39–16b}$$



Thus the frequency decreases (the wavelength increases) in this case. The visible spectrum is shifted toward the red colors, and Eqs. (39–16) are said to describe a relativistic *redshift*.

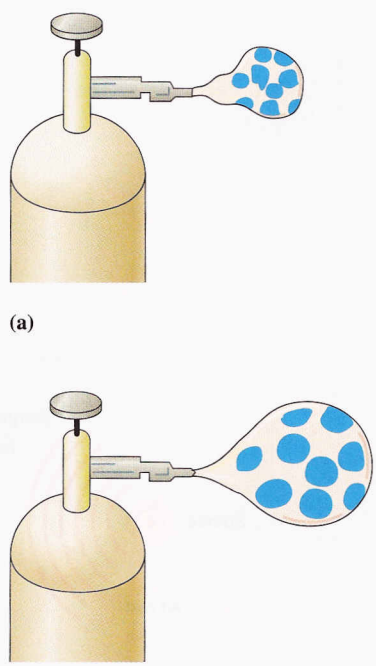
CONCEPTUAL EXAMPLE 39–4 A very bright source of radiation is in a (presumed) circular gravitational orbit about a large mass. The plane of the orbit is along the line of vision. Can we determine the size of the orbit even if its angular size seen from Earth is too small to be observed directly?

Answer When the source emerges from behind the central mass, it comes toward us, and the spectrum will be blueshifted. When it is moving away from us on the other side of the orbit, its spectrum is redshifted. The amount of the shift gives us the speed of the source. The time between the blueshifted and redshifted stages is half the period of the orbit, and given both the speed and the orbital period, the size of the orbit is easily calculated.

The Doppler Shift for Light and Cosmology

Measurements of the Doppler shift of starlight have proved crucial in the evolution of modern astrophysics and cosmology. In one application, the Doppler shift is used to establish the velocities of stars or other radiating bodies. As we know from our discussion of spectral lines in Chapter 38, radiation emitted by atoms and molecules is characterized by *spectral lines*, discrete or very narrow frequency bands of especially intense radiation. These spectral lines provide a unique signature for elements and compounds. If an entire sequence of spectral lines in starlight is observed to correspond to a

◀ **FIGURE 39–12** The spectral lines that can be attributed to a specific element are shifted if the source moves relative to the observer. The spectral lines emitted by Star A, moving toward Earth, are shifted to the blue, while those of Star B, moving away from Earth, are shifted to the red.



sequence of laboratory-observed spectral lines all shifted by the same factor, then we know that the source of the starlight is the same as the laboratory source but moves at a velocity that can be calculated from equations such as Eqs. (39–16) (Fig. 39–12).

One of the most interesting uses of the Doppler shift was made by the astronomer Edwin Hubble. In the 1920s, 1930s, and 1940s he studied the spectral lines of a large number of stars in distant galaxies, estimating their distance from Earth using known characteristic brightness of these stars. Hubble discovered that the spectra of most of these distant stars are redshifted, which means that their galaxies are receding from us. He found that *the recession velocity of the galaxies relative to our galaxy is proportional to their distance from Earth*. This result is known as **Hubble's law**, and it takes the mathematical form

$$D = u/H. \tag{39–17}$$

Here, D is the distance to a galaxy, u is the recession speed relative to us, and H is the so-called *Hubble parameter*, measured today with 1 percent accuracy to be $H \cong 2.32 \times 10^{-18}\ \text{s}^{-1}$. The fact that the distance and speed are measured relative to Earth appears superficially to give Earth a central position, but some thought shows that conclusion is wrong. If all stars and galaxies are moving away from each other according to Hubble's law, then an observer located at *any one of them* would report the same effect. This is easily visualized if we consider a simple model of dots painted uniformly on a balloon (Fig. 39–13a). As the balloon is inflated, all the dots move farther away from each other, and each dot "sees" the others moving away from it (Fig. 39–13b). In fact, a more detailed analysis shows that a picture in which the recession speed is linearly dependent on the distance, just as in Eq. (39–17), is the *unique* picture that does not privilege any one position. This picture, in which galaxies move away from each other according to Hubble's law, is part of the cosmological theory of the *Big Bang*, which proposes that the universe started from a tiny region with all of space undergoing a subsequent expansion, an expansion that still continues. In this theory, the age of the universe is on the order of H^{-1}, roughly 13 billion years.

Measurements of the Doppler shift, together with Hubble's law, allow us to calculate distances to galaxies. In the 1960s, astronomers working with radio telescopes discovered very powerful pointlike sources of radiation in which very large redshifts ($f_1/f_0 \cong 0.3$) were observed. These sources are *quasars*, or *quasistellar objects*.

▲ **FIGURE 39–13** (a) Dots painted on the surface of a balloon represent an analogy to Hubble's expanding universe. (b) As the balloon expands, the dots move away from one another at a speed that depends on the distance between them.

Astronomers concluded that quasars emit huge amounts of energy, which left a puzzle as to a mechanism by which that much energy is produced. The explanation has to do with the existence of very massive black holes, which exert a very strong gravitational pull on neighboring matter. As that matter is attracted to the black hole, it undergoes a rapid acceleration, becoming ionized by collisions along the way. The resulting charged particles emit enormous amounts of radiation as a result of their large acceleration.

EXAMPLE 39–5 Studies of a quasar show that a spectral line whose wavelength in the laboratory is 121 nm has a measured wavelength of 358 nm. With what speed is the quasar receding from Earth? Assuming that Hubble's law holds, what is the distance in light-years of the quasar from Earth?

Strategy Given the wavelength in the rest frame and in the moving frame, λ_0 and λ_1, respectively, we can invert Eq. (39–16), the Doppler shift formula for wavelengths, to find the recession speed. The distance can then be obtained from the relation $D = u/H$.

Working It Out Equation (39–16b) is the Doppler-shift formula for wavelengths for source and receiver moving apart (a redshift). We can solve it for the ratio u/c:

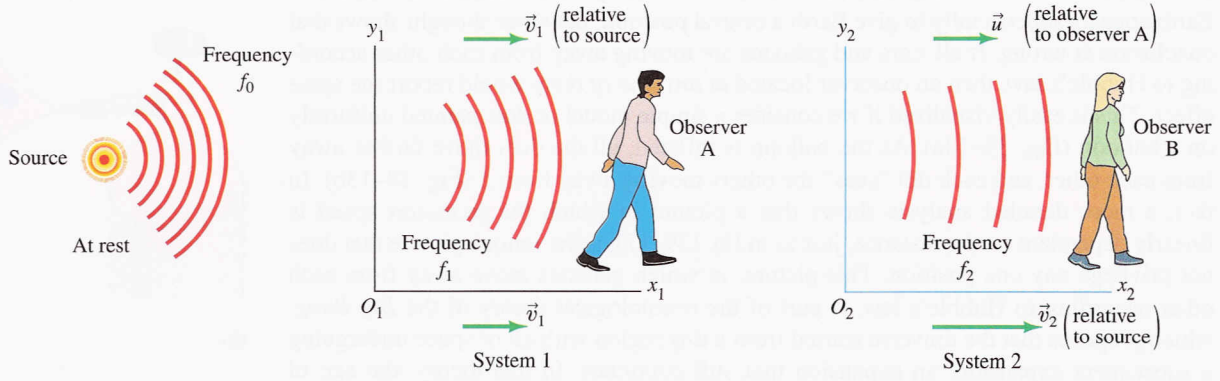
$$\frac{u}{c} = \frac{(\lambda_1/\lambda_0)^2 - 1}{(\lambda_1/\lambda_0)^2 + 1}.$$

The data give $\lambda_1/\lambda_0 = (358\text{ nm})/(121\text{ nm}) = 2.96$, so $u/c = 0.79$, and

$$u = (0.79)(3.00 \times 10^8\text{ m/s}) = 2.4 \times 10^8\text{ m/s}.$$

To find the distance, we apply Eq. (39–17):

$$D = \frac{u}{H} = \left(\frac{2.4 \times 10^8\text{ m/s}}{2.32 \times 10^{-18}\text{ s}^{-1}}\right) = 1.0 \times 10^{26}\text{ m}.$$



Because $1\text{ ly} = (3.15 \times 10^7\text{ s})(3.00 \times 10^8\text{ m/s}) = 0.95 \times 10^{16}\text{ m}$, we obtain $D = 1.1 \times 10^{10}\text{ ly}$. Such a distance is nearly at "the edge of the universe," and the light reaching Earth gives information about a quasar emitting light 10 billion years ago.

What Do You Think? Is there a limit to how much the wavelength of a given spectral line can be redshifted?

The Relativistic Addition of Velocities

Suppose that observer A measures the velocity of an object as $\vec{v}_1$; in turn, observer B measures observer A to move with velocity $\vec{u}$ with respect to him. According to the Galilean law of velocity addition, observer B would measure the object to move with velocity $\vec{v}_2 = \vec{v}_1 + \vec{u}$. It should be no surprise that this simple result cannot be consistent with special relativity; for example, for $v_1 = v_2 = 0.8c$, $v_1 + v_2$ is $1.6c$, and our expressions for time dilation and length contraction [Eqs. (39–9) and (39–11)] do not allow speeds greater than c.

We can use the Doppler shift for light to find the important relation that describes how velocities add—that is, what observer B would actually measure for the velocity of our object. Suppose that a source emits light with the rest-frame frequency f_0 (Fig. 39–14). This source is our object. An observer A moving away from the source at speed v_1 along the x-axis receives a redshifted frequency f_1. If that observer immediately

▲ **FIGURE 39–14** A light source emits a frequency f_0, seen as frequency f_1 by an observer A who moves at speed v_1 to the right. Observer A re-emits the light with frequency f_1, which is seen by an observer B who moves to the right at speed u with respect to observer A (Observer B moves at speed v_2 with respect to the original source.) Observer B measures a light frequency f_2, consistent with the law of addition of velocities.

reradiates with frequency f_1 to observer B, who is moving away in the same direction at speed u with respect to A, we would expect that the relationship between the received frequency f_2 and the original frequency f_0 would be the frequency f_0 shifted by the speed v_2 of observer B relative to the source. We can thus extract the correct relativistic expression for v_2 in terms of v_1 and u by finding f_2 in terms of f_1 and f_0.

We do this by starting with the frequency f_1 measured by observer A: According to Eq. (39–16a),

$$f_1 = f_0\sqrt{\frac{1 - (v_1/c)}{1 + (v_1/c)}}.$$

If observer A immediately reradiates the light toward observer B, moving away at speed u relative to observer A, then the frequency seen by observer B is

$$f_2 = f_1\sqrt{\frac{1 - (u/c)}{1 + (u/c)}}.$$

We now eliminate f_1 by expressing f_2 in terms of f_0 and the (as yet unknown) velocity v_2 of observer B relative to the source. We have

$$f_2 = f_0\sqrt{\frac{1 - (v_1/c)}{1 + (v_1/c)}}\sqrt{\frac{1 - (u/c)}{1 + (u/c)}},$$

which, if v_2 is the speed with which observer B sees the original object move, must also take the form

$$f_2 = f_0\sqrt{\frac{1 - (v_2/c)}{1 + (v_2/c)}}.$$

When we square (f_2/f_0) in its two forms and equate the two, we obtain

$$\frac{1 - (v_2/c)}{1 + (v_2/c)} = \frac{[1 - (v_1/c)][1 - (u/c)]}{[1 + (v_1/c)][1 + (u/c)]}.$$

If we solve this equation for v_2, the result is:

$$v_2 = \frac{v_1 + u}{1 + (v_1u/c^2)}.$$

In order to remove the emphasis from what is an observer and what is an object and make the result appear more symmetric, it is best at this point to change the notation a bit. The symbol v_1 will continue to represent the velocity of an object 1 with respect to some origin O, while rather than using the symbol u to represent the velocity of another object with respect to a second origin centered on object 1, we use the symbol v_2. Then V will represent the velocity of the second object with respect to origin O, rather than v_2 as in the equation above. We are supposing that the motion is along a single direction, so that the vectorial aspect is handled with a sign. Our result for the *law of addition of velocities* is therefore

$$V = \frac{v_1 + v_2}{1 + (v_1v_2/c^2)}. \tag{39–18}$$

ADDITION OF VELOCITIES

We see that in the nonrelativistic limit where v_1/c and v_2/c are both small, Eq. (39–18) reduces to the Galilean law of addition of velocities: $V = v_1 + v_2$. But if, for example, $v_1 = v_2 = 0.8c$, then Eq. (39–18) gives $V = 0.98c$, not $1.6c$. If $v_1 = c$, we get $V = c$, *independent of* v_2. The speed of light is in fact the maximum speed allowed, and it is never exceeded. Equation (39–18) is a beautiful illustration of how relativistic kinematics smoothly adjoins the nonrelativistic (Galilean) form while providing a very different general result.

EXAMPLE 39–6 A light source flashes with a frequency of 1.0×10^{15} Hz. The radiation is reflected by a mirror that moves at a speed of 100 km/s away from the source. How much does the frequency of the reflected radiation received back at the source differ from the original emitted frequency?

Strategy We can proceed as we did to work out the relativistic addition of velocities. The source has frequency f_0 at the source, while the mirror moves with speed u away from a source at the origin. It therefore "sees" (absorbs) the frequency redshifted down to a value f_1. It then reemits at f_1, and the detector at the source receives a frequency f_2 shifted down from f_1 because the reemitter (the mirror) is moving away with speed u. By superposing the two shifts, we find f_2 in terms of the original frequency f_0.

Working It Out The frequency seen at the mirror is

$$f_1 = f_0\sqrt{\frac{1 - u/c}{1 + u/c}}.$$

The mirror reemits light of this frequency, and because the mirror is moving away from the observer at the source, the observer sees f_1 shifted down (redshifted) by the same factor:

$$f_2 = f_1\sqrt{\frac{1 - u/c}{1 + u/c}} = f_0\frac{1 - u/c}{1 + u/c}.$$

The difference between f_2 and f_0 is

$$f_2 - f_0 = f_0\left(\frac{1 - u/c}{1 + u/c} - 1\right) = -f_0\frac{2u/c}{1 + u/c}.$$

The minus sign properly indicates that $f_2 < f_0$. The factor u/c is small [order of 10^{-4}], and we can drop it compared to 1 in the denominator. We are left with

$$f_2 - f_0 \cong -f_0(2u/c) \cong -7 \times 10^{11} \text{ Hz},$$

only 7×10^{-4} times the original frequency.

This example illustrates the operation of a police speed radar. There are two Doppler shifts as the car whose speed is measured reflects a beam of a given emitted frequency. The returned beam is very nearly the same frequency as the emitted one; the very small shift, which as above is approximately proportional to the vehicle's speed, is detected by means of a "beat" (see Chapter 15).

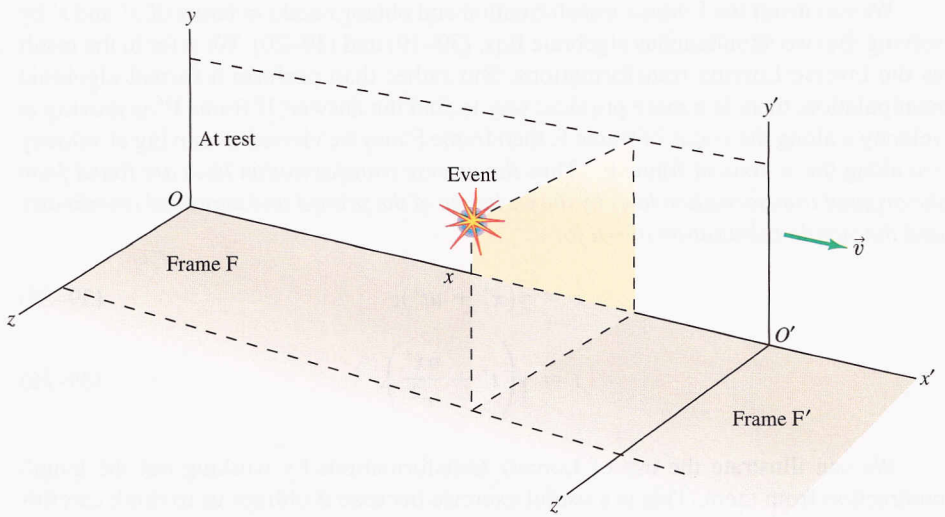
Alternative Solution We can also solve this problem by thinking of the image of the source in the mirror as radiating directly back to the source. The mirror sees the original source receding from it at speed u, and the mirror equally sees the image receding from it at the same speed. Therefore, an observer at the source sees the image receding from it at a speed V given by Eq. (39–18) with $v_1 = v_2 = u$. The Doppler shift with V as a recession speed will then give f_2.

What Do You Think? What does the color of the image of the light source reflected in the mirror look like to an observer back at the source?

39–6 The Lorentz Transformations

In this section we find the transformation laws between measured values of time and space in different inertial frames. We are looking for a set of relations like the *Galilean transformations*, Eqs. (39–3) and (39–4). We have already argued that the Galilean transformations are inconsistent with the Einstein condition that the speed of light is the same in all inertial frames. But then what are the correct transformation laws, the ones that must hold in a world in which the speed of light is the same in all inertial frames?

To proceed, we focus on an **event**, something that happens at a particular place and at a particular time. Examples are the collision of two particles, the tick of a clock, or an explosion. In an inertial frame F, the event will be described by the *space-time* coordinates (x, y, z, t). What are the coordinates (x', y', z', t') of the event in another inertial frame F′, a frame that moves with velocity u along the x-axis relative to frame F (Fig. 39–15)? (The vectorial aspect of u is entirely described by its sign.) We'll assume that the origins of the two frames coincide at times $t = t' = 0$. The expression for the coordinates (x', y', z', t') of our event in terms of the event's coordinates (x, y, z, t) in F are our desired transformation laws.



As we'll confirm below, the correct transformation laws—known as the **Lorentz transformations** for their discoverer, who formulated the laws in 1890†—are given by

$$x' = \gamma(x - ut) \tag{39–19}$$

$$t' = \gamma\left(t - \frac{ux}{c^2}\right). \tag{39–20}$$

THE LORENTZ TRANSFORMATIONS

†This date is well before 1905, when Einstein published his work. Einstein's key role was perhaps less in discovering new formulas than in formulating a conceptual whole.

◀ **FIGURE 39–15** The origins of the coordinate systems of frames F and F′ coincide at time $t = t' = 0$. An event occurs some time later. An observer in frame F would describe the space–time coordinates of the event differently than an observer in frame F′.

Here γ is defined by

$$\gamma \equiv \frac{1}{\sqrt{1 - (u^2/c^2)}}. \tag{39–21}$$

To these equations, we should add two others:

$$y' = y; \tag{39–22}$$

$$z' = z. \tag{39–23}$$

Equations (39–22) and (39–23) reflect the fact that with the relative motion of the frames along the x-direction, the description of the y- and z-coordinates of an event is the same in frames F and F′.

Note carefully the nature of these transformations. Not only does the event location x' in the frame F′ depend on both the position x and time t of the event in the frame F, *but so does the time t' of the event*. That x' depends on x and t is not surprising—it is that way in the intuitive Galilean transformation as well. But the idea that the time of the event in frame F′ also depends on both the time and position of the event in the frame F is both new and unintuitive.

As a first step to confirming the Lorentz transformation, we observe that when the relative speed of the two frames is small compared to c ($u/c \ll 1$), as would be the case for most everyday situations we experience, then $\gamma \cong 1$ and the Lorentz transformations reduce to the Galilean transformations, Eqs. (39–3) and (39–4). This is why the necessity for the Lorentz transformations is not evident from everyday experience. It is also easy to show that the location of a wave front for a light pulse emitted from the joint origin of frames F and F′ at $t = t' = 0$ is given by $x^2 + y^2 + z^2 - c^2t^2 = 0 = x'^2 + y'^2 + z'^2 - c^2t'^2$ (see Problem 44) or, in other words, that the light pulse spreads at the speed of light along a spherical front in both frames. This result reflects the necessity that the speed of light be the same in both frames and is the crucial step that distinguishes the Lorentz transformations. In fact, the Lorentz transformations show more: *In general*, you can easily verify that

$$x'^2 + y'^2 + z'^2 - c^2t'^2 = x^2 + y^2 + z^2 - c^2t^2. \tag{39–24}$$

Equation (39–24) states that the quantity $x^2 + y^2 + z^2 - c^2t^2$ is *invariant*, meaning that its value is the same in all inertial frames.

We can invert the Lorentz transformation and obtain x and t in terms of x' and t' by solving the two simultaneous algebraic Eqs. (39–19) and (39–20). We refer to the result as the inverse Lorentz transformations. But rather than perform a formal algebraic manipulation, there is a more physical way to find the answer: If frame F′ is moving at velocity u along the x-axis of frame F, then frame F may be viewed as moving at velocity $-u$ along the x'-axis of frame F′. Thus *the inverse transformation laws are found from the original transformation laws by the exchange of the primed and unprimed coordinates and the simple substitution of $-u$ for u*:

$$x = \gamma(x' + ut'); \tag{39–25}$$

$$t = \gamma\left(t' + \frac{ux'}{c^2}\right). \tag{39–26}$$

We can illustrate the use of Lorentz transformations by working out the length contraction from them. This is a useful exercise because it obliges us to think carefully about what is meant when we talk about a length measurement. Consider a rod at rest in frame F. The measurement of its length L involves "events" that consist of each end being at a particular place at a particular time. The length of an object in its own rest frame is called its **proper length**. In frame F the coordinates of the ends of the rod are $x_1 = 0$ and $x_2 = L$. Since the rod is at rest in frame F, there is no confusion about when the measurements are made. But what is the length of the rod in frame F′? As we emphasized earlier, when an object is moving in a certain reference frame, a length measurement makes sense only when the coordinates of the two ends are located simultaneously. Let us denote by t_1' the time in frame F′ at which we measure the position x_1' of one end and by t_2' the time in frame F′ at which we measure the position x_2' of the other end. Then to measure the length we require that $t_1' = t_2'$. We can choose this common time to be zero; that is, we make the length measurement at time $t_1' = t_2' = 0$. Let's see what these times are in frame F. We have from the Lorentz transformations

$$t_1' = \gamma\left(t_1 - \frac{ux_1}{c^2}\right).$$

Because $x_1 = 0$ and $t_1' = 0$, we obtain

$$t_1 = 0.$$

We also have

$$t_2' = \gamma\left(t_2 - \frac{ux_2}{c^2}\right).$$

With $t_2' = 0$ and $x_2 = L$, we find that

$$t_2 = \frac{uL}{c^2}.$$

We note that $t_1 \neq t_2$: The length measurements are made at different times in frame F. Events that are simultaneous in one frame are not simultaneous in another. With t_1 and t_2 given, we may now use the Lorentz transformations to find the coordinates of the two ends in frame F′:

$$x_1' = \gamma(x_1 - ut_1) = 0;$$

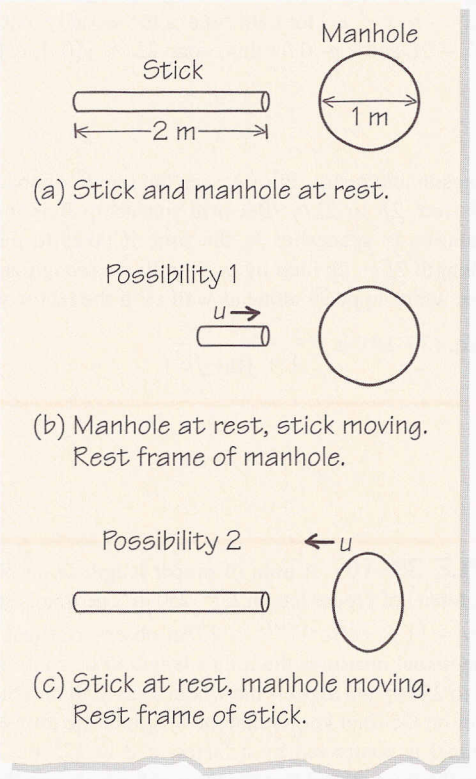
$$x_2' = \gamma(x_2 - ut_2) = \gamma\left(L - \frac{u^2L}{c^2}\right) = L\gamma\left(1 - \frac{u^2}{c^2}\right) = \frac{L}{\gamma}. \tag{39–27}$$

The observer in frame F′ measures a length $L' = x_2' - x_1' = L/\gamma$, just the length contraction of Eq. (39–11).

CONCEPTUAL EXAMPLE 39–7 Suppose you wanted to use the Lorentz transformation to confirm the time dilation factor. What "events" would you want to measure and compare in two inertial frames, and how would you use the Lorentz transformations to make this comparison?

Answer The question concerns the time interval between ticks of a clock, and these successive ticks are the events. Our two frames are F, within which the clock is at rest, and F′ moving with velocity u along the x-direction. (With this arrangement, we need only keep track of the x-coordinate in space.) Our clock's ticks occur at times t_1 and t_2 in frame F and are the time coordinates of the events in F. We can always set $t_1 = 0$, and we shall do so here. We are also free to place the spatial origin in F at the clock's location in F—in other words, the two events are at $x_1 = x_2 = 0$. We want now to give the time coordinates t'_1 and t'_2 of the two events in the frame F′; the time interval $t'_2 - t'_1$ in terms of $t_2 - t_1$ give the time dilation. But times t'_1 and t'_2 are given directly by the Lorentz transformations, in particular Eq. (39–20). (The Lorentz transformations assume that the origins of F and F′ coincide at the times $t = 0 = t'$. This is just a question of setting the origins of time and space and has no consequence for physical manifestations such as time dilation.)

The use described above of the Lorentz transformation, Eq. (39–20), is so simple that we can carry it through before leaving the example:



$$t'_1 = \gamma\left(t_1 - \frac{ux_1}{c^2}\right) = 0; \qquad t'_2 = \gamma\left(t_2 - \frac{ux_2}{c^2}\right) = \gamma t_2.$$

Thus $t'_2 - t'_1 = \gamma(t_2 - t_1)$. A tick in the moving frame is a factor γ longer than T, and we have confirmed the time-dilation factor.

What Do You Think? Suppose you have a clock that consists of a mass attached to a spring oriented along the x-axis and oscillating with some frequency. An observer moving with uniform speed along the x-axis will see the spring contracted. Does this explain the time-dilation effect?

CONCEPTUAL EXAMPLE 39–8 A perfectly smooth horizontal road has in it an open manhole 1 m in diameter. A stick of proper length 2 m is aligned with the road (Fig. 39–16a, which shows the stick and the manhole at rest with respect to one another). The stick slides along the road with a constant speed u such that its length in the rest frame of the manhole is 0.5 m. Someone working in the manhole therefore says that when the stick slides over the manhole, it will fall in (possibility 1, as in Fig. 39–16b). However, someone in the rest frame of the stick sees the manhole approaching with the same speed u and thus sees the length of the hole along the direction of motion to be only 25 cm. That observer says the stick won't fall in (possibility 2, as in Fig. 39–16c). How can these two points of view be reconciled? (Ignore the fact that the stick doesn't have time to fall very far if the acceleration of gravity were that of Earth's—you can always imagine that the acceleration of gravity is arbitrarily large.)

Answer The first point to observe is that the notion of a rigid object is not compatible with special relativity. If there were such a thing as a rigid stick, one could push one end of it and move something with the other end *simultaneously*, in violation of the requirement that no signal can move faster than the speed of light. The resolution of the two points of view follows from a careful examination of the simultaneity or nonsimultaneity of events. In the rest frame of the manhole, the front and rear ends of the stick are unsupported *at the same time* and the stick will indeed fit in. In the rest frame of the stick, the front end and rear ends of the stick are never simultaneously over the hole. In this frame the stick "snakes" into the hole, with the front entering first, and the rear following later, when the front end is already under the road. This distortion is possible because of our comments about rigidity made above.

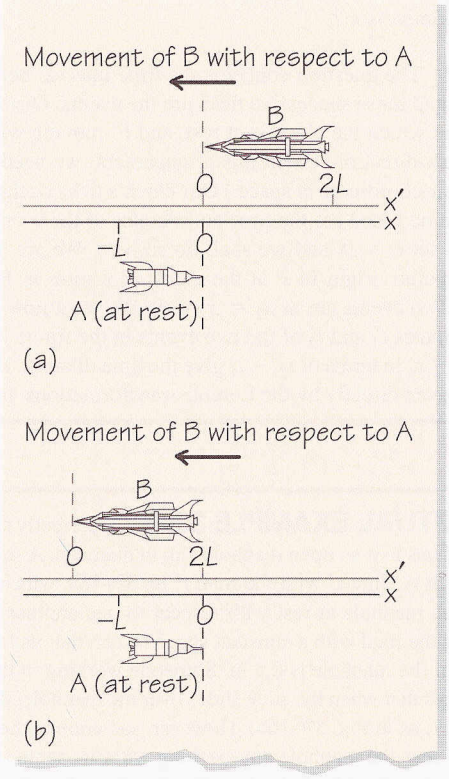
▲ **FIGURE 39–16** A stick sliding over a manhole cover presents us with a possible conflict typical of special relativity.

EXAMPLE 39–9 As seen from Earth, spaceship A of proper length L is traveling east at speed v_1 and spaceship B of proper length $2L$ is traveling west at speed v_2. The pilot of spaceship A sets his clock to zero when the front of spaceship B passes him. (The spaceship pilots sit in the nose cones.) Use the Lorentz transformations to calculate the time at which, according to the pilot of spaceship A, the tail of spaceship B passes him.

Setting It Up This involves the use of two frames and two events that must be precisely specified. We will take frame F to be the rest frame of spaceship A, with the origin at the pilot and coordinates (x, t). The frame in which spaceship B is at rest is frame F′, with (x', t') describing events and a spatial origin at the pilot.

(continues on next page)

This means that the front of spaceship A is at $x = 0$, and the back is at $x = -L$, as the sketch in Fig. 39–17 shows, while the front of spaceship B is at $x' = 0$ and its back is at $x' = +2L$. Finally we set the respective clocks so that when the nose cones of the two ships pass each other, $t = 0 = t'$.



Strategy We must first specify the events whose coordinates will be related by the Lorentz transformations. The first event is when the two nose cones pass each other, which occurs at $(x, t) = (0, 0)$ and $(x', t') = (0, 0)$. The second event is the coincidence of the back of spaceship B with the front of spaceship A. The coordinates of this event are $(x, t) = (0, t)$ and $(x', t') = (2L, t')$. The Lorentz transformation now allows us to find the time t at which the second event is seen in the frame A. In particular, we can use the transformation $x' = \gamma(x + ut)$ and solve it for t in terms of the known quantities x' and x. The plus sign appears here because spaceship B is moving west (leftward, or toward negative x) with respect to spaceship A. One last issue: The Lorentz transformation involves the *relative* velocity of the two frames, so that the transformations between the two frames contain a relative velocity u given by the relativistic addition of the two velocities v_1 and v_2.

Working It Out As described above, we solve the Lorentz transformation $x' = \gamma(x + ut)$ for t, the time of the second event in frame A, using $x' = 2L$ and $x = 0$ for this event: $2L = \gamma(0 + ut)$, or

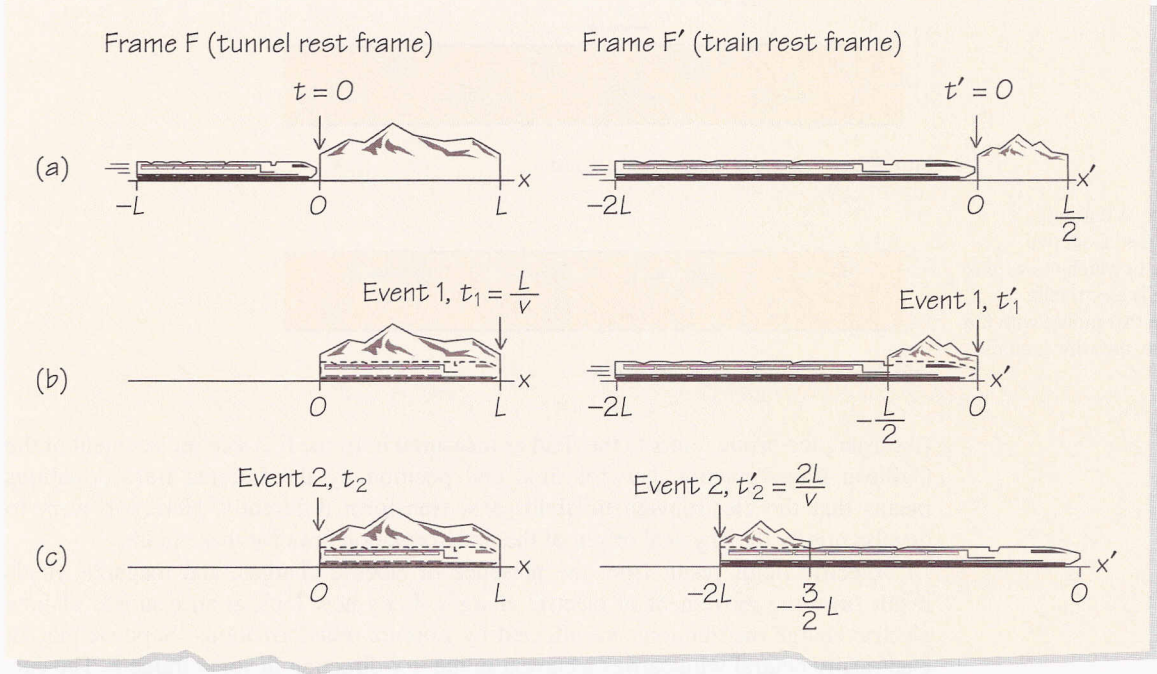
$$t = \frac{1}{u}\frac{2L}{\gamma}.$$

This is a reasonable result: Pilot A sees the length of spaceship B contracted from $2L$ to $2L/\gamma$. Because spaceship B is moving at speed u relative to spaceship A, the time it takes to pass is its observed length $2L/\gamma$ divided by u. Finally we recognize that we must find u, which appears alone as well as in the factor γ. This is given by Eq. (39–18), $u = \dfrac{v_1 + v_2}{1 + (v_1 v_2/c^2)}$.

What Do You Think? What time does the pilot of B record for the second event? Is the answer what you expected?

▲ **FIGURE 39–17** (a) The event specified by the passing of the fronts of spaceships A and B. (b) The event specified by the passing of the rear of spaceship B by the front of spaceship A. Both cases are from the viewpoint of an observer in spaceship A, so spaceship B is shortened.

EXAMPLE 39–10 A train of proper length $2L = 500$ m approaches a tunnel of proper length $L = 250$ m. The train's speed v is such that $\gamma = [1 - (v^2/c^2)]^{-1/2} = 2$. An observer at rest with respect to the tunnel measures the train's length to be contracted by a factor of 2 to 250 m and expects the whole train to fit into the tunnel. An observer on the train knows that the length of the train is 500 m, and the tunnel is contracted by a factor of 2 to 125 m. Thus the observer on the train argues that the train will not fit into the tunnel. Who is right?



Setting It Up We label two frames: frame F, the rest frame of the tunnel, and frame F′, the rest frame of the train, with the usual unprimed and primed coordinates. We set $x = 0$ at the front of the tunnel and $x' = 0$ at the front of the train. We start both clocks at 0 when the points $x = 0$ and $x' = 0$ coincide (i.e., when the front of the train enters the tunnel, Fig. 39–18a). The right side of the tunnel—the exit—is $x = L$ in frame F (Fig. 39–18b), while the rear of the train is $x' = -2L$ in frame F′ (Fig. 39–18c).

Strategy Conceptually this problem is similar to that of a rapidly sliding stick falling into a manhole. We recognize events, in this case the coincidence of the front of the train with the exit of the tunnel (event 1) and of the back of the train with the entrance of the tunnel (event 2). These two events are marked by arrows in Fig. 39–18b and c respectively, with Fig. 39–18a marking the entry of the front of the train. The event coordinates in space and time are:

event 1: $(x, t) = (L, t_1 = L/v)$ and $(x', t') = (0, t_1')$;

event 2: $(x, t) = (0, t_2)$ and $(x', t') = (-2L, t_2' = 2L/v)$.

We are able to find the times t_1 and t_2' without thinking about frame dependence. Time t_1 is the time in the tunnel frame for the train to reach the exit: The length of the tunnel is L in the tunnel frame, and the front of the train moves at speed v. Time t_2' is the time in the train frame for the back of the train to reach the entrance: The train length is $2L$ in the train frame, and the tunnel rushes by at speed v. We are left with two unknowns here,—t_1', the time for the front of the train to reach the entrance according to the train-based observer, and t_2, the time that the rear of the train reaches the entrance according to the tunnel-based observer. We can use the Lorentz transformations to find out these times. In doing so we will check that the train does indeed fit into the tunnel as measured in frame F, while it does not as measured in frame F′. The manner in which this happens will resolve the apparent paradox.

▲ **FIGURE 39–18** (a) The unnamed event specified by the coincidence of the front of the train with the tunnel entry—this event sets origins of space and time. (b), (c) Two events associated with the passage of a very fast train through a tunnel: event 1, the coincidence of the front of the train first with the right end (exit) of the tunnel, and event 2, the coincidence of the back of the train first with the left end (entry) of the tunnel. Both parts show the events according to two observers, one in the rest frame of the tunnel and another at rest in the train.

Working It Out Let's first find time t_2 corresponding to event 2. It follows from the inverse transformation Eq. (39–26) that

$$t_2 = \gamma\left(t_2' + \frac{vx_2'}{c^2}\right) = \gamma\left(\frac{2L}{v} + \frac{v(-2L)}{c^2}\right) = \gamma\frac{2L}{v}\left(1 - \frac{v^2}{c^2}\right) = \frac{2L}{v\gamma},$$

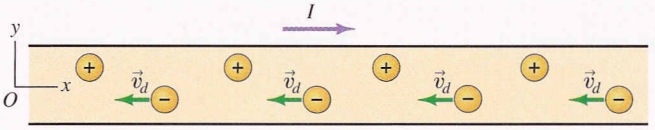
where in the last step we have recognized that $(1 - v^2/c^2) = 1/\gamma^2$. But in this problem $\gamma = 2$, so the time $t_2 = L/v$: In the tunnel frame the back of the train is at the tunnel entrance *at exactly the same time that the front of the train is at the tunnel exit*. The front and back are at the two ends of the tunnel *simultaneously* in the tunnel frame, and this is what we mean by the train fitting the tunnel (Figs. 39–18b and c).

We find the second unknown, t_1', the time in the train frame that the front of the train is at the exit (event 1), from the Lorentz transformation Eq. (39–20),

$$t_1' = \gamma\left(t_1 - \frac{vx_1}{c^2}\right) = \gamma\left(\frac{L}{v} - \frac{vL}{c^2}\right) = \gamma\frac{L}{v}\left(1 - \frac{v^2}{c^2}\right) = \frac{L}{v\gamma}.$$

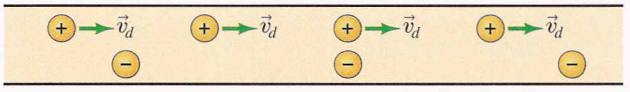
But this time is not t_2', the time in the train frame when the back of the train is at the tunnel entrance—for $\gamma = 2$, it is exactly one quarter that value (Fig. 39–18b). In other words, for the observer in the train, only one quarter of the train will be in the tunnel when the train's front end is at the exit, and it will be some time after the front of the train has left the tunnel exit before the rear of the train reaches the tunnel entrance—the tunnel is shorter than the train to the train-based observer.

There is no contradiction. The differences between the interpretations of the two observers stem from their different notions of simultaneity. These differences allow both observers to be correct in their claims!



What Do You Think? Is all this consistent with our nonrelativistic world?

Lorentz Transformations of Electric and Magnetic Fields



Maxwell's equations predict the speed of light. Therefore, electric and magnetic fields play a distinct role in special relativity. In Section 30–6, we saw that in order to maintain Galilean invariance (invariance under the transformation laws $\vec{r}' = \vec{r} - \vec{u}t$ and $t' = t$) of the Lorentz force equation, the electric and magnetic fields must mix among themselves when we observe them from different reference frames. In Eqs. (30–20) we derived Galilean transformation laws for these fields:

$$\vec{E}' = \vec{E} + (\vec{u} \times \vec{B})$$

$$\vec{B}' = \vec{B}.$$

(a) Frame F: Positive charges (wire) at rest

(b) Frame F′: Negative charges at rest

▶ **FIGURE 39–19** A current-carrying wire as observed from two frames. (a) The frame in which the wire is at rest. Here, the wire is electrically neutral. (b) The frame that moves with the negative charges. Here, the wire acquires a net charge density.

(As usual, the prime refers to the field as measured in frame F′.) The replacement of the Galilean transformation law for time and position by the Lorentz transformations means that the electromagnetic fields also transform differently. Here, we want to discuss briefly the physical origin of the transformation laws for these fields.

Electric fields result from the presence of electric charges, and magnetic fields result from the movement of electric charges. Let's now look at an example of how electric charge distributions are affected by Lorentz transformations. Suppose that an electrically neutral wire carries a current in the $+x$-direction in some frame F. The current consists of negative charges that move at some drift speed v_d in the $-x$-direction against a background of stationary positive charges with the same spacing (Fig. 39–19a). This wire produces a magnetic field but no electric field.

Now let's consider the same wire as observed from a frame F′ that moves at the drift velocity $\vec{v}_d$ (Fig. 39–19b). An observer in frame F′ would see the electrons in the wire at rest and the positive charges (the ions) move in the $+x$-direction. And there is a surprise: Special relativity implies that *the wire is not electrically neutral in frame* F′. Because of the Lorentz contraction, an observer in frame F would measure the electrons to have less space between them than the F′ observer does. In other words, the F′ observer measures *more* space between the electrons than does the F observer. Moreover, the F′ observer measures *less* space between the positive ions than does the F observer: To the F′ observer, the positive ions are moving. Thus if the F observer sees the same spacing between electrons as between positive ions—a neutral wire—the F′ observer will not, and the wire will no longer be electrically neutral to the F′ observer. The F′ observer sees an electric field.

We have thus seen that the space and time aspects of special relativity imply that the presence of a magnetic field alone in one frame introduces an electric field in another. In other words, an observer in one frame sees a different combination of electric and magnetic fields than an observer in another frame. It is in this way that transformation laws between fields come about. A careful quantitative analysis of situations such as the one just described gives the full set of Lorentz transformations between electric and magnetic fields. These transformation laws, together with the Lorentz transformations for space and time, leave the physical consequences of Maxwell's equations invariant. Because the speed of light is one of the physical consequences of Maxwell's equations, that speed is the same in all frames. We have come full circle with a consistent description.

39–7 Momentum and Energy in Special Relativity

Momentum

The need to modify our notions of space and time suggests that the definitions of other kinematical quantities that are based on measurements in space and time also require modification. In nonrelativistic mechanics, the *momentum* of a particle that moves with velocity $\vec{v}$ is

$$\vec{p} = m\vec{v}.$$

We sometimes call the coefficient of $\vec{v}$ in this expression the *rest mass m*. In the absence of external forces, the sum of the momenta of interacting particles is constant; that is, the total momentum is conserved:

$$\sum \vec{p}_i = \vec{P} = \text{a constant.}$$

Momentum conservation has its origin in Newton's third law and is a principle that holds both nonrelativistically and relativistically. However, as we shall now see, the momentum takes a different form when relativity is taken into account.

Momentum in relativity is a quantity ascribed to moving particles and has the following properties: (a) In the absence of external forces, the sum of momenta of interacting particles is conserved, and (b) in the limit that $\vec{v} \to 0$, $\vec{p} \to m\vec{v}$. On purely dimensional grounds, we expect that

$$\vec{p} = mf(v)\vec{v},$$

where the function $f(v)$ must be 1 for $v = 0$ and $f(v)$ is dimensionless. The function $f(v)$ depends only on the magnitude of $\vec{v}$, so $f(v)$ must be a function of v^2. Because f is dimensionless, it must be a function of v^2/c^2 or, equivalently, of the now familiar combination $\gamma = 1/\sqrt{1 - (v^2/c^2)}$.

An analysis of collisions between equal-mass particles—an analysis too long to present here—leads to the result that $f(v) = \gamma$, giving us the relativistic momentum

$$\vec{p} = m\gamma\vec{v} = \frac{m\vec{v}}{\sqrt{1 - (v^2/c^2)}}. \tag{39–28}$$

RELATIVISTIC MOMENTUM

For $v/c \ll 1$, this reduces to the familiar low-velocity result $\vec{p} = m\vec{v}$. Newton's second law now reads

$$\vec{F} = \frac{d\vec{p}}{dt} = m\frac{d}{dt}(\gamma\vec{v}). \tag{39–29}$$

One consequence of the relativistic modification of the expression for momentum is that $\vec{F}$ and $d\vec{v}/dt$ no longer have to point in the same direction (see Problem 65).

Kinetic Energy

The work-energy theorem together with Eq. (39–29) leads to the relativistic expression for the kinetic energy K: The work–energy theorem tells us that the work done to bring a particle of mass m from rest to speed v will be the kinetic energy of the particle. The result of this calculation is that

$$K = mc^2(\gamma - 1) = mc^2\left(\frac{1}{\sqrt{1 - (v^2/c^2)}} - 1\right). \tag{39–30}$$

As we already pointed out in Section 6–6, $[1 - (v^2/c^2)]^{-1/2} \cong 1 + (v^2/2c^2)$ for small v^2/c^2, so that in the low-velocity limit K reduces to the familiar $mv^2/2$.

To derive the result above from the work–energy theorem, we must evaluate

$$K = \int F\,dx = \int \frac{d(mv\gamma)}{dt}\frac{dx}{dt}\,dt = \int \frac{d(mv\gamma)}{dt}v\,dt.$$

The evaluation of the integral is long but straightforward and yields Eq. (39–30).

Energy Associated with Mass

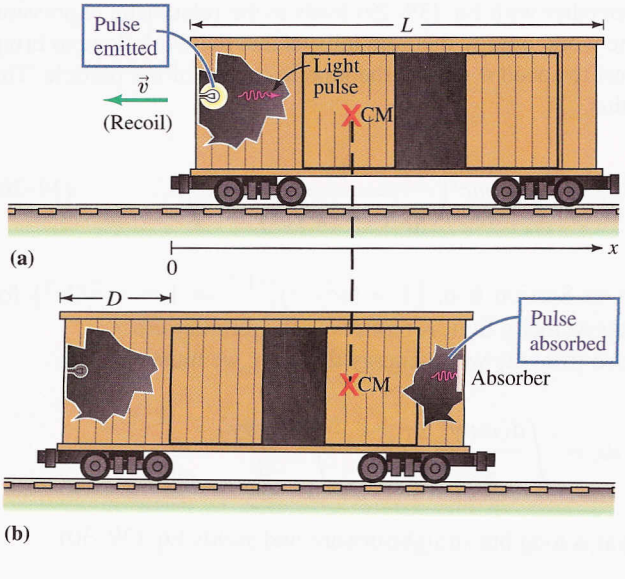
Einstein first showed that energy and inertial mass are closely related. A thought experiment demonstrates this fact. Consider a railroad car of mass M and length L standing on rails. Imagine a flashbulb attached to the left interior wall of the car (Fig. 39–20a). At a particular time, the bulb emits a burst of light toward the right wall of the railroad car. As we learned in Chapter 34, if the energy of the light pulse is E, then there is momentum of magnitude E/c associated with the pulse. Momentum conservation implies that the railroad car must move with an equal and opposite momentum toward the left (Fig. 39–20b). Because the mass of the car is M, the car will move with a velocity such that

$$Mv = E/c.$$

The time t that the pulse spends between the walls is given by

$$ct = L - vt.$$

The right side is less than L because the right wall is now moving toward the light pulse. Solving for t, we find



$$t = \frac{L}{c + v} = \frac{L}{c + (E/Mc)}.$$

The distance traveled by the car in that time is

$$D = vt = \left(\frac{E}{Mc}\right)\frac{L}{c + (E/Mc)} = \frac{EL}{E + Mc^2}. \tag{39–31}$$

Finally the car comes to a stop after it has moved a distance D when the light along with its momentum is absorbed by the right wall of the car.

If momentum is to be conserved, the center of mass of the railroad car with the flashing bulb must not move. Yet the car has moved to the left. From this, we must infer that the energy in the light is equivalent to a mass μ carried by the light flash and that this mass moves to the right when the car moves to the left such that the center of mass remains stationary. We can find μ by equating the position X of the overall center of mass before and after the flash event. Place the initial position of the left-hand side of

▶ **FIGURE 39–20** (a) A light source in a railroad car emits an electromagnetic pulse that carries energy E. The recoil momentum $p = E/c$ sets the car in motion. (b) This motion ceases when the pulse is absorbed at the other end of the car. (The displacement of the car is greatly exaggerated here.)

the car at $x = 0$. The car can be treated as a point mass M, initially at $x = L/2$. Then, before the light is emitted,

$$X = \frac{(\mu)(0) + (M)(L/2)}{\mu + M} = \frac{M}{\mu + M}\frac{L}{2}.$$

After the light has been absorbed at the right-hand side, at position $x = L - D$,

$$X = \frac{\mu(L - D) + M[(L/2) - D]}{\mu + M}.$$

We equate these and solve for the mass μ:

$$\mu = \frac{MD}{L - D}.$$

From Eq. (39–31), $L - D = LMc^2/(E + Mc^2)$; when we substitute for $L - D$ as well as for D in the equation for μ, we get

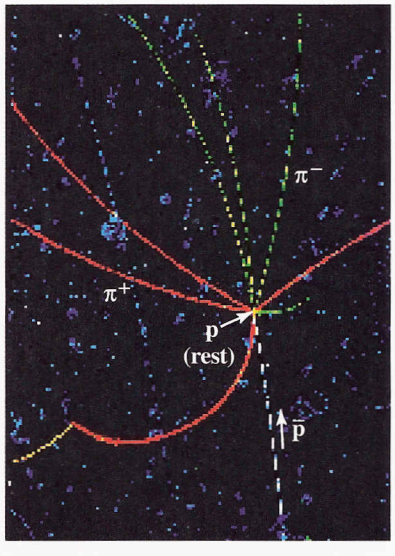
$$\mu = \frac{MEL/(E + Mc^2)}{LMc^2/(E + Mc^2)} = \frac{E}{c^2}.$$

E is therefore equivalent to a mass μ given by

$$E = \mu c^2. \tag{39–32}$$

MASS-ENERGY EQUIVALENCE

This very important result shows that mass and energy are interchangeable concepts. We can reverse the reasoning here to say that if an object has a mass m, then it has an energy that we refer to as the **rest energy** $E = mc^2$. Light has no mass in the usual sense, but any energy it has is equivalent to a mass E/c^2. The total energy E of any object is now the sum of the kinetic energy, the rest energy (or mass energy, E_{mass}), and the potential energy. For a particle on which no forces act, there is no potential energy, and



$$E = E_{\text{mass}} + K = \frac{mc^2}{\sqrt{1 - (v^2/c^2)}} = \gamma mc^2. \tag{39–33}$$

It follows from this result and from Eq. (39–28) that

$$\vec{v} = \frac{c^2\vec{p}}{E}. \tag{39–34}$$

RELATIVISTIC EXPRESSION FOR VELOCITY

The mass-energy equivalence has immediate experimental consequences, and it has been tested innumerable times in a large variety of nuclear reactions (see Example 39–11). Perhaps the most dramatic confirmation of this law came with the discovery of *antimatter*. Quantum mechanics and relativity together show that, for each particle, there is a corresponding *antiparticle*. Particles and antiparticles each have the same mass, while the antiparticle has a charge opposite that of the particle; an antiparticle and a particle can annihilate each other to produce electromagnetic radiation, all their mass going into the energy of the radiation (Fig. 39–21). Similarly, a particle-antiparticle pair, complete with their masses, can be created out of radiation energy alone. The conversion of energy (in the form of radiation) into mass is thereby exhibited unambiguously. We'll revisit this issue in our study of nuclei and elementary particles in Chapters 44 and 45.

▲ **FIGURE 39–21** In this color-enhanced bubble-chamber photo, an incoming antiproton (light blue) strikes and annihilates with a proton at rest, producing 4 positive pions (red) and 4 negative pions (green), which are antiparticles of the positive pions.

EXAMPLE 39–11 The nucleus ^{8}Be is an unstable isotope of beryllium. It decays into two alpha particles (helium nuclei), $^8\text{Be} \rightarrow {}^4\text{He} + {}^4\text{He}$. The masses of these nuclei in atomic mass units u are $M(^8\text{Be}) = 8.005305$ u and $M(^4\text{He}) = 4.002603$ u. Assume that a nucleus ^{8}Be decays while it is at rest. Find the kinetic energy of the helium nuclei (the alpha particles) in MeV.

Strategy The basic principles that apply here are energy and momentum conservation. The energy must include the mass energy—you can see from the numbers above $2M(^4\text{He}) \neq M(^8\text{Be})$, so that the mass energies do not cancel from the energy conservation equation.

We can start with the conservation of momentum, whose consequence is very simple here: The initial momentum is zero, so that the two (identical) helium nuclei must go off back-to-back, with the same momentum magnitude and hence the same kinetic energy K. This observation tells us that the conservation of energy equation can be used to find the single remaining unknown K.

We now turn to energy conservation. The initial energy is that of the beryllium nucleus, and since it is at rest, this energy is $E_{\text{initial}} = M(^8\text{Be})c^2$. The final energy is the rest energy of the two helium nuclei together with the total kinetic energy in the final state, so that $E_{\text{final}} = 2M(^4\text{He})c^2 + 2K$. From the equality of the initial and final energies we can get K.

Working It Out $2K = [M(^8\text{Be}) - 2M(^4\text{He})] = [8.005305\text{ u} - 2(4.002603\text{ u})]c^2 = (0.000099\text{ u})c^2$.

The conversion $1\text{ u} = 931.5\text{ MeV}/c^2$ shows that each helium nucleus carries kinetic energy

$$K = \frac{1}{2}(0.000099\text{ u})\left(\frac{931.5\text{ MeV}/c^2}{\text{u}}\right)c^2 = 0.046\text{ MeV}.$$

The fact that the masses of the two alpha particles are less than the mass of the parent ^{8}Be nucleus allows the alpha particles to have nonzero kinetic energy. The overall "mass defect" is the total kinetic energy in the final state, $2K$, also referred to by specialists in nuclear reactions as the *Q-value* of the reaction.

What Do You Think? Suppose the two decay products were some other nuclei whose masses were not equal. Could one still calculate the separate kinetic energies?

EXAMPLE 39–12 A 1.0-kg meteorite of antimatter strikes Earth. (This is just a thought experiment; there is no evidence at all of antimatter in such large lumps.) How much energy is liberated in the annihilation process in which all the antimatter and an equal amount of matter are converted to radiant energy? Neglect the kinetic energy of the meteorite; $(v/c) \ll 1$.

Strategy The calculation is a simple matter of conversion. The rest energy of mass M is Mc^2. The antimatter interacts with an equal amount of matter to annihilate, so the amount of energy liberated is $2Mc^2$.

Working It Out

$$E = 2Mc^2 = 2(1.0\text{ kg})(3 \times 10^8\text{ m/s})^2 = 1.8 \times 10^{17}\text{ J}.$$

To gain some idea of the significance of this number, the amount of (chemical) energy in 1 ton of TNT is 4.2×10^9 J. The meteorite explosion would generate the equivalent of 4×10^7 tons of TNT or about 40 hydrogen bombs. Antimatter–matter annihilation has been suggested as a source of fuel for manned planetary journeys because it is the most efficient fuel possible.

What Do You Think? Can you think of reasons why this proposal for interplanetary travel is at this time technologically impossible?

The Relation Between the Momentum and Energy of a Particle

In nonrelativistic physics there is a direct relation between the momentum and energy of a moving particle, namely $E = p^2/2m$. This expression does not include the rest energy. The correct relativistic analogue, which must reduce to the nonrelativistic case for speeds much less than that of light, is of some importance. From Eq. (39–33) we have

$$E^2 = \frac{m^2c^4}{1 - (v^2/c^2)}.$$

Moreover, Eq. (39–28) gives us an expression for p^2c^2, a quantity with the same dimension as E^2:

$$p^2c^2 = \frac{m^2v^2c^2}{1 - (v^2/c^2)}.$$

The speed does not appear in the difference between these results,

$$E^2 - p^2c^2 = \frac{m^2c^4}{1 - (v^2/c^2)}\left(1 - \frac{v^2}{c^2}\right) = m^2c^4. \qquad (39\text{–}35)$$

This relation, or its square root, gives us the desired relation between E and p:

$$E = \sqrt{p^2c^2 + m^2c^4}. \tag{39–36}$$

RELATIVISTIC ENERGY-MOMENTUM RELATION

This relation helps us understand the velocity of particles. From Eq. (39–34) we have

$$v = \frac{c^2p}{E} = c\frac{\sqrt{E^2 - (mc^2)^2}}{E} = c\sqrt{1 - \left(\frac{mc^2}{E}\right)^2}. \tag{39–37}$$

For light, $m = 0$ and therefore $v = c$. The lightest particles we know about are *neutrinos*, symbol ν, particles whose mass is of the order of one millionth of that of an electron, $m_\nu c^2 < 2$ eV. (While we do know that the neutrino has a mass, we do not yet know the actual mass, only that it must be less than this value. See Chapter 45 for more.) Thus in any nuclear reaction, which always involve energies at least of the order of kilovolts, the square root factor in Eq. (39–37) can be replaced by unity. Neutrinos always move at very nearly the speed of light.

The energy momentum relation, Eq. (39–36), also shows that the combination $E^2 - p^2c^2$ is *invariant*. Invariant quantities have the same value in every inertial frame, just as $c^2t^2 - x^2$ does [see Eq. (39–24)]. This is a valuable tool in the analysis of relativistic collision phenomena.

THINK ABOUT THIS. . .

IS THE ELECTRON CHARGE AN INVARIANT?

The electron mass is an invariant. We also know that electric charge is an invariant—by this we mean that the total electric charge is measured to have the same value in any inertial frame. What is the evidence? An electrically neutral piece of metal contains positive ions and some nearly free electrons in addition to a lot of atoms in which the electrons are closely attached to the ions. Suppose we heat up that piece of metal. We know from equipartition that the constituents of the metal increase their kinetic energy. Electrons are thousands of times less massive than ions, so that for a given increase in kinetic energy their velocities increase much more than those of the ions. If the electric charge were to increase, for example, as a function of velocity, then a piece of metal that was neutral at one temperature would be charged at another. This is an effect that could be easily measured, and there is no evidence of a departure from neutrality as temperature changes. Finally, you may wonder if this is consistent with our remarks about how a current seen from a moving frame appears to have charge—we used this argument to motivate the mixing of electric and magnetic fields in Section 39–6. But there we spoke about the density of charge, not a total charge, and it is not surprising that charge density, a charge per unit volume, is not an invariant, because the volume is not an invariant.

*39–8 Beyond Special Relativity

The Equivalence Principle

Special relativity expresses the physical equivalence of all inertial reference frames. In noninertial, or accelerating, frames, another physical equivalence holds. It is expressed by the *equivalence principle*, formulated by Einstein in 1911:

> **Provided that the observations take place in a small region of space and time, it is not possible by experiment to distinguish between an accelerating frame and an inertial frame in a suitably chosen gravitational potential.**

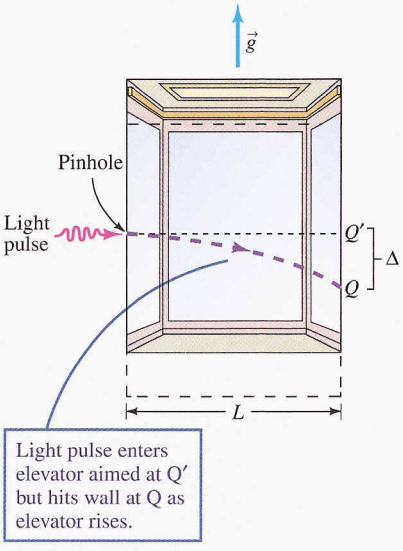
This is the principle behind *general relativity*, also known as Einstein's theory of gravitation. We described a number of consequences of the equivalence principle in Section 12–8. We list these again:

A. The Equality of Gravitational Mass and Inertial Mass: The *gravitational mass* m_g, the attribute of an object that appears in Newton's expression for the gravitational force, of magnitude

$$F = -\frac{Gm_{1g}m_{2g}}{r^2}$$

and the *inertial mass* m_i, the attribute of an object that appears in the expression for the proportionality of force and acceleration,

$$F = m_i a,$$



must be equal. As a consequence, all objects fall at equal rates in a given gravitational field: If an object of mass m is subject to a gravitational force due to an object of mass M, the relation $F = ma$ reads

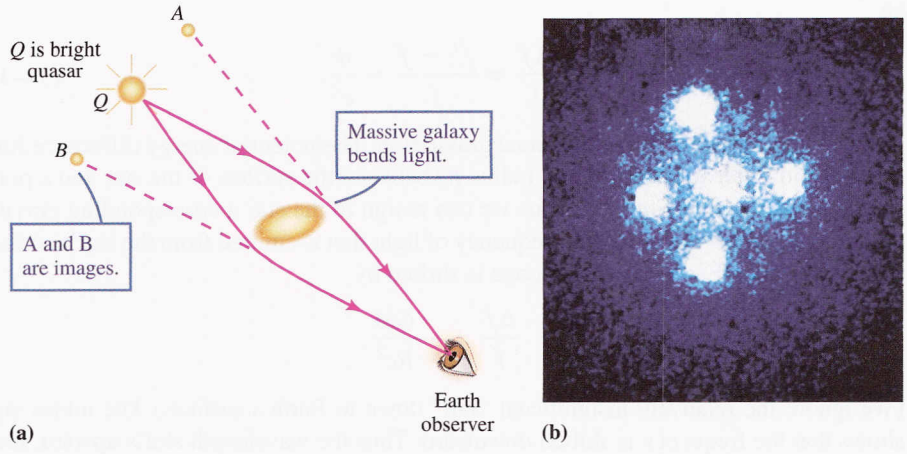
$$\frac{Gm_gM}{r^2} = m_i a;$$

if $m_i = m_g$, the acceleration does not depend on the mass of the object. The equality of the inertial mass and gravitational mass has been verified experimentally to an accuracy of one part in 10^{11}.

CONCEPTUAL EXAMPLE 39–13 An automobile at a stop light, with all its windows closed, contains a balloon filled with helium floating over the back seat. The light changes and the automobile accelerates. Will the balloon move relative to the back seat, and if so, in which direction?

Answer This can be answered by a simple application of the equivalence principle. The forward acceleration of the automobile is experienced by the driver as a pressure on her back. Just as the effect of an upwardly accelerating elevator is indistinguishable from the gravitational force due to a mass below one's feet, the effect on everything and everyone within the automobile is indistinguishable from the gravitational force due to a mass behind the car. Effectively the acceleration is equivalent to the sudden placement of a planet behind the car. Just as near Earth's surface helium balloons rise as a result of their buoyancy, here the balloon moves forward with respect to the back seat!

▲ **FIGURE 39–22** A pulse of light is directed into an elevator. If the elevator is at rest, the pulse would eventually arrive at point Q'. If the elevator accelerates upward with magnitude g as the light pulse crosses, an observer within the elevator would see the light pulse follow the parabolic path shown, eventually arriving at point Q on the opposite wall, a distance Δ below Q'.



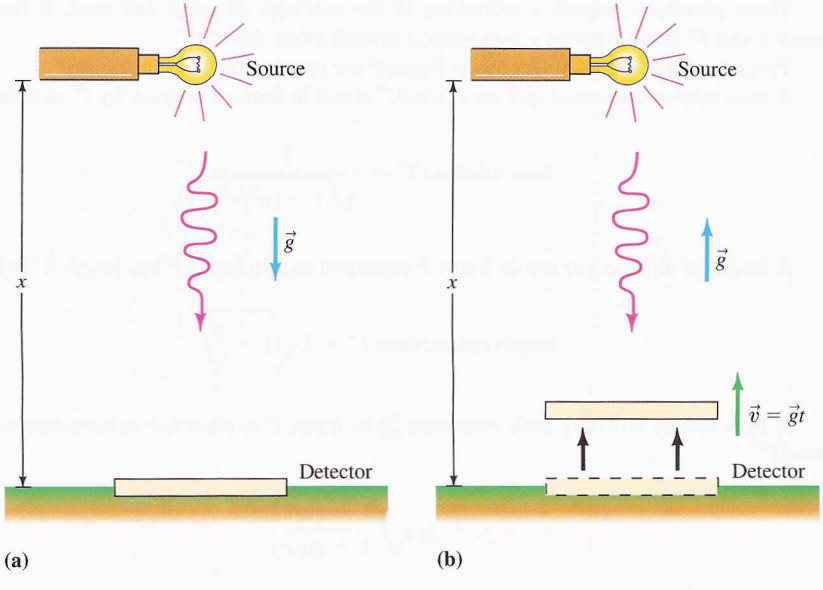
B. The Gravitational Deflection of Light: If a horizontal beam of light enters a pinhole in an elevator that is accelerating upward with an acceleration g, then, in the time t that it takes for the light to cross the elevator, the horizontal level of the pinhole will have moved upward by a distance $gt^2/2$. If the width of the elevator is L, the light will hit a spot Q that is a distance

$$\Delta = \frac{1}{2}g\left(\frac{L}{c}\right)^2$$

below the spot Q', which is horizontally across from the pinhole; indeed, if you followed the light path you would see a parabola (Fig. 39–22). In other words, an observer within the elevator sees the light *falling*. According to the equivalence principle, no experiment can determine whether the elevator has accelerated upward or has remained at rest within the influence of a gravitational force. Therefore light must fall under the influence of the gravitational force due to a mass. Note that Δ is the same distance that any massive body would fall. The implications are twofold:

1. Everything that has energy falls downward with the same acceleration as a result of the influence of a gravitational force.
2. Light is deflected toward a star as it passes it, a phenomenon whose consequences are discussed in Chapter 12 (Fig. 39–23).

C. The Gravitational Redshift: When light "falls," it undergoes a frequency shift. Consider a source at a height x above the ground in the presence of local gravity,



◀ **FIGURE 39–23** (a) The formation of an image by a gravitational lens. If a light ray "bends" toward mass, we should see the effect as additional images in the sky. (b) A mass (a relatively nearby galaxy) has bent the light from a quasar behind it such that four distinct images of the quasar can be observed from Earth. The fuzzy spot in the center is the galaxy's core.

emitting radiation with frequency f (Fig. 39–24a). According to the equivalence principle, the physics should be described equally well by an observer who sees the system being accelerated upward with acceleration g in empty space. If both the source and the detector are at rest at the time of emission, then, according to the observer who sees the entire apparatus accelerating upward, in the time that the radiation has reached the detector ($t = x/c$), the detector will have acquired an upward velocity of magnitude $v = gt = gx/c$ (Fig. 39–24b). Thus the detector sees the radiation with a frequency f', Doppler shifted upward from the emitting frequency f. These are related by

$$\frac{f'}{f} = \sqrt{\frac{1 + (v/c)}{1 - (v/c)}} \cong 1 + \frac{v}{c} = 1 + \frac{gx}{c^2}.$$

The factor gx may be regarded as a *gravitational potential*, ϕ: We express the potential energy of a mass m in the vicinity of Earth as $mgx = m\phi$. In this way, the effect of Earth is isolated in the factor $\phi = gx$. Our result for the frequency ratio then takes the form

$$\frac{f'}{f} = 1 + \frac{\phi}{c^2}, \tag{39–38}$$

◀ **FIGURE 39–24** (a) An apparatus to measure the frequency of emitted light on Earth, in Earth's gravitational field; $\vec{g}$ is the (downward) acceleration due to gravity. (b) The measurement of a Doppler shift due to the acceleration of the detector (as part of the whole system) is indistinguishable from what is observed when the apparatus is in a gravitational potential; $\vec{g}$ is the (upward) acceleration of the system.

so

$$\frac{\Delta f}{f} \equiv \frac{f' - f}{f} = \frac{\phi}{c^2}. \tag{39–39}$$

Let's now apply our result to universal gravitation. The potential energy difference for a mass m and a star (of mass M and radius R) between the surface of the star and a point far from the star is $-GmM/R$. Thus we can assign to the star a corresponding gravitational potential of $-GM/R$. The frequency of light that is emitted from the star's surface and arrives at an Earth-based telescope is shifted by

$$\frac{\Delta f}{f} = -\frac{GM}{Rc^2}.$$

(We ignore the relatively insignificant "fall" down to Earth's surface.) The minus sign shows that the frequency is shifted downward. Thus the wavelength shifts upward, indicating a *gravitational redshift*. For the Sun, $M = 2 \times 10^{30}$ kg and $R = 7 \times 10^8$ m, so $\Delta f/f = 2 \times 10^{-6}$. Measurements of some characteristic spectral lines of sodium in the solar spectrum have confirmed this to an accuracy of 5 percent.

In a terrestrial measurement of the gravitational redshift carried out in 1960 by Robert Pound and Glen Rebka, light was "dropped" from a tower at Harvard University. This experiment measured a fractional shift of 3.3×10^{-15} to an accuracy of 1 percent.

When the gravitational potential is very large, the frequency shift $\Delta f/f$ becomes large. In the extreme case that $\Delta f/f = 1$, the frequency of the light is shifted to zero; that is, no light can be seen. A *black hole* has been formed. This occurs when $(GM/Rc^2) > 1$. When Einstein's full theory of gravitation is taken into account, it is for the modified condition $GM/Rc^2 > \frac{1}{2}$ that a black hole is formed. Although when they were first proposed, black holes may have seemed at most an abstract possibility, they turn out to be ubiquitous in the universe. The center of our galaxy, the Milky Way, for example, almost surely contains a very large one.

Summary

The special theory of relativity is based on the postulates that

1. The laws of physics are the same in all inertial reference frames.
2. The speed of light in empty space is the same in all inertial frames.

The first postulate generalizes the notion of Galilean invariance that we applied to the laws of mechanics. The second postulate is justified by the experimental result of Michelson and Morley.

These postulates require a rethinking of the concepts of space and time. If two inertial frames F and F′ move at speed u with respect to each other, then:

Two events that are simultaneous in frame F are not simultaneous in frame F′.

A time interval measured as T on a "clock" at rest in frame F is given by T' in frame F′:

$$\text{time dilation: } T' = \frac{T}{\sqrt{1 - (u^2/c^2)}}. \tag{39–9}$$

A length of an object at rest in frame F measured as L in frame F has length L' in frame F′:

$$\text{length contraction: } L' = L\sqrt{1 - \frac{u^2}{c^2}}. \tag{39–11}$$

A light source radiating with frequency f_0 in frame F is observed to have frequency f_1 in frame F′:

$$f_1 = f_0\sqrt{\frac{1 - (u/c)}{1 + (u/c)}}. \tag{39–16a}$$

If two objects are moving at velocities v_1 and $-v_2$, respectively, with respect to an observer, then the velocity of one object as seen in the rest frame of the other is

$$\text{law of addition of velocities: } V = \frac{v_1 + v_2}{1 + (v_1 v_2/c^2)}. \tag{39–18}$$

The relativistic Doppler shift for light has important astronomical implications. The measurement of the redshift of the light from a galaxy, given by Eq. (39–16), leads to a value for the speed u with which that galaxy recedes from Earth. That speed is in turn related to the distance D of the galaxy by Hubble's law:

$$D = u/H; \tag{39–17}$$

here H is the Hubble parameter, a number characteristic of the age of the universe, around 13 billion years.

The space–time coordinates of an event are described in reference frames F and F′ by (x, t) and (x', t'), respectively. These coordinates are related by the Lorentz transformations

$$x' = \gamma(x - ut) \tag{39–19}$$

and

$$t' = \gamma\left(t - \frac{ux}{c^2}\right), \tag{39–20}$$

where $\gamma \equiv 1/\sqrt{1 - (u^2/c^2)}$. An event can be specified by any two of (x, t, x', t'), and the other two coordinates can then be found from the Lorentz transformation laws, which must be supplemented by $y' = y$ and $z' = z$ when the relative motion is along the x-axis.

The relativistic momentum is defined by

$$\vec{p} = \frac{m\vec{v}}{\sqrt{1 - (v^2/c^2)}}. \tag{39–28}$$

The general relation between energy and inertial mass μ is $E = \mu c^2$, Eq. (39–32). The total energy of a particle is

$$E = \frac{mc^2}{\sqrt{1 - (v^2/c^2)}}, \tag{39–33}$$

and consists of a rest energy associated with the mass of the particle, $E_{\text{mass}} = mc^2$, plus the relativistic kinetic energy,

$$K = mc^2\left[\frac{1}{\sqrt{1 - (v^2/c^2)}} - 1\right]. \tag{39–30}$$

The velocity of a particle is given in terms of the momentum and energy according to

$$\vec{v} = \frac{c^2\vec{p}}{E}.$$

The energy and momentum are related by

$$E = \sqrt{p^2c^2 + m^2c^4}. \tag{39–36}$$

Einstein extended his theory beyond inertial reference frames with the equivalence principle, according to which it is not possible by experiment to distinguish between an accelerated frame and an inertial frame in a suitably chosen gravitational potential, provided that the observations take place in a small region of space and time. This principle has some important consequences, including:

Inertial and gravitational masses are equal, a result known to be accurate to one part in 10^{11}.

Light falls in a gravitational field.

A source radiating with frequency f will be observed in a gravitational potential ϕ at a frequency f' such that

$$\frac{f'}{f} = 1 + \frac{\phi}{c^2}. \tag{39–38}$$

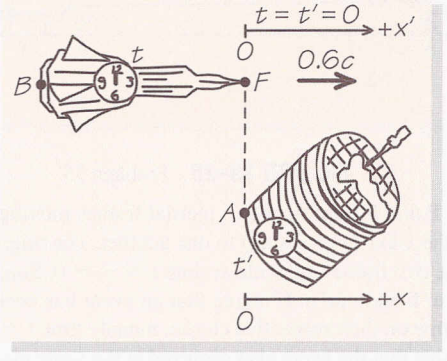
Understanding the Concepts

1. Can there be such a thing as a perfectly rigid object?
2. Does the statement "moving clocks run slow" depend on the direction in which a clock is moving?
3. The rest mass of a proton is given as 937 MeV/c^2. How can a mass involve energy units?
4. Describe the constituents of an antiatom of ^{4}He.
5. Two events occur simultaneously at the same position in space in a given inertial frame of reference. Is it possible that the events will not occur simultaneously in another inertial frame of reference?
6. As measured from Earth, what is the shortest possible travel time between Earth and Alpha Centauri, the second nearest star system to us, which is located 4.3 ly away? Why can it not be made any shorter?
7. Suppose that the Michelson–Morley experiment were carried out over one arbitrarily short time period, much less than 1 day, and showed no sign of movement through an ether. Is this result enough to rule out the presence of an ether?
8. According to one solution proposed to make the presence of an ether consistent with the results of the Michelson–Morley experiment, there is an *ether drag*: For some reason, Earth carries a bubble of the ether with it as it moves through space. Can you think of experimental consequences that could be used to rule out such an idea?
9. If a mirror recedes at speed $0.75c$ from a light source, does the image recede at speed $1.5c$ from the source?
10. By looking at a very distant quasar some years ago, astronomers found that the separation distances of certain peaks in brightness increase at a rate of 0.2 ms of arc/yr. The quasar is so far away that the separation speed translates into $v \cong 8c$! Is this the death knell of the special theory of relativity?
11. Suppose you are traveling relative to Earth, with speed u such that $1 - u/c = 10^{-5}$. If you are holding a mirror and looking at your reflection, will there be any distortion in shape or in the color of the image?
12. In Fig. 39–2, light makes a single round trip between the half-silvered mirror and the two remaining mirrors. In a real version of the Michelson–Morley experiment, the light bounces back and forth many times. Why?
13. Suppose an experimenter found that some particle, such as a neutrino, travels in a vacuum just a bit faster than the speed of light in vacuum. Would we have to give up the special theory of relativity?
14. Folklore has it that, as a teenager, Einstein worried about what would happen if somebody were looking in a mirror while accelerating to a speed faster than that of light. What could Einstein have been worried about?
15. Suppose that current in a wire is carried by little green men who pass negative charges along a chain from person to person while standing on positive charges, such that the wire is electrically neutral. Would the modified mechanism for the current flow change the observed behavior of a charge q that lies outside the wire? How would this look to an observer who is moving with some velocity along the wire?
16. A closed box of little mass sits on a horizontal frictionless surface. The inside walls are perfect mirrors and reflect back all radiation. A laser is inside on the left-hand wall and projects a very short burst of light directly at the right-hand wall. What is observed from the outside, and why?
17. According to Hubble's law, a single spectral line characteristic of a single atom is redshifted by an amount proportional to the distance of the star from Earth. How do we know that the radiation of a particular color seen to come from a distant star is the redshifted radiation of a particular known spectral line?
18. The length-contraction experiment seems to imply that a meter stick accelerated to the speed of light would shrink to a point, and all the calibration markings on the meter stick would be lost. Is there something wrong with this reasoning?
19. Light falls in an accelerating elevator. But if an elevator moves upward at a constant velocity, a horizontal light beam would hit a spot *below* the horizontal projection on the opposite wall of the elevator. Does this mean that light falls in an elevator that moves at constant velocity?
20. When the supernova 1987a occurred, bursts of neutrinos—particles that have mass that is too small to be detected directly in accelerator-based experiments—arrived at detectors at various places on Earth's surface. These neutrinos are thought to have been emitted by the supernova all at once. How could differences in the arrival times of the neutrinos be used to test whether or not neutrinos have mass?
21. A very long fence has a sinusoidal curve painted on it. Will an observer moving rapidly along the fence see the curve as Doppler-shifted?

Problems

39–1 Is an Ether Necessary?

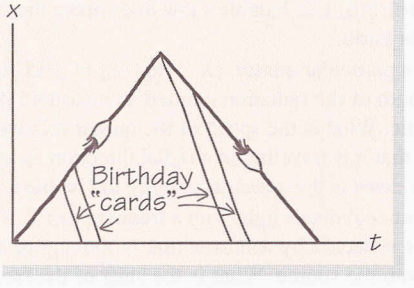
1. (I) An airplane flies at an air speed of 600 mi/h. It travels east from town A to town B and returns to A without stopping. In the absence of wind, the journey takes exactly 4 h. A town C is the same distance away from A and is located due north of A. Suppose that a wind with ground speed 60 mi/h is blowing east to west. Calculate the times it takes for the plane to make journeys ABA and ACA.
2. (II) In one version of the Michelson–Morley experiment, light of wavelength 633 nm emitted by a He–Ne laser travels through a total path length of 4.7 m in each arm of the interferometer. To the accuracy of the apparatus, a shift of 1/15 of a fringe, no shift was seen. Estimate the greatest value possible for the speed of Earth through the ether.



39–2 The Einstein Postulates

3. (II) A small, powerful laser is placed on a turntable that rotates at 900 rev/s. The laser, whose beam makes a 25° angle with the horizontal, shines on clouds 70 km away. Calculate the speed with which the light spot on the clouds moves. Does this speed violate the limitation of the speed of light? Explain.

39–4 Time Dilation and Length Contraction



4. (I) A muon (a subatomic particle) moves at a speed of $0.40c$. How much slower does its "clock" tick than if it were at rest?
5. (I) Two twins wave good-bye to each other. One twin, an astronaut, travels to Mars. The trip takes 1.0 yr in each direction, and the average speed with respect to Earth is 20,000 km/h. What will the approximate time difference in the twins' clocks be when they are together again on Earth?

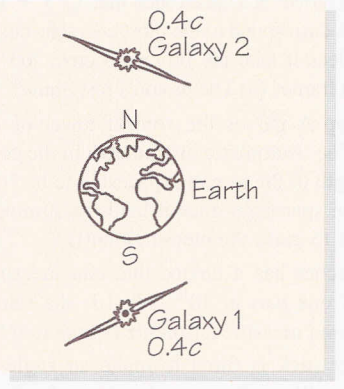
6. (I) Proxima Centauri, the star nearest our own, is some 4.2 ly away. (a) If a spaceship could travel at a speed of $0.24c$, how long would it take to reach the star according to the spaceship's pilot? (b) What would someone in the frame that moves along with the spaceship measure as the distance to Proxima Centauri?
7. (I) According to a passenger, how long will it take a spaceship moving at $0.999c$ to cross a galaxy with a diameter, as measured in the galaxy's rest frame, of 2.5×10^{19} m?
8. (I) The space shuttle orbits Earth at 16,300 mi/h in 111 min. How much time will an astronaut's atomic clock have lost during a total trip that takes 7 d?
9. (I) The diameter of our galaxy is about 10^5 ly, or 10^{21} m. Suppose that a proton moves at a speed such that $\sqrt{1 - (v^2/c^2)} \cong 10^{-7}$. (Such speeds correspond to the most energetic cosmic rays known). How long does it take the proton to cross the galaxy in (a) the galaxy's rest frame? (b) The proton's rest frame?
10. (I) Spaceship A passes the control tower of a spaceport at a speed of $0.76c$. Automatic instruments in the control tower measure the length of the moving spaceship to be 143 m. What is the length of the spaceship once it lands (assuming you could wait long enough to make the measurement!)
11. (I) A researcher has a device that can measure lengths to an accuracy of one part in 10^{12}. What is the minimum speed for which he could measure a Lorentz contraction?
12. (II) A meter stick is tilted to make an angle of 30° with the x-axis. How will an observer, at rest in a frame F′ that moves at velocity $v = 0.85c$ in the $+x$-direction relative to the meter stick, describe the stick?
13. (II) A student must complete a test in 1 h in the teacher's frame of reference F. The student puts on his rocket skates and soon is moving at a constant speed of $0.75c$ relative to the teacher. When 1 h has passed on the teacher's clock, how much time has passed on a clock that moves with the student, as measured by the teacher?
14. (II) As measured by an observer in an inertial frame, a small clock moving at a constant speed of $0.75c$ traverses a distance of 60 km. The moving clock records 10,000 ticks during the passage. How many ticks pass on an identical clock at rest relative to the observer?
15. (II) A spaceship of length 30 m travels at $0.60c$ past a satellite. Clocks in frame S′ of the spaceship and S of the satellite are synchronized within their respective frames of reference and are set to zero so that $t' = t = 0$ at the instant the front of the spaceship F passes point A on the satellite, located at $x' = x = 0$ (Fig. 39–25). At this time, a light flashes at F. (a) What is the length of the ship as measured by an observer on the satellite? (b) What time does the observer on the satellite read from her clock when the trailing edge B of the spaceship passes her? (c) When the light flash reaches B at the rear of the spaceship, what is the reading t'_1 of a clock at B? (d) What is the reading t_1 on the clock on the satellite when, according to the observer on the satellite, the flash reaches B?

▲ FIGURE 39–25 Problem 15.

16. (II) One can construct a helpful graph called a *Minkowski diagram* that represents the motion of a particle as a function of time. The x-axis represents the distance traveled (we deal here with straight-line motion only), and the y-axis represents the time, or more accurately ct. Draw (a) the "path" of a particle that is at rest; (b) the line representing the motion of a wave front of light; (c) a line representing the motion of a particle moving with speed $c/2$. (d) Does the line making an angle of 30° with the x-axis represent something physical?
17. (II) Consider the graphical representation of particle motion in the previous problem. On the same graph plot the motion of the two twins in the twin paradox. Suppose the non-traveling twin sends out regular light signals to her sibling. Will these be received regularly? Is there a difference between the frequency of the pulses received on the way out and that of the pulses received on the return journey?
18. (III) Jessica embarks on a cosmic journey at a speed of $(12/13)c$ relative to Earth. Before leaving, she tells her twin brother Tom, who stays on Earth, that she will travel outward for 26 yr of Earth time, then back for another 26 yr of Earth time. Tom will thus be 52 yr older when she returns. She promises to send a radio message on each of her birthdays (Fig. 39–26). According to an Earth-based clock, when will these messages reach Tom, and how much older than the age at which she leaves will Jessica be when she returns to Earth?

▲ FIGURE 39–26 Problem 18.

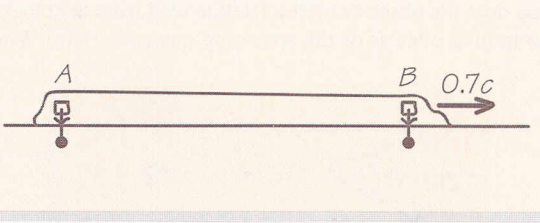
19. (III) A relativistic sprinter running at speed v, near the speed of light, passes beneath a victory arch a height h above his eyes. Show that he will continue to see the arch, even though his eyes face forward, until he has run a distance $hv/\left[c\sqrt{1 - (v^2/c^2)}\right] = \gamma hv/c$ *beyond* the arch. [*Hint*: Work in the rest frame of the sprinter, and think of the top of the arch as emitting pulses of light, the last of which can be seen when it travels vertically downward toward the sprinter.]



39–5 The Relativistic Doppler Shift

20. (I) The sodium doublet refers to light waves emitted by sodium in a closely spaced pair of frequencies. The wavelengths of this doublet are at 589.0 nm and 589.6 nm. Suppose that the lower-wavelength member of this doublet is Doppler redshifted to a wavelength of 593.2 nm in the light emitted by a certain star. What happens to the wavelength of the second member of the doublet?
21. (I) A spaceship accelerates at a rate of $0.1\ \text{m/s}^2$ away from Earth. How long will it take (as measured in Earth's reference system) before a yellow beacon on Earth ($\lambda = 600$ nm) looks green ($\lambda = 500$ nm) to the crew of the spaceship?

22. (I) The wavelength of a spectral line in the laboratory is measured to be 108 nm. The same line is observed in light coming from a distant galaxy; in this observation, the wavelength is found to be 124 nm. What is the speed of motion of the galaxy relative to Earth?
23. (I) A particular spectral line measured in the emission of light by the star Alpha Centauri has wavelength $\lambda = 512.311$ nm. That same line measured in the laboratory has wavelength $\lambda = 512.350$ nm. Determine the radial velocity of Alpha Centauri relative to Earth.
24. (I) Spaceship A, moving at a speed of $0.92c$ relative to a certain star, is pursued by spaceship B, which is moving in the same direction at speed $0.98c$ relative to the same star. (a) With what speed does the pilot of spaceship A see spaceship B approaching? (b) Spaceship C passes both moving in the opposite direction with speed $0.75c$ relative to the star. At what speeds does the pilot of C see spaceships A and B passing?
25. (II) An observer in a large spaceship traveling east to west with speed $0.6c$ relative to Earth measures the distance between two points on Earth aligned in the east-west direction to have separation 500 m. A flea in the spaceship has developed high intelligence and is itself traveling within a tiny spaceship within the first spaceship, in the same direction with respect to Earth as the large spaceship and at a speed $0.2c$ with respect to the large spaceship. What does the flea measure for the separation of the two points on Earth?
26. (II) A driver was caught running a red light. His defense is that he saw the light as green, as a result of the Doppler shift. He is arrested. What for? Estimate the seriousness of his transgression.
27. (II) Yellow light at 587.6 nm, characteristic of helium, is found to be redshifted as it is observed in a certain star; the wavelength is measured to be 611.7 nm. (a) How fast is the star receding from Earth? (b) Use Hubble's law to estimate the distance of the star from Earth.
28. (II) For a particular quasar, $(\lambda - \lambda_0)/\lambda_0 = 2.45$, where λ_0 is the wavelength of the radiation emitted as measured in the quasar's rest frame. What is the speed of the quasar relative to Earth, assuming that it is traveling in a radial direction away from Earth? How far away is the quasar according to Hubble's law?
29. (II) A source radiates light with a frequency of 2×10^{15} Hz. The signal is reflected by a mirror that is moving at speed 1 km/s away from the source. What is the shift of the frequency of the reflected radiation, as observed at the source?
30. (II) The equation $\lambda/\lambda_0 = \sqrt{(1+\beta)/(1-\beta)}$, where $\beta = v/c$ and v is the speed of a source that is moving away from an observer or of an observer who is moving away from the source, takes a simple form if v is small compared to c. Show that if $\lambda = \lambda_0(1 + x)$, then for small β, $x \cong \beta$.
31. (III) During the journey described in Problem 18, Tom sends a radio message to Jessica on each of his birthdays adding to a total of 52 messages. With what interval in her rest frame does Jessica receive these messages during the outward part of the journey? During the return trip? Use this information to calculate how much Jessica ages during her trip according to an Earth-based clock.
32. (III) A source emits pulses with a frequency f_0. A spaceship moving at speed v_1 away from the source will receive a redshifted frequency f_1. Suppose that the spaceship immediately reemits the signals with the frequency f_1. A second spaceship, moving at speed v_2 relative to the first spaceship and in the same direction, will receive the signals with a redshifted frequency f_2. (a) Calculate f_1 and f_2. (b) If we were to eliminate the first spaceship, we could view f_2 as the redshifted frequency received by the second spaceship, which moves at some speed v relative to the source. Show that if both $v_1 \ll c$ and $v_2 \ll c$, then $v = v_1 + v_2$, as expected from the ordinary rules that govern relative motion. (c) Calculate v for arbitrary values of v_1 and v_2. This result is the relativistic law of addition of velocities, which differs from $v = v_1 + v_2$ when v_1 and v_2 are not very small compared with c.



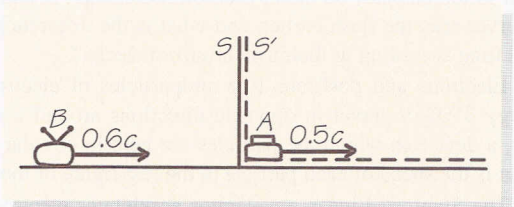
39–6 The Lorentz Transformations

33. (I) Measurements of distant galaxies show that all galaxies are receding from one another at a speed proportional to their intergalactic distances. Suppose that we see galaxy 1 move away from us at a speed of $0.4c$ along the South Pole, and galaxy 2, equally far away, move away from us at the same speed along the North Pole (Fig. 39–27). What would an observer in galaxy 1 measure for the speed with which galaxy 2 moves away from him?

▲ **FIGURE 39–27** Problem 33.

34. (I) Events A and B are simultaneous in frame F and are 18 km apart on a line that defines the x-axis. A series of spaceships all pass at the same speed in the $+x$-direction, and they have synchronized their clocks so that together they make up a moving frame F′. They time events A and B to be separated by 0.80 μs. What is the speed of the spaceships? How far apart in space do they measure the two events to be?
35. (II) Two friends decide to demonstrate the Lorentz contraction of a train. They sit at the two ends of the 100-m-long train, with their watches properly synchronized. At $t = 0$, each drops a small bag out of the window; these bags act as markers (Fig. 39–28). Later, they go back and measure the distance between the bags. (a) Does this distance represent the length of the train relative to a coordinate system fixed to the ground? (b) What is the distance between the bags if the speed of the train is $0.7c$? (Neglect the time it takes for the bag to reach the ground!)

▲ **FIGURE 39–28** Problem 35.



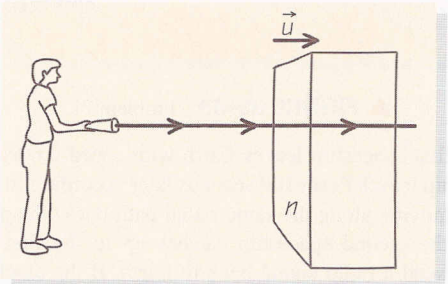
36. (I) Let F and F′ represent two inertial frames moving at speed u along the x-axis with respect to one another. The origins and axes of these two frames coincide at time $t = t' = 0$. Suppose an observer in F and one in F′ agree that an event has occurred at the same time on their respective clocks, namely time $t = t' = t_0$. Is it possible that the event also occurred at the same place—that is, the same space coordinate—in each frame?

37. (I) An unmanned spaceship launched with speed $0.8c$ explodes after 24 s as measured in its own rest frame. (a) Assuming that the launching coordinates are $x = t = 0$ in the spaceship coordinate system, what are the coordinates of the explosion point in the coordinate system of the spaceship? (b) If the launching coordinates in the rest frame of the launching pad are $x' = t' = 0$, what are the coordinates of the explosion point in the frame of the launching pad?

38. (II) In a given reference frame, event 1 occurs at time $t_1 = 0$ s and position $x_1 = 0$ m, while event 2 occurs at $t_2 = 3.6 \times 10^{-4}$ s and $x_2 = 0.60 \times 10^5$ m. Is there a second frame in which these events could be at the same position but different times? If so, specify its motion with respect to the first frame. If not, what is the frame in which the events have the least possible separation in distance? [*Hint*: Use invariants.]

39. (II) A new Klingon battleship races at a top speed of $0.20c$ away from the planet XG4T. The starship *Enterprise* follows at a speed of $0.25c$ relative to the Klingon ship. With what speed does the *Enterprise* appear to catch up with the Klingon ship according to an observer on the planet?

40. (II) Spaceship A moves with velocity $0.50c$ in the positive x-direction of a reference frame S. Spaceship B, moving in the same direction with a speed of $0.60c$, is 3.0×10^9 m behind (Fig. 39–29). At what times, in reference frame S and in the reference frame of spaceship A, will B catch up with A?



▲ **FIGURE 39–29** Problem 40.

41. (II) An observer in frame S measures two events to occur at the same point in space and separated by a time interval Δt. Show that in every other inertial frame, these events are separated by a larger time interval.

42. (II) A particle in frame F has velocity $v_x\hat{i} + v_y\hat{j}$. What is the velocity seen by an observer at rest in frame F′, a frame that moves at velocity $u\hat{i}$ relative to frame F?

43. (II) You shine light that moves at speed c/n through a medium of index of refraction n (Fig. 39–30). Suppose that the medium moves at speed u relative to you, parallel to the direction of the light. What is the speed of light in the medium as seen by you? [The result for $(u/c) \ll 1$ gives a result that is different from $(c/n) + u$, and it was first obtained by Augustin Fresnel in 1818. The measurements confirming the result were made by Hippolyte Fizeau in 1851.]

▲ **FIGURE 39–30** Problem 43.

44. (II) Use the Lorentz transformations to show that, as in Eq. (39–5), the location of a wave front for a plane wave emitted at $t = t' = 0$ from the joint origin of reference frames F and F′ is given by $x^2 - c^2t^2 = 0$ and by $x'^2 - c^2t'^2 = 0$.

45. (III) The electric field obeys the wave equation

$$\frac{\partial^2 E}{\partial t^2} - c^2\frac{\partial^2 E}{\partial x^2} = 0$$

when electromagnetic waves propagate along the x-axis. What is the form of the equation for a wave seen in a Lorentz-transformed frame that moves at speed u along the x-axis? [*Hint*: Use the Lorentz transformation laws to obtain expressions for $\partial/\partial t$ and $\partial/\partial x$ in terms of $\partial/\partial t'$ and $\partial/\partial x'$.]

39–7 Momentum and Energy in Special Relativity

46. (I) A spaceship of mass 7.5×10^3 kg has a kinetic energy that is 0.12 times its rest energy. What is its total energy?

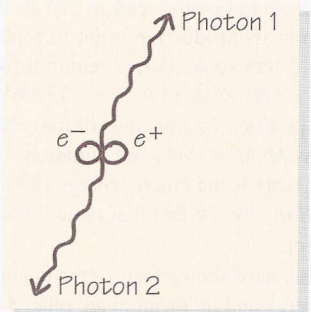
47. (I) Assume here that the neutrino has a rest mass of zero. What is the momentum, in SI units, of a neutrino with energy 4 MeV? (The neutrino mass is actually small but nonzero.)

48. (I) *Estimate* the mass lost when 1 million tons of TNT explodes. Assume that each chemical reaction between individual molecules involves 10 eV of energy.

49. (I) Humans generate energy at a rate of some 10^{13} W worldwide. (The United States, with less than 10 percent of the world's population, uses about 25 percent of the energy.) At what rate is mass being lost due to relativistic effects?

50. (I) A particle, the π^0, has a rest mass of 135 MeV/c^2. It decays at rest into two identical massless particles. What is the momentum of each of the two decay products of the π^0?

51. (II) Energy from the Sun reaches Earth (above the atmosphere) at a rate of about 1400 W/m^2. How fast is the sun losing mass due to energy radiation?

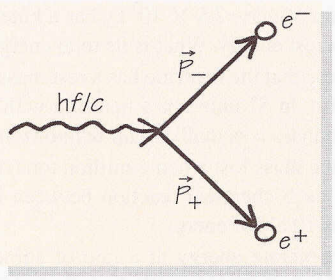


52. (II) What value of v/c must a particle of rest mass m have in order for its momentum to have magnitude $p = 8.0mv$?

53. (II) How much work has to be done on a proton to accelerate it (a) from rest to $0.01c$; (b) from $0.8c$ to $0.81c$; (c) from $0.9c$ to $0.91c$; (d) from $0.99c$ to c?

54. (II) An electron that is accelerated in the Stanford Linear Accelerator in California has a total energy of 56 GeV. How much of this is kinetic energy? What is the momentum of the electron? What is its speed?

55. (II) A proton accelerated at Fermi National Laboratory in Illinois has a momentum of 746 GeV/c. (a) What is the proton's velocity? (b) The proton's kinetic energy?



56. (II) An electron and its antiparticle of identical mass, the positron, annihilate each other and produce two photons (Fig. 39–31). Both the electron and the positron were initially at rest. What are the energy and momentum of each photon?

▲ **FIGURE 39–31** Problem 56.

57. (II) A photon is the quantum unit of light. It has an energy $E = hf$, where h is Planck's constant and f is the frequency of the light. Show that when a photon is absorbed by a free electron, without anything else occurring, energy and momentum cannot be conserved simultaneously.

58. (II) Show that energy and momentum conservation do not allow a high-energy photon to turn into a positron–electron pair with no other result. This process, called pair production, *can* occur if another object participates in the reaction (Fig. 39–32). What is the minimum energy required for the photon to give rise to an electron–positron pair, if the third object is very massive compared with the electron? [*Hint*: For the electron and positron $mc^2 = 511$ keV, and the third object, if it is a lead nucleus, has mc^2 about 4×10^5 times larger.]

▲ **FIGURE 39–32** Problem 58.

59. (II) You analyze the track of a particle in a photographic plate placed in a magnetic field, and find that the total energy of the particle is 1130 MeV. The bending in the magnetic field gives information about momentum, and you learn that the particle's momentum is $p = 830$ MeV/c. What is the mass of the particle?

60. (II) In a generalization of Example 39–11, a ^{8}Be nucleus is moving in the x-direction with 3.5 MeV of kinetic energy when it decays into two alpha particles. Both alpha particles move off along the x-axis. What are their kinetic energies? [*Hint*: Note that $Q \ll M(^4\text{He})c^2$.]

61. (II) In the nuclear reaction $^{241}\text{Am} \rightarrow {}^4\text{He} + {}^{237}\text{Np}$, there is an energy release of 6 MeV. In the approximation in which the value of mc^2 for the Am nucleus is (241)(938 MeV), that of the He nucleus is 4(938 MeV) and that of the Np nucleus is (237)(938 MeV), calculate the value of pc (p = momentum) of the ^{4}He nucleus emitted from a ^{241}Am nucleus at rest (a) using nonrelativistic kinematics and ignoring the recoil of the ^{237}Np nucleus; (b) using nonrelativistic kinematics and taking the recoil motion of the ^{237}Np nucleus into account; and (c) using relativistic kinematics and taking the recoil motion of the ^{237}Np nucleus into account.

62. (II) The lifetime of a particle called the neutral pion, π^0, is 0.9×10^{-16} s in the particle's rest frame. With what energy would one π^0 have to be produced so that its decay point is distinguishable from its production point in a photographic plate? Assume that a 1-mm separation is required for a measurement. The pion mass corresponds to $mc^2 = 135$ MeV.

63. (II) The decay products of a nucleus of mass M^* include another nucleus of mass $M(M < M^*)$ and radiation. If the decaying nucleus is at rest, what is the kinetic energy of the remnant nucleus of mass M? [*Hint*: Use the fact that radiation of energy E carries momentum E/c].

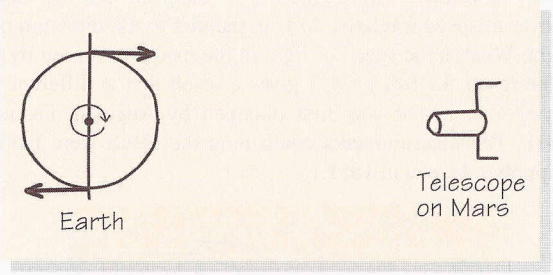
64. (III) Experiments have shown that for the quantum of radiation (a photon), the energy and momentum are related by $E = pc$, corresponding to a particle with mass $m = 0$. Suppose that in the observation of a supernova 170,000 ly away, the first bursts of photons with an energy range of $E = 10$ eV to 10^4 eV arrive within 10^{-8} s of each other. What limits does this set on the mass of a photon? [*Hint*: Use the fact that mc^2 is small, so $E = pc + (m^2c^3/2p)$ is a good approximation.]

65. (III) Calculate an expression for the force as defined by $m\dfrac{d(\gamma\vec{u})}{dt}$, and show that the force and the acceleration $d\vec{u}/dt$ do not necessarily point in the same direction.

*39–8 Beyond Special Relativity

66. (II) A neutron star has a mass of 2.4×10^{30} kg and a radius of 8.5 km. What is the gravitational redshift of radiation emitted with a frequency of 2×10^{19} Hz from the star's surface?

67. (III) A clock on a disk rotating with angular speed ω, when placed at a distance R from the center of the disk, experiences an acceleration toward the center of the disk. What gravitational potential will an observer at rest relative to the clock assume that he or she is in? (Use the equivalence principle.) Will the clock be slow or fast relative to a clock at the center of the disk?



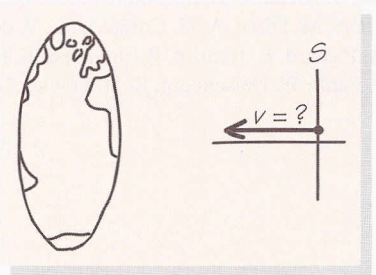
General Problems

68. (I) A photographer takes a flash-illuminated photo of a train car as the car passes moving to the left at 12 m/s. The flash goes off when the midpoint of the car is adjacent to the camera. Will two observers, one at each end of the 18-m-long train car, receive the flash simultaneously on their synchronized clocks? If not, which observer sees the flash earlier, and what is the difference in arrival time according to their synchronized clocks?

69. (II) Electrons and positrons (the antiparticles of electrons) of energy 35 GeV travel in opposite directions around a storage ring, a device in which the particles are held in circular orbits. What is the speed of each particle in the rest frame of the other?

70. (II) The Stanford Linear Accelerator accelerates electrons to a total energy of 50 GeV. How long does a meter stick at rest appear to a hypothetical observer at rest with respect to one such electron?

71. (II) An astronomer on Mars measures the optical spectrum of Earth. Averaged over a long period, she will see the spectral lines broadened by the Doppler effect due to Earth's rotation (Fig. 39–33). Calculate the width of the spectral line at 650 nm; i.e., the difference between the longest and shortest wavelength of a 650-nm line as seen by the astronomer, assuming that she is positioned in Earth's equatorial plane. Ignore the motion of Mars.



▲ **FIGURE 39–33** Problem 71.

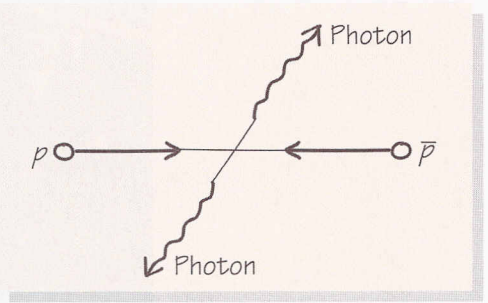
72. (II) A first spaceship leaves Earth with speed $0.60c$. A second spaceship leaves Earth 100 seconds later according to a clock on Earth, moving along the same radial path but with speed $0.75c$. When the second spaceship catches up to the first one, they jointly send a radio signal back to Earth. If the clock on Earth had been set to 0 at the moment the first spaceship leaves, what will that clock read when the signal is received on Earth?

73. (II) Consider the situation described in the previous problem. How long, according to a clock in the lead spaceship, will it be till the second one catches up? How long will it be, according to a clock in the second spaceship? Each clock starts at the departure time of the first spaceship.

74. (II) In 1990, an SR-71 Blackbird reconnaissance airplane on its way to retirement at the Smithsonian Air and Space Museum set several speed records. The plane averaged 2153 mi/h during the 2300-mi trip from Los Angeles to Washington D.C., and 2242 mi/h during the 311-mi trip from St. Louis to Cincinnati. What would have been the difference in time elapsed for the two record-setting segments between an atomic clock placed in the airplane and another atomic clock on the ground?

75. (II) A cosmic ray is approaching Earth from outer space. A hypothetical observer in a frame that moves with the cosmic ray measures Earth as a flattened ball whose thickness is 3/7 of its diameter (Fig. 39–34). (a) With what speed is the cosmic ray approaching Earth? (b) The cosmic ray is identified as a proton, with mass m and mass energy given by $mc^2 = 1$ GeV. What is the energy of the approaching proton, as seen from Earth?

▲ **FIGURE 39–34** Problem 75.



76. (II) A new Klingon battleship has a proper length of 780 m and travels at speeds of $0.26c$ with respect to its home planet. The Klingons prepare to battle the *Enterprise*, which is moving at the same speed with respect to the same planet (Fig. 39–35). If the Klingons are heading straight at the *Enterprise*, what is the length of the Klingon ship as measured by Captain Kirk?

▲ **FIGURE 39–35** Problem 76.

77. (II) A particle of mass M is at rest. It decays into two identical particles, each of mass m, with $2m < M$. (a) If one of the two decay particles moves north with a momentum of magnitude p, what is the momentum of the other particle? (b) Use energy conservation to find p.

78. (II) In a quantum mechanical model, a proton and an antiproton annihilate each other and produce a pair of photons, light quanta whose frequency is related to their energy by the relation $E = hf$, where h is Planck's constant ($h \cong 6.63 \times 10^{-34}$ J·s). The proton and the antiproton are nearly at rest when they annihilate. Find the frequencies of the emitted photons (Fig. 39–36). What are these frequencies if the proton and the antiproton are approaching each other in a head-on collision in which each particle has a kinetic energy of 1600 MeV? For both protons and antiprotons, $mc^2 \cong 938$ MeV.

▲ **FIGURE 39–36** Problem 78.

79. (II) According to Chapter 19, the distribution function for the z-component of the velocity of a gas at temperature T is

$$G(v_z) \propto e^{-(mv_z^2/2kT)},$$

where k is Boltzmann's constant and m is the mass of one gas molecule. If a molecule at rest emits a spectral line, light at a characteristic frequency of f_0, then what is the distribution of frequencies of the light given off by the gas of such molecules when heated to temperature T? Assume that you are looking along the z-direction and take into account only motion in this direction. The effect described here is known as *Doppler broadening* of a spectral line. It is a tool for determining the temperature of stars and interstellar gases.

80. (II) Particles with energies as high as 10^{18} eV have been observed. Suppose that one of those particles collides with a photon of cosmic background radiation of wavelength $\lambda = 10^{-3}$ m. After a head-on collision, what will the final wavelength of the photon be? [*Hint:*These energies are so high that the particles can be treated as massless.]

81. (II) A charged pi meson (a particle of mass about 140 MeV/c^2) is ejected from a nuclear collision with a kinetic energy of 250 MeV. Pi mesons have a half-life (the time over which half of a given collection will decay radioactively) of about 1.5×10^{-8} s. Calculate (a) the pi meson's speed and (b) momentum. (c) How far will a collection of pi mesons travel before half of them decay?

82. (II) The *rapidity* V of a moving body is defined by $\tanh(V/c) = v/c$, where v is the body's relativistic speed. An observer in frame S′, moving at speed u in the $+x$-direction with respect to a frame S, measures a body to have speed v along the x-axis. Show that an observer in frame S measures the body to have rapidity W, given by $W = U + V$. Here, U is the rapidity of frame S′ with respect to frame S. The rapidity thus adds like a Galilean velocity.

83. (III) A proton moves with a momentum of magnitude p in the $+x$-direction. It strikes a second proton, which is at rest. Three protons and one antiproton result from the collision. The four particles in the final state remain together; that is, they have no motion relative to one another. Use energy and momentum conservations to find p. For both protons and antiprotons, $mc^2 \cong 938$ MeV.

Quantum Physics

The results of a vast array of experiments that explore systems on both the macroscopic and microscopic scale cannot be explained by classical physics; indeed, they are often in direct contradiction with it. These experiments show that radiation *also* exhibits particle-like behavior, that matter *also* exhibits wavelike behavior, and some aspects of the behavior of systems have no classical analog whatsoever. The explanation of these phenomena requires a new way of looking at the world, an approach that is provided by *quantum mechanics*. The ideas and techniques of quantum mechanics represent a scientific revolution as deep and as important as the one generated by Newtonian mechanics. It reconciles the particle-wave contradictions shown in the experiments, although in doing so it requires that we abandon some ideas about how well we can measure quantities such as position and velocity. Most important of all, the theory abandons the traditional causal view of physical phenomena: It makes no predictions about individual events, but rather predicts the *probabilities* that these events occur.

Quantum mechanics does not have an evident role to play in the everyday phenomena around us. But it has been enormously successful in the quantitative description of atoms, nuclei, and more fundamental particles and their interactions, as well as of the behavior of materials. In recent decades it has also had a big impact on technology, through its role in *mesoscopic* systems, those that lie in scale between the atomic and "human" scale. For example, many properties of the circuits that act in computers rely to some degree on quantum phenomena. Some familiarity with quantum mechanics is an essential part of a scientific education. In this chapter we describe the particle nature of radiation, the wave nature of particles, and the limitations on the concepts of position and momentum, all basic

ideas of quantum mechanics. In a succeeding part of this book we explore a large range of phenomena that can only be understood with the help of quantum physics.

40–1 The Particle Nature of Radiation

Blackbody Radiation

The discovery of quantum mechanics did not come through a study of atoms or other microscopic systems. The first hints of it came through the work of Max Planck (Fig. 40–1), who was trying to understand the experimental data on *blackbody radiation*, the name given to a spectrum of electromagnetic radiation in thermodynamic equilibrium at a temperature T, a situation most easily arranged within a cavity (Chapter 17). The radiation inside a cavity can be studied by making a tiny hole in the cavity walls and looking at what emerges. One finds that blackbody radiation has energy distributed across a continuum of frequencies. The distribution is described by an energy density $u(f, T)$, whose meaning is that *the electromagnetic energy of the radiation in the frequency range from f to $f + df$ within a cavity of unit volume in equilibrium at temperature T is $u(f, T)\,df$*. We considered this function in Section 17–5, and you may want to review that discussion.

▲ **FIGURE 40–1** Max Planck.

The allowed frequencies for blackbody radiation in a cavity do not in fact form a continuum. Standing waves in a cavity, such as those formed by the electromagnetic field in a microwave oven, resemble the standing waves in a guitar string fixed at the two ends, and the possible frequencies are discrete, depending on the shape and size of the cavity. There is a fundamental frequency as well as a first, second, . . . nth harmonic. Each allowed frequency represents a degree of freedom for the radiation as far as the equipartition of energy is concerned (see Chapter 19). Using this classical principle, one expects the energy density for a given frequency to be proportional to the temperature T. In 1900 Lord Rayleigh and James Jeans accordingly predicted that for radiation in a cavity, the energy density should have the form

$$u(f, T) = \frac{8\pi f^2}{c^3} kT. \tag{17–18}$$

This result agrees with experiment for low frequencies but strongly disagrees with observations for high frequencies. The same year the Rayleigh–Jeans result was published, Planck arrived at a remarkable formula, Eq. (17–16), that fits the observed energy density over the full range of frequencies:

$$u(f, T) = \frac{8\pi h}{c^3} \frac{f^3}{e^{hf/kT} - 1}. \tag{17–16}$$

This formula involves a new fundamental constant h, now called Planck's constant, with the value $h = 6.63 \times 10^{-34}\ \text{J} \cdot \text{s}$. Figure 17–19 shows the precise agreement between measured values of $u(f, T)$, and the Planck formula for a temperature of 2.7K.

CONCEPTUAL EXAMPLE 40–1 You have no doubt seen pictures of steel mills, with molten iron at 2000°C visible through the doors of the furnaces. Why does this fact show that the Rayleigh–Jeans formula [Eq. (17–18)] cannot be correct?

Answer We must start with the assumption that looking through a small hole into a cavity such as the door to a furnace allows us to "see" blackbody radiation. There is then a striking reason to doubt the Rayleigh–Jeans formula. This formula does not correlate the color of the radiation with the temperature—the formula picks out no prominent frequency, or color, that changes with the temperature. Yet a cavity at room temperature certainly has a different color than one at the temperature of molten iron. More generally, as the temperature increases, the color of a fire changes systematically, from dull red through a bright orange to a brilliant yellow. The full Planck formula does indeed contain such a correlation, and we discussed the fact that it has a maximum as a function of frequency that changes with temperature in Section 17–5.

Planck was able to derive his formula only by making a strange assumption: The walls of the cavity constantly absorb and reemit the radiation, and Planck assumed that the absorption and emission of radiation was limited to "bundles" of energy. Each bundle had an energy proportional to its frequency, according to the formula

$$E = hf. \tag{40–1}$$

This assumption, which has no grounding in classical physics, was translated by Albert Einstein in 1905 into a more general assertion: *Electromagnetic radiation consists of* ***quanta****, or identical, indivisible units, each carrying energy* hf*, where* f *is the frequency of the radiation.* In other words, the walls are observed to absorb and emit in bundles of radiation because the radiation only comes in such bundles.

We shall soon discuss other experiments that confirm these quanta of radiation and show how they behave as particles. These particle-like quanta of radiation are called **photons**. Because the momentum and energy of any particle that travels at the speed of light are related by $p = E/c$, a photon of energy $E = hf$ carries momentum of magnitude

$$p = \frac{E}{c} = \frac{hf}{c}. \tag{40–2}$$

For radiation,

$$\lambda = \frac{c}{f} = \frac{hc}{hf} = \frac{hc}{E} = \frac{h}{p}. \tag{40–3}$$

This formula, connecting a wavelength and a momentum through Planck's new constant, was later adopted for matter by de Broglie in his daring conjecture concerning the wave properties of matter (see Section 40–2).

EXAMPLE 40–2 How many photons in the visible range (around 550 nm) are emitted every second by a 60-W lightbulb? Only about 10 percent of the total power emitted as radiation by an incandescent lightbulb is in the visible range.

Strategy If the total power emitted by the bulb is P, then the power emitted in the visible range, which we assume is concentrated at $\lambda = 550$ nm, is $(0.1)P$. Since the energy carried by a single photon is $hf = hc/\lambda$, the number of photons of visible light emitted per second is $n =$ (total energy emitted as visible light/sec)/(energy per visible-light photon) $= (0.1P)/(hf)$.

Working It Out Numerical evaluation gives

$$n = \frac{(0.1)P}{(hc/\lambda)} = \frac{(0.1)P\lambda}{hc} = \frac{(0.1)(60\,\text{J/s})(550 \times 10^{-9}\,\text{m})}{(6.6 \times 10^{-34}\,\text{J}\cdot\text{s})(3 \times 10^{8}\,\text{m/s})}$$
$$= 1.7 \times 10^{19}\ \text{photons/s}.$$

It is obvious from this number that direct detection of individual photons from such a bulb would be quite difficult.

What Do You Think? What happens to the other 90 percent of the power? *Answers to* ***What Do You Think?*** *questions are given in the back of the book.*

EXAMPLE 40–3 A bright star, easily visible to the naked eye, emits radiation such that the intensity (power per unit area) at Earth's surface is $I = 1.6 \times 10^{-9}\ \text{W/m}^2$ at a wavelength of 560 nm. Estimate the rate at which photons enter the night-adapted eye from such a star.

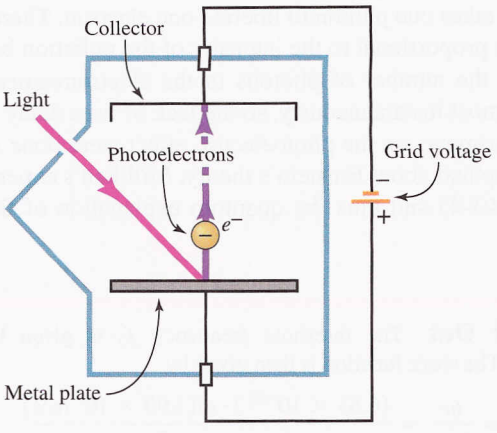
Setting It Up We have the power per unit area, and to find the power or the number of photons per unit time that enters the eye, we need to assume an area for the pupil. We shall take the pupil in nighttime conditions to be a circle with a diameter of 0.5 cm.

Strategy The frequency of the radiation needs to be calculated using the relation $f = c/\lambda$. The energy per photon is $hf = hc/\lambda$, where λ is the wavelength of the light. The intensity I can be converted into the number of photons per m^2 per second by dividing I by the energy per photon. The number of photons entering the eye is this result multiplied by the area $\pi d^2/4$ of the pupil.

Working It Out We write the intensity as NE, where N is the number of photons striking Earth per square meter per second. Thus

$$N = \frac{I}{E} = \frac{I\lambda}{hc} = \frac{(1.6 \times 10^{-9}\,\text{J/m}^2\cdot\text{s})(560 \times 10^{-9}\,\text{m})}{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})(3.0 \times 10^{8}\,\text{m/s})}$$
$$= 0.45 \times 10^{10}\ \text{photons/m}^2\cdot\text{s}.$$

The area of the pupil is estimated to be $A = \pi(d/2)^2 = \pi(2.5 \times 10^{-3}\,\text{m})^2 = 2.0 \times 10^{-5}\,\text{m}^2$, so the number of photons that enter the eye in 1 s is

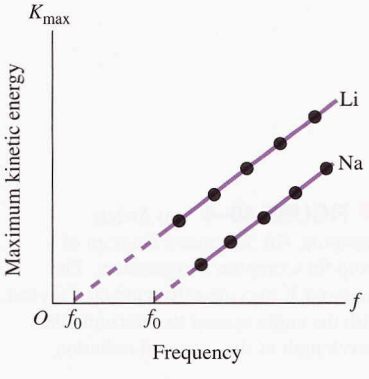


$$NA = (0.45 \times 10^{10}\ \text{photons/m}^2\cdot\text{s})(2.0 \times 10^{-5}\,\text{m}^2)$$
$$= 0.90 \times 10^{5}\ \text{photons/s}.$$

The human eye can register as few as several photons per second (see Problem 17).

What Do You Think? Assume that the human eye responds to a rate of 15 photons/s. At this wavelength, how much farther away could this star be and still be seen?

The Photoelectric Effect



Support of a different kind for the quantum nature of radiation came from the work of Albert Einstein, who used the quantum nature of radiation to explain the *photoelectric effect* in 1905. This effect was discovered by Heinrich Hertz in 1887 in experiments shown schematically in Fig. 40–2.

◀ **FIGURE 40–2** Schematic diagram of an experimental setup for measuring the photoelectric effect. Light strikes a metal plate in an evacuated chamber. The electron current is measured by a collector, and the kinetic energy is determined by the grid voltage needed to stop the electrons from reaching the collector.

The simplest statement of the photoelectric effect is that when a polished metal plate is exposed to electromagnetic radiation, it may emit electrons. These electrons are sometimes termed *photoelectrons*. The mere fact that electrons are emitted from metals subjected to electromagnetic radiation can be understood without invoking quantum ideas. Metals contain free electrons, and because electrons do not leak out of a metal freely, it is reasonable to expect that a minimum of energy must be deposited in the metal to liberate electrons. Moreover, in classical electromagnetic theory the energy delivered by radiation to the metal is proportional to the square of the electric field, $\vec{E}$; that is, to the intensity of the incoming radiation. We would therefore expect the energy carried off by the electrons to be proportional to the intensity. For example, a doubling of the intensity would double the number of electrons emitted with a given kinetic energy. And indeed, if the frequency is held constant, the magnitude of the emitted current of electrons is proportional to the intensity of the light source.

However, when one looks more closely at the characteristics of the photoelectric effect, one finds that there are many features that don't make much sense in the classical picture. For example, in the classical picture, electrons should not be emitted at all at very low intensities. Yet they are, and the maximum kinetic energy of the emitted electrons is independent of the intensity of the light source. In the classical picture, the maximum kinetic energy of the emitted electrons should not depend on the frequency of the radiation, only on its intensity, yet the maximum kinetic energy of the emitted electrons in fact varies linearly with the frequency of the incident light (Fig. 40–3). In the classical picture, energy should be delivered for all radiation frequencies, yet in fact no matter how large the intensity, electrons are emitted only if the frequency of the incident light exceeds a threshold value—that is, $f > f_0$. (The value of the *threshold frequency* f_0 may vary with the particular metal.) In the classical picture, we would expect that with low-intensity radiation, the energy required to liberate a certain number of electrons would have to be collected over some time, and that there would be a time delay (increasing with decreasing intensity) before the electrons would appear. Yet in fact experiments show that to an accuracy of 10^{-9} s, there is no measurable time delay between the arrival of the radiation and the appearance of the electron current.

▲ **FIGURE 40–3** Data for the photoelectric effect, showing the maximum kinetic energy of the emitted electrons (of lithium, Li, and sodium, Na) as a function of light frequency. Note the linear relationship and the presence of a minimum frequency f_0.

Einstein explained these phenomena by postulating that electrons are emitted because individual electrons absorb individual photons. The photons that correspond to radiation with frequency f carry energy $E = hf$. If there is a minimum energy W required to liberate an electron, then no electrons will be emitted when hf is less than W. When hf exceeds W, the excess energy can go into kinetic energy of the emitted electrons:

$$\frac{1}{2}mv^2 = hf - W. \tag{40–4}$$

The quantity W is a kind of potential energy that must be acquired before the electron can be liberated; it is called the *work function*. The work function is a characteristic of the particular metal that emits electrons, typically taking on a value in the range of several eV. (Recall $1\text{ eV} = 1.6 \times 10^{-19}$ J; using the fact that kT is an energy, one finds that the equivalent of an eV in temperature is around 1.2×10^4 K. The electron-volt is

discussed in detail in Section 24–2.) It takes one photon to liberate one electron. Therefore, the current of emitted electrons is proportional to the intensity of the radiation because the intensity is proportional to the number of photons in the electromagnetic wave. An electron absorbs a photon almost instantaneously, so the lack of time delay is also explained. The first accurate experiments on the photoelectric effect were done in 1916 by Robert Millikan, who was skeptical about Einstein's theory. Millikan's experiments unequivocally confirmed Eq. (40–4) and thus the quantum explanation of the photoelectric effect.

EXAMPLE 40–4 The longest wavelength of light that will induce a photoelectric effect in potassium is 564 nm. Calculate the work function for potassium in electron-volts.

Strategy We must recognize that the longest wavelength of light corresponds to the lowest or threshold frequency f_0 necessary to induce the photoelectric effect, with the photoelectrons barely moving as they leave the metal—they have minimal kinetic energy. We then have an application of Eq. (40–4) for $v = 0$, and the work function is $W = hf_0$.

Working It Out The threshold frequency f_0 is given by $f_0 = c/\lambda_{\max}$. The work function is then given by

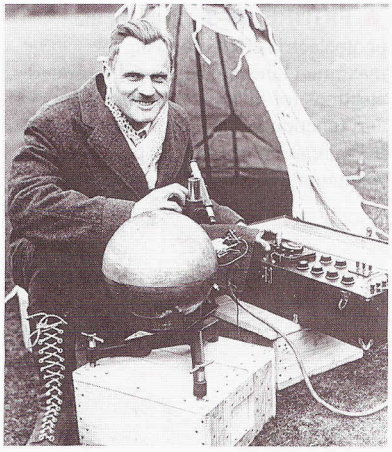
$$W = hf_0 = \frac{hc}{\lambda_{\max}} = \frac{(6.63 \times 10^{-34}\ \text{J}\cdot\text{s})(3.00 \times 10^{8}\ \text{m/s})}{5.64 \times 10^{-7}\ \text{m}}$$

$$= 3.53 \times 10^{-19}\ \text{J} = (3.53 \times 10^{-19}\ \text{J})\frac{1\ \text{eV}}{1.60 \times 10^{-19}\ \text{J}}$$

$$= 2.20\ \text{eV}.$$

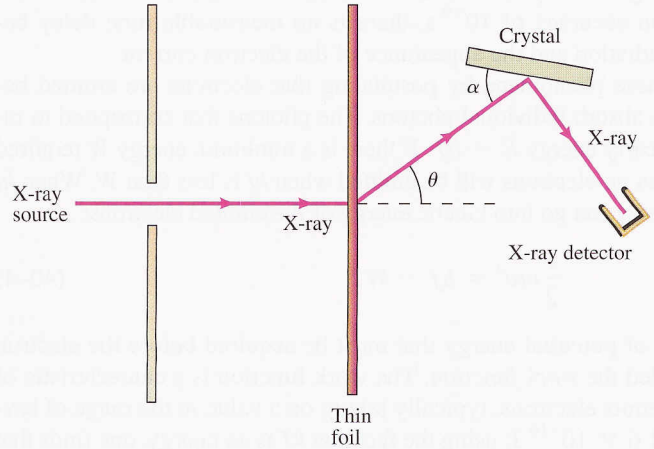
What Do You Think? What do you expect to happen if radiation of a shorter wavelength is incident on potassium? What if the radiation has a longer wavelength?

The Compton Effect



More compelling evidence for the particle properties of photons came from experiments of Arthur Compton in 1922 (Fig. 40–4a). Compton sent X rays through thin metallic foils (Fig. 40–4b) and discovered that the scattered X rays emerge with one of two wavelengths. One component emerges with the same wavelength λ_0 as the incident radiation. The other component emerges with a longer wavelength λ'. This result is in contrast to the prediction of classical radiation theory, in which the electrons absorb radiation and reradiate it as dipole radiation without any change in wavelength. The experiments show that λ' varies with the scattering angle θ of the X ray (Fig. 40–5), satisfying the relation

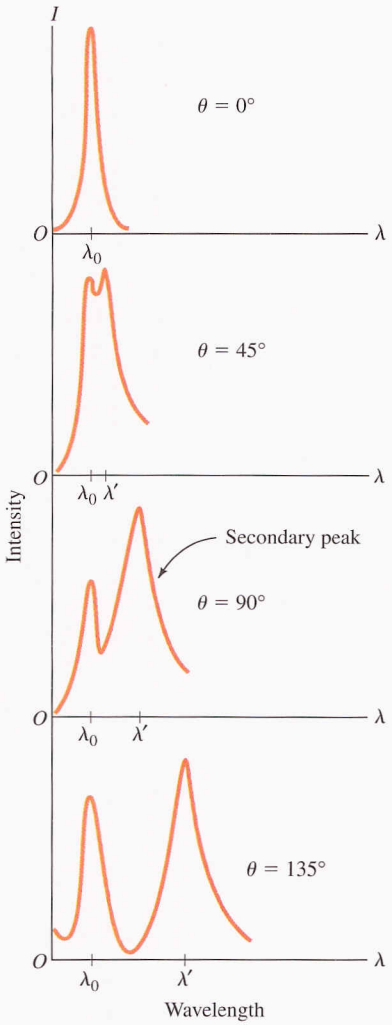
$$\lambda' - \lambda_0 = \frac{h}{mc}(1 - \cos\theta), \tag{40–5}$$



where m is the electron mass. The presence of h indicates that quantum mechanical effects are involved, and because the result does not depend on the metal used in the foils and the electron mass is present in the formula, Compton concluded that the effect had nothing to do with the metal's crystal structure.

Compton was able to derive Eq. (40–5) (see Problem 16) by treating the photon as a particle of energy hf and, as in Eq. (40–2), momentum hf/c colliding elastically with a

▼ **FIGURE 40–4** (a) Arthur Compton. (b) Schematic diagram of a setup for Compton's experiment. The scattered X rays are diffracted by a crystal, with the angle α used to determine the wavelength of the scattered radiation.

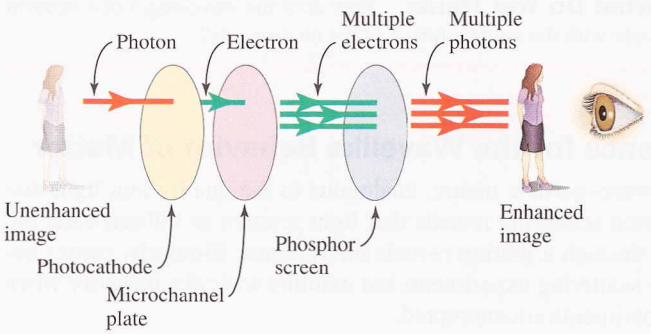


(a)

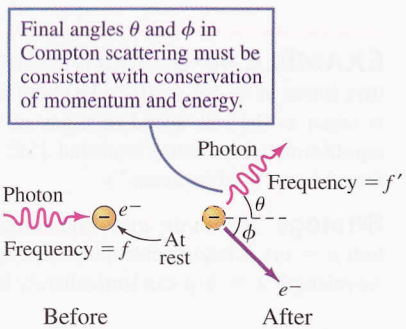
(b)

target electron at rest—in other words, a standard two-body collision, complete with momentum and energy conservation (Fig. 40–6). The treatment of the collision follows the methods for elastic collisions in space (see Chapter 8), with the difference that it is necessary to take the electron's final energy in the relativistic form $E_e = \sqrt{p^2c^2 + m^2c^4}$, where p is the final electron momentum. The energy of the scattered photon can be calculated, and it differs from that of the incident photon, just as would be true in a collision of billiard balls. And because the energy of the scattered photon is different from that of the incident photon, so is its wavelength. Equation (40–5) correctly emerges. The quantity h/mc, called the *Compton wavelength* of the electron, has the dimensions of length and magnitude 2.4×10^{-12} m. Why are there two peaks in Fig. 40–5? The peak at the original wavelength λ_0 corresponds to the collision of a photon with an ion, which is thousands of times more massive than the electron. This is like the elastic scattering of a classical particle from a wall; the photon loses no energy, and the shift of the photon wavelength is very nearly zero.

Experiments such as the scattering of X rays from matter, designed to study the particle nature of radiation, do in fact see radiation exhibiting particle behavior. At the same time, experiments that probe the wave character of radiation, such as interference experiments, confirm the wave character of radiation, even at extremely high frequencies—Bragg's law, for example, concerns the diffraction of X rays from regular structures. *Light has a dual wave-particle nature.*



▲ **FIGURE 40–5** Experimental data for Compton's experiment. The secondary peak, due to X-ray scattering by free electrons, becomes more pronounced as the scattering angle increases.



THINK ABOUT THIS. . .

CAN ONE ACTUALLY "SEE" INDIVIDUAL PHOTONS?

The human eye is an instrument of incredible efficiency, but not quite good enough to respond to a single photon. However, single photons can be detected by using a device called a *photomultiplier*. This device amplifies the effect of a single photon in the following way. The incident photon strikes a material and produces a photoelectron. The material is said to form a *photocathode*. The photoelectron is projected into an evacuated region in which an electric potential is set up. This potential accelerates the electron, and when it strikes another surface, the *dynode*, it has enough energy to release several more electrons through collisions with the material. These electrons are then accelerated by another potential until each electron is energetic enough to again release a small number of electrons in collisions with another surface. By the time many such stages are completed, the single incoming photon has produced a cascade of up to 10^9 electrons, enough to generate a measurable electric current. The magnitude of the pulse created by the current can be translated into a measurement of the energy deposited by the photon. This cascading mechanism is utilized in the *image-intensifier tube*, which is at the heart of one type of night-vision viewer (Fig. 40–7). The device works by collecting individual photons, then using the photoelectric effect to amplify their presence. A lens system sends any collected light to a glass plate coated on the back side with a photoelectric material. The photoelectrons are accelerated through a potential difference of several hundred volts to a "channel plate" containing many holes, typically 10 microns in diameter. There are many such holes, and they are designed to "hold the image together" as the cascade proceeds. When a photoelectron strikes the sides of a hole, it releases several electrons. These collide further with the sides of the hole and produce still other electrons. The electrons may be passed on to other channel plates in a series of repeating steps, ending with a large number of electrons aligned with the holes, and since few photons will produce few electrons, the numbers of electrons in various locations will reproduce the image. A final acceleration stage to a fluorescent screen produces photons and hence a visible image.

◀ **FIGURE 40–7** An *image-intensifier tube* produces a visible image from only a few photons—even one photon produces a cascade of electrons that can in turn form a visible signal.

▲ **FIGURE 40–6** Light of frequency f scatters from an electron as though the light were a particle (photon). As in the collision of any two particles, the photon's energy changes when the photon scatters, and by the laws of quantum mechanics, its frequency changes to f'. The phenomenon is known as the Compton effect.

40–2 The Wave Nature of Matter

The presence of both wavelike and particle-like aspects in light stimulated Louis de Broglie to inquire whether particles such as electrons would also exhibit wavelike behavior. In his 1924 doctoral thesis, he proposed that when particles are subject to experiments that test wavelike properties—basically interference experiments—they do indeed exhibit wavelike properties. More precisely, particles with momentum p act like waves with a de **Broglie wavelength** λ given by

$$\lambda = h/p. \tag{40–6}$$

This expression involves *the same Planck's constant* as appears in the photon energy-frequency relation. In fact, it is *exactly* the relation between momentum and wavelength that holds for photons [Eq. (40–3)].

De Broglie's wavelength-momentum relation may also be written in terms of a wave number $k = 2\pi/\lambda$:

$$k = \frac{2\pi}{\lambda} = \frac{2\pi p}{h} = \frac{p}{\hbar}. \tag{40–7}$$

We have here written the commonly occurring combination $h/2\pi$ as $\hbar$:

$$\hbar \equiv h/2\pi \cong 1.05 \times 10^{-34}\ \text{J}\cdot\text{s}. \tag{40–8}$$

The small size of h makes the wave character of matter evident only on a very small scale, where the relevant momenta are extremely small and the wavelengths large enough to have observable effects. For example, a dust particle of mass 10^{-6} g traveling at a speed of 1 m/s has a wavelength of

$$\lambda = \frac{h}{p} = \frac{h}{mv} = \frac{(6.63 \times 10^{-34}\ \text{J}\cdot\text{s})}{(10^{-9}\ \text{kg})(1\ \text{m/s})} \cong 7 \times 10^{-25}\ \text{m}.$$

This wavelength is far too small to detect: Dust particles, baseballs, and airplanes do not reveal their wavelike aspects. On the atomic scale, however, things are quite different. Electrons ($m_e = 9.1 \times 10^{-31}$ kg) moving at a speed of 10^6 m/s, typical of electron speeds in atoms, have a wavelength

$$\lambda = \frac{(6.63 \times 10^{-34}\ \text{J}\cdot\text{s})}{(9.1 \times 10^{-31}\ \text{kg})(10^6\ \text{m/s})} \cong 0.7\ \text{nm}.$$

This wavelength is of the same magnitude as interatomic spacing in matter and so can be tested by diffraction experiments, such as those described in Chapter 38 for X rays.

EXAMPLE 40–5 What is the de Broglie wavelength of a neutron (mass $m = 1.6 \times 10^{-27}$ kg) with a speed $v = 1500$ m/s? (If v is taken as the rms speed of a gas of neutrons, the corresponding equilibrium temperature is around 35K. These neutrons are often referred to as "cold neutrons.")

Strategy Given the mass and velocity of a particle, its momentum $p = mv$ is readily calculated, and by the de Broglie formula, the wavelength $\lambda = h/p$ can immediately be obtained.

Working It Out The wavelength is

$$\lambda = \frac{h}{mv} = \frac{(6.63 \times 10^{-34}\ \text{J}\cdot\text{s})}{(1.6 \times 10^{-27}\ \text{kg})(1.5 \times 10^{3}\ \text{m/s})} = 0.28\ \text{nm}.$$

This value is comparable to the typical spacing between atoms in a crystal, so that we would expect diffraction to be visible in the scattering of such neutrons from a crystal.

What Do You Think? How does the wavelength of a neutron scale with the temperature T of the neutron gas?

Experimental Evidence for the Wavelike Behavior of Matter

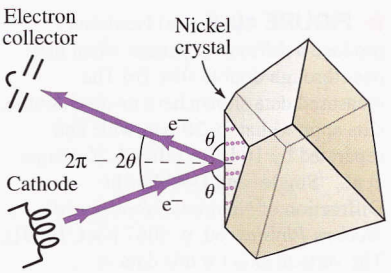
Every particle has a dual wave–particle nature, analogous to the duality that light displays. For example, Compton scattering reveals that light scatters as billiard balls do, while the passage of light through a grating reveals interference. Similarly, matter behaves classically in simple scattering experiments but exhibits wavelike behavior when the proper interference experiments are attempted.

The first experiments to confirm de Broglie's conjecture about the wavelike aspects of matter were carried out in 1927 by Clinton J. Davisson and Lester H. Germer, and independently by George Paget Thomson. They found that certain scattering directions are preferred when electrons are scattered by a crystal, a behavior typical of the scattering of a wave from a regular array such as a crystal. We found the interference condition for this situation, *Bragg's law*, in Chapter 38, in our discussion of the scattering of electromagnetic radiation, which we expect classically to show interference. Bragg's law [Eq. (38–17)] states that when waves of wavelength λ are reflected from a succession of crystal planes separated by a distance d, there will be constructive interference for angles θ that satisfy (Fig. 40–8)

$$k(2d)\sin\theta = 2\pi n, \tag{40–9}$$

where n is an integer and $k = 2\pi/\lambda$ is the wave number. From Eq. (40–9), we have constructive interference at angles θ that satisfy

$$\sin\theta = \frac{n\lambda}{2d}. \tag{40–10}$$



In the Davisson–Germer experiment, it was not radiation but rather a beam of electrons that was sent through a crystal (Fig. 40–8). The spacing between the scattering planes in the crystal had been determined by X-ray diffraction experiments to be $d = 0.091$ nm. Davisson and Germer then accelerated electrons through a potential of 54 V, giving them an energy of 54 eV, or 86.4×10^{-19} J. They scattered these electrons and observed a diffraction maximum, and therefore *wavelike behavior* at 65°. The kinetic energy of the electron corresponds to a momentum p:

$$p = \sqrt{2m_eE} = \sqrt{2(9.1 \times 10^{-31}\,\text{kg})(86.4 \times 10^{-19}\,\text{J})} = 39.7 \times 10^{-25}\,\text{kg}\cdot\text{m/s}.$$

Knowing the momentum, we can find the angle of constructive interference from Eq. (40–10),

$$\sin\theta = \frac{n\lambda}{2d} = \frac{n}{2d}\frac{h}{p} = \frac{n}{2(9.1 \times 10^{-11}\,\text{m})}\frac{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})}{(39.7 \times 10^{-25}\,\text{kg}\cdot\text{m/s})} = 0.92n.$$

For $n = 1$, this yields $\theta = 67°$, in agreement with the measured value to the accuracy of their experiment.

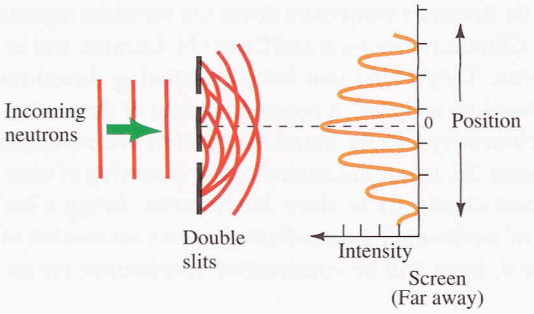
▲ **FIGURE 40–8** Experimental setup for the experiment of Davisson and Germer. Electrons from a cathode strike a surface of a nickel crystal and are scattered to an electron collector. The dots represent the regular array of nickel atoms that make up the crystal.

EXAMPLE 40–6 At what angles do diffraction peaks occur for electrons of kinetic energy 120 eV incident on a crystal whose scattering planes are 0.12 nm apart?

Strategy We must find the conditions for maxima as a function of the wavelength of the electrons, and this is given by Eq. (40–10). The wavelength itself is determined in terms of the momentum according to $\lambda = h/p$. The momentum is in turn given in terms of the energy by the nonrelativistic kinetic energy–momentum relation $p = \sqrt{2m_eE}$. We must make sure that all the units are consistent and convert where necessary to SI.

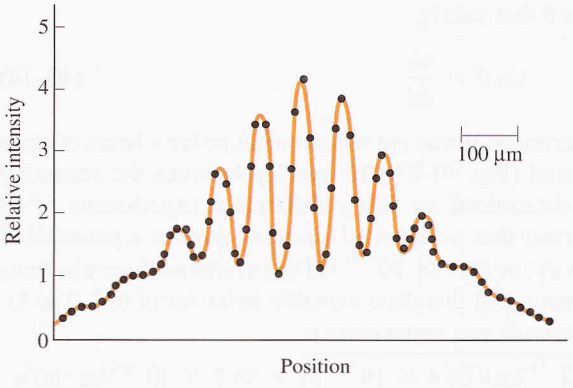
Working It Out The energy of the electrons is $120\,\text{eV} = (120\,\text{eV})(1.6 \times 10^{-19}\,\text{J/eV}) = 1.9 \times 10^{-17}\,\text{J}$. Thus the wavelength is

$$\lambda = \frac{h}{p} = \frac{h}{\sqrt{2m_eE}} = \frac{6.6 \times 10^{-34}\,\text{J}\cdot\text{s}}{\sqrt{2(9.1 \times 10^{-31}\,\text{kg})(1.9 \times 10^{-17}\,\text{J})}}$$
$$= 1.1 \times 10^{-10}\,\text{m} = 0.11\,\text{nm}.$$



With a crystal plane separation of $d = 0.12$ nm, the angles for constructive interference are

$$\sin\theta = \frac{n\lambda}{2d} = \frac{n(0.11\,\text{nm})}{2(0.12\,\text{nm})} = 0.47n.$$



There will be diffraction peaks at $\theta = 28°$ ($n = 1$) and at 70° ($n = 2$).

What Do You Think? Would there be more or fewer diffraction peaks with neutrons at the same kinetic energy?

Diffraction experiments have been performed with a variety of particles. In Example 40–5, we calculated the wavelength of neutrons that move at a certain speed; the wavelengths of these neutrons satisfy the conditions for substantial diffractive effects in scattering from crystals. The diffraction of neutrons by crystal surfaces is of practical importance in the study of those surfaces. Neutrons are ideal for such experiments because they can be slowed by collisions in hydrogenous materials such as paraffin, and slower neutrons have

(a)

(b)

▶ **FIGURE 40–9** (a) Neutrons produce a diffraction pattern when they pass through double slits. (b) The measured data shown here involve double slits approximately 20 μm wide and separated by 104 μm (after A. Zeilinger et al., "Single- and Double-Slit Diffraction of Neutrons," *Reviews of Modern Physics,* 60, p. 1067 [Oct. 1988]). The vertical axis for this data is proportional to the rate at which neutrons arrive at a screen.

longer wavelengths. Figure 40–9 shows the results of a 1988 experiment in which neutrons of de Broglie wavelength 2 nm were incident on a screen with two slits approximately 100 μm apart, a classical wave phenomenon of the most basic type.

The simplicity of the effects described here should not mask their extraordinary nature. In many respects, electrons and neutrons are like classical particles. Electrons were discovered by subjecting them to electric and magnetic fields and studying their trajectories through observation of their impact on the screen of a cathode-ray tube. These trajectories are those of a particle of mass m_e and charge $-e$ subject to the force law $\vec{F} = -e(\vec{E} + \vec{v} \times \vec{B})$. Similarly, neutrons produced in nuclear collisions move in paths that are described by Newton's laws. In contrast, an ordinary water wave does not move as a classical particle. Yet electrons and neutrons deflected by regular structures produce interference patterns, just as a water wave would!

The mystery—How can something be simultaneously a particle and a wave?—is a repetition of the mystery of the particle properties of photons. On one hand, photons participate in collisions as if they were point masses with energy and momentum; on the other hand, we know that light is a wave phenomenon. Both of these mysteries are reconciled by quantum mechanics, as we shall discuss in Section 40–3.

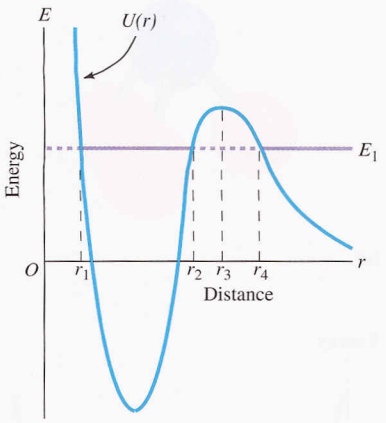
CONCEPTUAL EXAMPLE 40–7 You want to explore the shape of a certain molecule by scattering electrons of momentum p from a gas of the molecules and studying the deflection of the electrons. You will be able to see finer details in the molecules by (a) increasing p; (b) decreasing p; (c) not worrying what p is.

Answer The process of observation with a beam of electrons is analogous to the study of an object with light. The limits to resolution in both cases are based on diffraction phenomena, with the resolution improving as the wavelength decreases. You can achieve better resolution with electrons of shorter wavelength and thus, by the de Broglie relation, with a larger value of momentum.

Tunneling

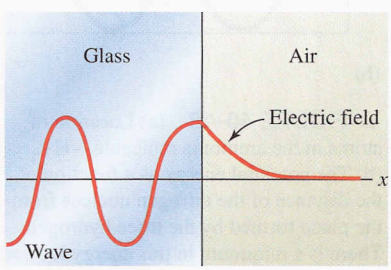
The phenomenon known as *tunneling*, or *barrier penetration*, is a more indirect manifestation of the wavelike properties of matter. Experiments and other natural phenomena such as nuclear fission show that particles, electrons or alpha particles (^{4}He nuclei) for example, are able to pass through a potential energy barrier from one region in space

to another. Consider a classical particle with energy E_1 that is confined to a region $r_1 < r < r_2$ by some potential energy function in the energy diagram of Fig. 40–10. As long as the energy of that particle is unchanged, it will always remain in that region. In the region $r_2 < r < r_4$ of Fig. 40–10 the particle's total energy would be less than its potential energy, so that its kinetic energy would be negative, an impossibility given its form $p^2/2m$. We say that the potential energy function forms a barrier. However, quantum mechanics allows a real particle that starts in the region $r_1 < r < r_2$ to appear in the region $r > r_4$, on the other side of the barrier.



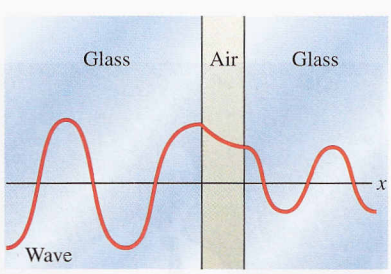
The idea of particle tunneling is completely unintuitive, inexplicable in terms of the particle aspects of matter. Still, the effect is real and is necessary to explain a large number of phenomena, including nuclear fission (Chapter 44). Tunneling today plays a large role in technology. One application you may have heard of is the tunneling microscope (Chapter 43), and there are applications in many microcircuit devices as well.

Tunneling can be explained in terms of the wavelike properties of matter. There is in fact such a thing as tunneling in optics, although it does not fall under that name. We can approach it by thinking about the phenomenon of total internal reflection in optics. When light traveling through glass reaches a glass–air surface at an angle that exceeds a critical angle, the light is completely reflected. We saw this as a consequence of Snell's law in Chapter 35, but it is really a consequence of Maxwell's equations together with the behavior of electric and magnetic fields at the interface between two different media. Solutions of Maxwell's equations reveal that the fields just outside the glass drop exponentially, not abruptly, to zero (Fig. 40–11a). If the air outside the glass forms a thin layer—no larger than a few wavelengths of the light—before another piece of glass is encountered, an exponentially reduced field remains at the second interface. Starting from there, the fields can again propagate as sinusoidal waves in the second piece of glass, although their amplitudes will be reduced by the amount of the exponential falloff that occurred in the air layer (Fig. 40–11b). *The light waves have tunneled through the air gap* with a calculable intensity. A laboratory experiment demonstrating this effect is shown in Fig. 40–12.



The mathematics of quantum mechanical tunneling is very similar to what we just described for classical electric and magnetic fields, although the interpretation of the quantities involved is very different. In quantum mechanics one calculates the reduction of the intensity of quantum mechanical "matter waves" that tunnel through a potential barrier. This turns out to be a calculation of *the fraction of the number of particles* that tunnel through the barrier. This fraction is very small under ordinary circumstances, which is why the phenomenon is not intuitively familiar to us. The fraction is given approximately by

$$\text{Fraction of particles getting through} \cong \exp\left[-(2a/\hbar)\sqrt{2m(\langle U\rangle - E)}\right]. \qquad (40\text{–}11)$$



Here a is the barrier's width and $\langle U\rangle$ is its average potential energy. For any macroscopic barrier the fact that $\hbar$ is so small means that this is the exponential of a huge negative quantity—the fraction is extremely small. Still, there are regimes in which a is small and the barrier height is small, and in those regimes tunneling is an observable fact.

(b)

▲ **FIGURE 40–13** (a) Location of atoms in the ammonia molecule NH_3. (b) The potential energy as a function of the distance of the nitrogen nucleus from the plane formed by the three hydrogens. There is a minimum in this energy located above the plane and a second minimum located equally far below the plane.

▲ **FIGURE 40–14** Werner Heisenberg.

THINK ABOUT THIS. . .

HOW IS TUNNELING USED IN ATOMIC CLOCKS?

A nice example of tunneling that makes use of the structure of the ammonia molecule led to one of the earliest atomic clocks. The ammonia molecule NH_3 has a tetrahedral structure (Fig. 40–13a). The nuclear "skeleton" of the molecule is formed by three hydrogen nuclei at the corners of an equilateral triangle lying in the xy-plane with the nitrogen nucleus lying on the z axis, which goes through the center of the triangle. The nitrogen nucleus lies above the plane of the triangle, its precise location determined by the location of a minimum of the electric potential energy shown in Fig. 40–13b created by the electrons and the hydrogen nuclei—moving the nitrogen nucleus farther away from, or closer to, the plane costs energy. There is, however, a symmetry: The potential energy *below* the triangle is identical to the one above, and the potential energy has *two* minima symmetrically placed above and below the plane formed by the hydrogen nuclei, with a potential barrier in between (Fig. 40–13b). Thus there are two equally possible equilibrium positions for the nitrogen nucleus, and if the nitrogen starts out in one, it has a certain probability, per unit time, of tunneling through to the other position. In other words, the interpretation in which a certain fraction of a large number of particles can tunnel through a barrier translates in this case into a rate at which a single particle—here the nitrogen nucleus—tunnels from one potential energy minimum to another. This tunneling rate is determined by quantum mechanics, and the regular back-and-forth tunneling of the nucleus in turn translates into an *oscillation frequency* between one minimum and another. This frequency is 23.87×10^9 Hz, and it provides a high-precision and highly reproducible clock, whose "readout" is performed by electronic circuits tuned to be in resonance with this frequency. This clock was one of the first atomic clocks because its frequency is in the so-called *radio-frequency* range, and technology using frequencies around this value was highly advanced due to the World War II development of radar. ■

40–3 The Heisenberg Uncertainty Relations

Although the electron behaves as a wave in an experiment that explictly tests for wavelike behavior, and as a particle in an experiment that tests for particle-like behavior, there are many experiments—we'll look at examples below—in which we can look at the behavior in both ways, and as we shall see, in these types of experiments there is an apparent conflict. Similar problems arise for electromagnetic radiation. We should emphasize that the difficulties are primarily conceptual; quantum mechanics gives unambiguous and correct predictions for all such experiments. Werner Heisenberg (Fig. 40–14) provided a framework in which these conflicts are resolved—or rather sidestepped. He found that within quantum mechanics one cannot assign to either matter or radiation both a well-defined position and a well-defined momentum (or velocity). Either one of them can be determined to an arbitrary degree of accuracy, but not both of them. If an experiment determines the position of a particle moving in the x-direction with an accuracy Δx, and the momentum in that same direction with an accuracy Δp_x, then there is an intrinsic limitation on these quantities given by the inequality

$$\Delta x \, \Delta p_x > \hbar. \qquad (40\text{–}12)$$

HEISENBERG UNCERTAINTY PRINCIPLE FOR POSITION AND MOMENTUM

This is known as the **Heisenberg uncertainty relation** or the **Heisenberg uncertainty principle**. The use of this relation gives us the means of avoiding the conflict between the particle and wave views of a given experiment. It is worth emphasizing that the uncertainty principle is not a limitation that can be improved by improving an experimental apparatus. It is, rather, an intrinsic uncertainty built into the physical world.

To see how the conflicts we referred to above arise, consider first a simple example: a beam of light with frequency f strikes a screen. There is a slit of width a in the screen. We know from optical observations that on passing through the slit, the beam will spread out and appear on a screen to have an angular spread of the order of $\theta \cong \lambda/a$.

But we now know that this beam actually consists of photons, and it is this beam of photons that spreads. How is this possible? After all, a single photon can only go to a single place. One possible explanation is that when there are lots of photons, they act collectively, the way a lot of individual water molecules act in an ocean wave. This explanation won't work, however, because it is possible to perform this experiment with a beam of such low intensity that each photon was many centimeters away from the one before and the one after it, and the results remain the same. (In one realization of this experiment, it took three months' worth of radiation to build up the diffraction pattern.)

The uncertainty relation tells us how to resolve the difficulty correctly. The answer is the following: We don't know the y-position of the photon when it passes through the slit, where y measures the distance *across* the slit, which means the uncertainty in its position is of order of a. In other words, $\Delta y \cong a$, and from Eq. (40–12) its transverse momentum (its momentum in the direction across the slit) is only known to an accuracy satisfying

$$\Delta p_y > \frac{\hbar}{\Delta y} \cong \frac{\hbar}{a}.$$

But an uncertainty in its transverse momentum means an uncertainty in its angle of deflection θ from the central line of the beam:

$$\theta \cong \frac{\Delta p_y}{p} \gg \frac{\hbar}{ap} = \frac{h}{2\pi ap} = \frac{1}{2\pi}\frac{\lambda}{a}.$$

This uncertainty in the direction holds for any single photon, and this accounts for the observed spread. A collection of photons, each one of which has an angular uncertainty given as above, will produce a pattern spread over the screen in a way that is identical to the pure wave treatment of the light.

Below we'll discuss this and other examples of how conflicts are resolved in more detail. Before we do this, we want to add a couple of remarks. First, there is another relation that emerges from quantum mechanics similar to Eq. (40–12), and it reads

$$\Delta E\, \Delta t > \hbar. \tag{40–13}$$

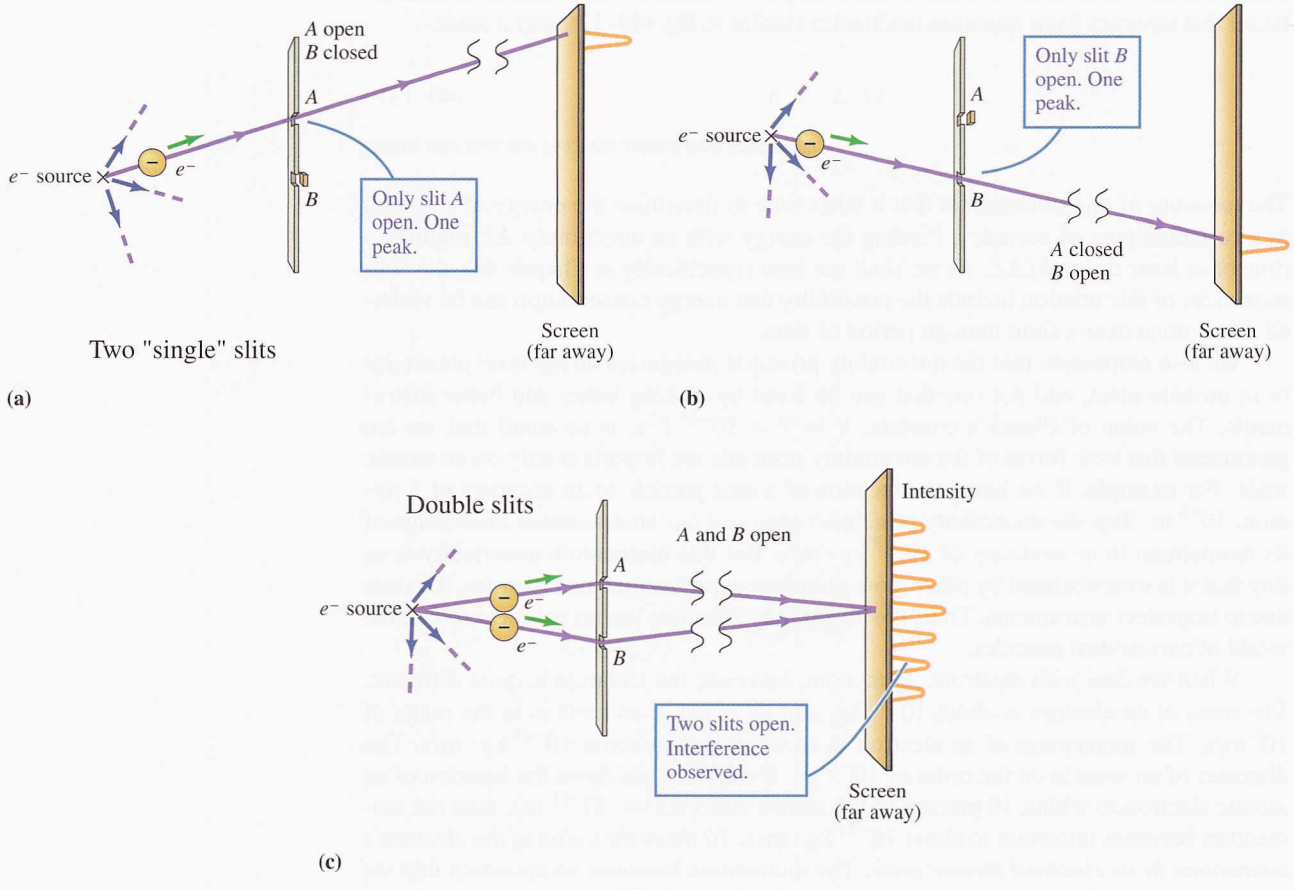
HEISENBERG UNCERTAINTY PRINCIPLE FOR TIME AND ENERGY

The meaning of this statement is that it takes time to determine the energy of a system to a certain degree of accuracy. Finding the energy with an uncertainty ΔE requires a time of *at least* $\Delta t \cong \hbar/\Delta E$. As we shall see later (specifically in Chapter 45), the consequences of this relation include the possibility that energy conservation can be violated if it is done over a short enough period of time.

We also emphasize that the uncertainty principle recognizes an *intrinsic* uncertainty in measurement, and not one that can be fixed by making better and better instruments. The value of Planck's constant, $h \cong 7 \times 10^{-34}\ \text{J} \cdot \text{s}$, is so small that we are guaranteed that both forms of the uncertainty principle are important only on an atomic scale. For example, if we know the location of a dust particle to an accuracy of 1 micron, 10^{-6} m, then the uncertainty principle constrains our simultaneous knowledge of its momentum to an accuracy of $10^{-28}\ \text{kg} \cdot \text{m/s}$. But this momentum uncertainty is so tiny that it is overwhelmed by other more mundane experimental uncertainties, the ones due to imperfect instruments. Thus, the uncertainty principle has no practical role in the world of cars or dust particles.

When we deal with electrons in an atom, however, the situation is quite different. The mass of an electron is about 10^{-30} kg, and its speed in an atom is in the range of 10^6 m/s. The momentum of an electron in an atom is then about $10^{-24}\ \text{kg} \cdot \text{m/s}$. The diameter of an atom is on the order of 10^{-10} m. If we try to pin down the location of an atomic electron to within 10 percent of the atom's size ($\Delta x \cong 10^{-11}$ m), then the momentum becomes uncertain to about $10^{-23}\ \text{kg} \cdot \text{m/s}$, *10 times the value of the electron's momentum in its classical atomic orbit*. The momentum becomes so uncertain that we are not even sure that the electron will stay within the atom! The uncertainty relation is so important for atoms and nuclei that Newtonian momentum is a concept that must be used with care when dealing with matter at this scale.

A closely related uncertainty relation arose in our discussion of pulses in Section 15–7. We pointed out there that a wave pulse is made of a superposition of waves with different wavelengths (or equivalently different wave numbers $k = 2\pi/\lambda$). Even though it is constructed from waves, a pulse, if it is short, resembles nothing more than a particle, and we are justified in thinking about this situation as another example of duality. We noted in Eq. (15–27) that if the pulse has a spatial width of Δx, then the spread Δk of wave numbers that go into making it up is constrained by the relation



$$\Delta x\, \Delta k \cong 1.$$

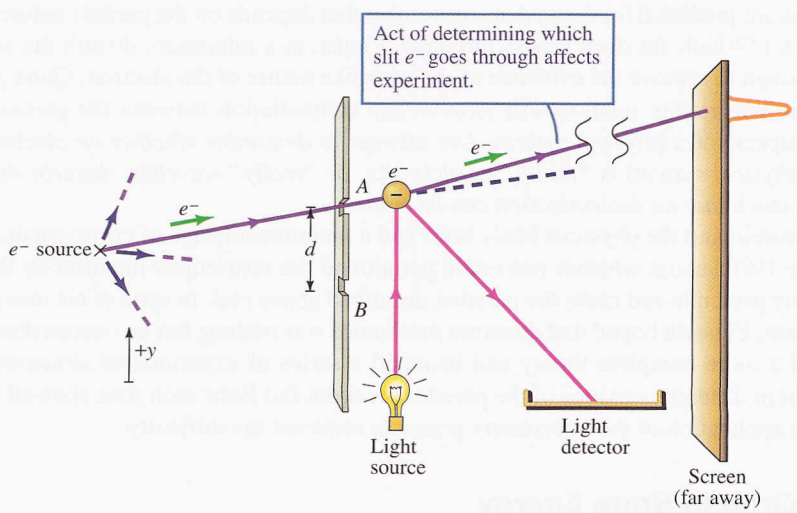
If we recall that the de Broglie relation between k and p is $\hbar k = p$, we see that this result is equivalent to the Heisenberg relation $\Delta x \Delta p \cong \hbar$.

In the remainder of this section, we shall explore in more detail how the uncertainty principle resolves conflicts inherent in a dual wave–particle model. We shall see that the uncertainty relations are also useful for making numerical estimates when quantum effects are important.

The Double-Slit Dilemma and Its Resolution

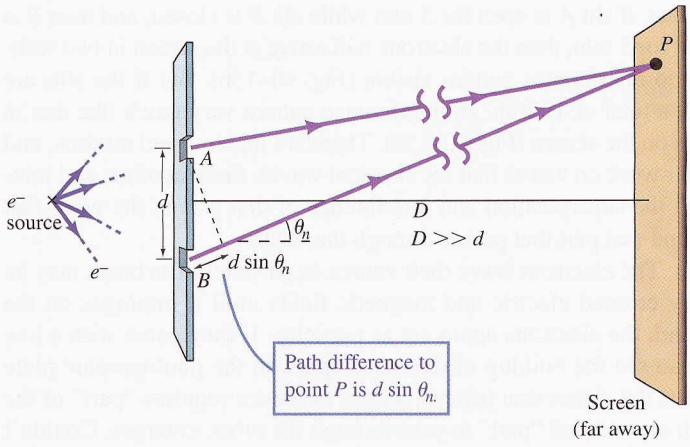
The double-slit experiment distills the conceptual difficulties of quantum mechanics to their starkest form. Diffraction experiments carried out with electrons, protons, neutrons, and a variety of molecular beams exhibit the same kinds of interference patterns seen for other waves and verify that these particles possess the wave properties predicted by quantum theory. Consider, then, a source of electrons emitted at some rate, so many per second, and impinging on a screen after they have passed through two slits in a wall (Fig. 40–15a). If we think of electrons as particles, we expect that each electron will go through

▲ **FIGURE 40–15** Schematic diagrams of the rate at which electrons arrive at a screen in a double-slit experiment: (a, b) the arrival-rate distribution, single peaks, when one slit is open at a time; (c) the arrival-rate distribution, an interference pattern, when both slits are open.



one slit or the other. In fact, if slit A is open for 5 min while slit B is closed, and then B is opened while A is closed for 5 min, then the electrons will arrive at the screen in two well-defined locations, with no interference pattern visible (Fig. 40–15b). But if the slits are open simultaneously for a total of 10 min, an interference pattern very much like that in Fig. 37–7 for light forms on the screen (Fig. 40–15c). There are maxima and minima, and we know from our earlier work on waves that for classical waves, these maxima and minima are built up through the superposition and interference of that part of the wave that passes through one slit and that part that passes through the other.

Here is the problem: The electrons leave their source as particles. The beam may be deflected and guided by crossed electric and magnetic fields until it impinges on the wall with slits. At the end, the electrons again act as particles. If they come with a low enough intensity, one can see the buildup of darkened spots on the photographic plate *one by one*. Nevertheless, the diffraction pattern, whose existence requires "part" of the electron to pass through one slit and "part" to pass through the other, emerges. Couldn't we just watch and see through which slit each electron passes? In fact, we could do better: We could watch closely enough to decide toward which slit the electron was heading and then close the other one. If we do, how can the diffraction pattern appear?



You might find the answer to this last set of questions surprising. The system of slits, together with the alert observer/monitor, does indeed give the same result as one finds by opening one slit at a time. *Somehow, observing the electrons closely enough to know through which of the two slits each electron passes destroys the interference pattern. But if we don't watch the electrons closely enough to know through which slit they pass, the interference pattern appears*. Quantum mechanics accounts for this very peculiar behavior through the position–momentum uncertainty relation.

In order to be able to tell which slit a given electron passes through in our double-slit electron experiment, an observer must use a monitor of some kind. But as we shall now see, any monitor that enables us to determine which slit each electron passes through will destroy the interference pattern. Any such monitor must be able to locate the electron's y-coordinate close to the slits to an accuracy $\Delta y < d/2$, where d is the separation distance between the slits and y is taken to be the direction across the slits (Fig. 40–16). The monitor must interact with the electrons to "see" where they are going. For example, the monitor may consist of a beam of light that reflects off the electron. The light carries momentum, and some of this momentum is transferred to the electron in a direction parallel to the screen (the y-direction in Fig. 40–16). If this momentum transfer is Δp_y, then the uncertainty relation states that

$$\Delta p_y > \frac{\hbar}{\Delta y} > \frac{2\hbar}{d}.$$

▲ **FIGURE 40–16** Schematic diagram of a monitor for a double-slit experiment designed to detect which slit an electron passes through. One mechanism: Shine light toward the slits and signal the passage of the electron by the pattern of reflected light.

▶ **FIGURE 40–17** Geometry of path-length differences for a double-slit experiment.

This much momentum imparted to the electron is sufficient to erase the interference pattern. For a slit separation d, the angles for constructive interference—interference maxima—are given by

$$d \sin \theta_n = n\lambda,$$

where θ_n is the angle that the line leading to the nth maximum makes with the central axis (Fig. 40–17). The distance between adjacent maxima on that screen is

$$D \sin \theta_{n+1} - D \sin \theta_n = \frac{(n+1)D\lambda}{d} - \frac{nD\lambda}{d} = \frac{D\lambda}{d},$$

where D is the distance to the viewing screen. But if the monitor gives the electron a sideways (y-direction) "kick," giving it an additional momentum Δp_y in the y-direction, the angle of deflection is changed by $\Delta p_y/p$ and thus its end-point at the screen by $D(\Delta p_y/p)$. In other words, using the uncertainty relation, the displacement at the screen has a new uncertainty

$$D\frac{\Delta p_y}{p} > \frac{D(2\hbar/d)}{p} = \frac{2D/d}{k} = \frac{D\lambda}{\pi d}.$$

This displacement uncertainty is comparable to the separation between the maxima. Thus the interference pattern is wiped out.

We have shown that there is no paradox. A pure double-slit experiment and an experiment that includes a monitor capable of determining the electrons' paths to an accuracy that tells us what slit they go through are different experiments, and different patterns are predicted for them. A measurement that depends on the particle nature of an electron ("Which slit does it pass through?") must, at a minimum, disturb the system just enough to remove the evidence of the wavelike nature of the electron. Quite generally, the uncertainty relation will remove any contradiction between the particle and wave aspects of a physical system. *Any attempt to determine whether an electron (or other physical system) is "really" particle-like, or "really" wavelike, disturbs the system so much that no determination can be made.*

Einstein and the physicist Niels Bohr had a famous exchange of correspondence in the late 1920s about whether one could get around the restrictions imposed by the uncertainty principle and make the paradox described above real. In spite of his many contributions, Einstein hoped that quantum mechanics was nothing but an intermediate step toward a more complete theory and invented a series of experimental situations that brought in different versions of the paradox; without fail Bohr each time showed how a correct application of the uncertainty principle removed the difficulty.

The Ground State Energy

Quantum mechanics tells us that the minimum possible energy of a particle is not the classical minimum in which a particle sits at rest at the very bottom of a potential well, but something a little greater. The minimum energy is called the **ground state energy**,

and the values of these energies for atoms and molecules is of great importance to chemistry and physics, because those states are the stable ones toward which an atom or molecule will normally gravitate. In Chapter 41 we'll see how quantum mechanics determines these energies precisely. Here we use the uncertainty relations to estimate the smallest possible energy of a particle under the influence of a given force.

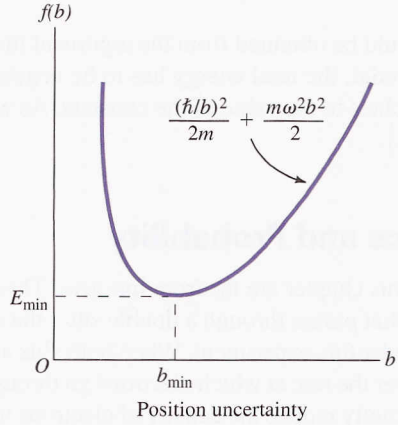
Consider a particle with a potential energy $U(x)$. We choose a coordinate system such that the minimum of the potential energy is located at $x = 0$, and we set the zero of the potential energy so that $U(0) = 0$. Because the total energy of the particle is given by $E = (p^2/2m) + U(x)$, the energy is lowest, $E = 0$, when both the kinetic energy and the potential energy are lowest; classically, this occurs for $p = 0$ and $x = 0$. However, quantum mechanics does not permit a perfect localization in both p and x. If we suppose that the particle is at $x = 0$ with an uncertainty Δx, then we impose an uncertainty in the momentum p of magnitude larger than $\hbar/\Delta x$. This means that p^2 can only be known to an accuracy $(\Delta p)^2 > (\hbar/\Delta x)^2$. Thus the energy is a function of Δx. We can find the value of Δx for which the energy has its lowest value, *but that minimum energy value cannot be zero.*

To understand how this works, take the example of a particle of mass m subject to the influence of a spring of spring constant k. The potential energy is $U(x) = m\omega^2x^2/2$, where $\omega = \sqrt{k/m}$ is the angular frequency of the classical motion. The particle's energy is

$$E = \frac{p^2}{2m} + \frac{m\omega^2x^2}{2}. \tag{40–14}$$

If the particle's position is known only to an accuracy $b(\Delta x = b)$, then the uncertainty in the momentum is $\Delta p > \hbar/b$. Thus the lowest value of the energy must obey the inequality

$$E > \frac{(\hbar/b)^2}{2m} + \frac{m\omega^2b^2}{2}. \tag{40–15}$$



The right-hand side of Eq. (40–15), which we call $f(b)$, is plotted in Fig. 40–18. We see that it has a minimum as a function of b. We find this minimum from the condition that the slope of $f(b)$ is zero at the minimum, $df/db = 0$:

$$\frac{df}{db} = \frac{-\hbar^2}{mb^3} + m\omega^2b = 0.$$

When we solve this equation for b^2, we find $b^2 = \hbar/m\omega$. Substituting this value into the expression for $f(b)$, we obtain the minimum value of $f(b)$. According to Eq. (40–15), this is the minimum value of E, or ground state energy:

$$E_{\text{min}} = \frac{\hbar^2}{2m(\hbar/m\omega)} + \frac{1}{2}m\omega^2\frac{\hbar}{m\omega} = \hbar\omega. \tag{40–16}$$

This estimate can be compared to a full quantum mechanical calculation, $E_{\text{min}} = \hbar\omega/2$. The minimum energy is never zero; the particle on the end of the spring can never be brought completely to rest. This is certainly a nonclassical result!

◀ **FIGURE 40–18** The right-hand side of Eq. (40–14), labeled $f(b)$, as a function of the position uncertainty b.

EXAMPLE 40–8 How would you use the position–momentum uncertainty relation to estimate the lowest energy of a particle of mass m in a one-dimensional box of width L?

Setting It Up What do we mean by saying the particle is in a box? We mean that there is a potential that confines the particle to the region from, say $x = 0$ to $x = L$, and leaves the particle free within that region. In effect, the potential is infinitely large outside the region $0 \leq x \leq L$.

Strategy This is another application of the technique described for the mass on the end of the spring. The energy consists of the purely kinetic term $p^2/2m$. This is as small as possible if the momentum itself as well as its uncertainty is as small as possible, making E_{min} take the form $\Delta p^2/2m$. But Δp is as small as possible according to uncertainty if Δx is as large as possible and this largest possible value is $\Delta x = L$—all we know about the particle is that it is *somewhere* in the box. In this case $\Delta p > \hbar/L$.

Working It Out $E_{\text{min}} = (\Delta p)^2/2m$, or

$$E_{\text{min}} = \hbar^2/2mL^2.$$

Note that this is an *estimate*. Had we used an expression for the uncertainty principle $\Delta x \Delta p_x > 2\hbar$, which is also acceptable, then E_{min} would have come out a factor 4 larger. The important result is that the energy is not zero. For comparison, the exact methods of quantum mechanics give for the ground state energy $E_{\text{min}} = \pi^2\hbar^2/2mL^2$. Note also that as the box becomes smaller, the particle is "squeezed" into a smaller and smaller space, and the minimum energy increases because in effect its minimum momentum is larger.

What Do You Think? Couldn't we have found this result by dimensional analysis?

If we accept the introduction of $\hbar$ into dimensional analysis of quantum mechanical energies, as in the "What do you think?" question for Example 40–8, then we can use dimensional analysis as another tool for estimating ground state (and other) energies. Consider as an example a hydrogen atom, an electron orbiting a proton. Classically, this system is like that of a planet that rotates around the Sun. The lowest classical energy of this system corresponds to an orbital radius of zero; the planet is directly on top of the Sun. The position–momentum uncertainty relation suggests that the configuration of minimum energy has a finite radius. The fact that there is a minimum energy is of paramount importance—it accounts for the stability of all atoms. Without this, electrons orbiting nuclei would radiate away energy and spiral into the nucleus.

To make a dimensional analysis of the hydrogen atom, we note that the parameters that enter into the problem are the electron mass m, the combination $e^2/4\pi\varepsilon_0$ (from Coulomb's law), and $\hbar$. (You might guess that the speed of light could also enter, but later analysis shows that the motion is basically nonrelativistic.) The dimensions of our three quantities are obtained as follows: Mass is dimension M. Since $e^2/(4\pi\varepsilon_0 R)$ is a potential energy, with dimensions ML^2T^{-2}, the dimensions of $e^2/4\pi\varepsilon_0$ are ML^3T^{-2}. Finally, the dimensions of $\hbar$ are energy/frequency; that is, ML^2T^{-1}. We now write the energy in the form

$$\begin{aligned} E &= m^a(e^2/4\pi\varepsilon_0)^b\hbar^c = M^a(ML^3T^{-2})^b(ML^2T^{-1})^c \\ &= M^{a+b+c}L^{3b+2c}T^{-2b-c}. \end{aligned}$$

Since this should have the dimensions ML^2T^{-2}, we require that $a + b + c = 1$, $3b + 2c = 2$, $-2b - c = -2$, and this gives $a = 1$, $b = 2$, $c = -2$, and dimensional analysis then gives

$$E = \text{constant} \times m\left(\frac{e^2}{4\pi\varepsilon_0\hbar}\right)^2.$$

The fact that the constant is negative could be obtained from the argument that since the electron is bound by the Coulomb potential, the total energy has to be negative. But dimensional analysis gives us no further clues to the value of the constant. As we shall see in Chapter 41, the constant is in fact $-\frac{1}{2}$.

40–4 Quantum Mechanics and Probability

The phenomena we have discussed in this chapter are far from intuitive. This is perhaps most pronounced for an electron beam that passes through a double slit—the experiment discussed in Section 40–3. Let's reconsider this experiment. When both slits are open, an interference pattern is produced, whatever the rate at which electrons go through the double-slit system. Suppose that we significantly reduce the density of electrons in the beam.

Then the interference pattern is built up by a one-by-one accumulation of electrons in regions of constructive interference, while no electrons accumulate in the regions of destructive interference. The arrival of any one electron is causally disconnected from the arrival of any other, so *each* electron must somehow carry information about the final interference pattern. Similarly, when we discussed using the uncertainty relation to reconcile particle and wave properties of photons going through a single slit, we said that the pattern would build up even if the photons came through spaced widely apart.

Quantum mechanics accounts for the double-slit experiment by assigning a **wave function** to the system. The wave function, which is a function of position, contains all the information about the diffraction pattern. The wave function (or strictly speaking, its square) at any given location on the screen is the *probability distribution function* for finding the electron at that location. The probability is largest where the magnitude of the wave function is largest. The probability that an electron will land on the screen where the waves from the two slits interfere destructively is very small; the probability for it landing where the interference is constructive is large. This implies that the outcome of the journey of any one electron is not determined; only the *probability* for a set of outcomes can be known.

An analogous situation arises when polarized light passes through an analyzer (see Chapter 35). If the polarizer makes a 45° angle with the polarization vector, then the intensity of the passed light is half that of the incident light. Classically, this is easy to understand—one component of a classical wave is blocked. But the classical description no longer works if light is formed from photons. Imagine an incident light intensity that is so low that the photons arrive one at a time. How will a particular photon "decide" whether to pass the analyzer or not? Remember that photons cannot be split into pieces that separately do different things. The resolution of this problem is that in quantum mechanics, a wave function describes the photon, the polarizer, and the analyzer, and with this wave function we can predict *only* that a given photon has a certain probability of passing the analyzer. We cannot predict whether or not a given photon will pass.

CONCEPTUAL EXAMPLE 40–9 Classical electromagnetic radiation can be polarized in directions perpendicular to the direction of propagation. Photons too can carry such polarization information. Consider photons propagating in the z-direction and passing through a polarizer arranged so that its axis is in the x-direction. As a result, all the photons that pass through the polarizer have polarization given by $\vec{e} = \hat{i}$. Let a second polarization screen—an analyzer—be placed so that its axis makes an angle θ with the x-axis. What will the polarization of one of our photons be after it passes the analyzer?

Answer As we discussed above, the probability of a single photon passing through the analyzer is $\cos^2\theta$. Just as a classical wave will have a polarization imposed by the analyzer, once the photon has passed through, it *must* have a polarization along the new axis. This polarization is $\vec{e} = \hat{i}\cos\theta + \hat{j}\sin\theta$. This is in fact confirmed by experiment. The passage through the analyzer has changed the *state* of the photon, another example of how a measurement affects the system being measured.

Example 40–9 leads to an interesting observation. Suppose the analyzer were at 90° to the axis of the polarizer. Then *no* photons would get through. If, however, we put an intermediate analyzer making an angle of 45° between the polarizer and the first analyzer, then the intermediate analyzer would pass 50 percent of the photons, and *then* the original analyzer would let 50 percent of those photons through. At the end, the photons that made it through (all 25 percent of them) will be polarized, along the y axis!

Saying that an electron has a certain probability to land at a certain spot on a screen, or that a photon has a certain probability to pass a polarizer, doesn't sound very much like Newtonian physics. Quantum mechanics is different from all other theories that we have studied so far in that it *does not make predictions about the outcome of single events. It makes predictions only about the probabilities of different outcomes.*

A particularly germane example of this type arises in nuclear radioactivity. Radioactivity occurs when a nucleus decays with the emission of, for example, an electron, an alpha particle (^{4}He nucleus), or a photon. Quantum theory predicts (and experiment confirms) that if we start with a certain number of radioactive nuclei N_0, then after a time t the number of nuclei left will be

$$N = N_0 e^{-t/\tau}. \tag{40–17}$$

The parameter τ has the dimensions of time and is called the *lifetime*, or *mean life*, of the radioactive nucleus. (If one knows enough about the decay mechanism, the lifetime can be calculated using quantum mechanical methods.) We see from Eq. (40–17) that after a time $t = \tau$, the number of nuclei that remains is $N_0 e^{-1}$, or about 0.37 N_0. Equivalently, the probability that a given nucleus will have decayed after a time $t = \tau$ is $1 - 0.37 \cong 0.67$. And here is what may surprise you: The value of τ is the same for a given undecayed nucleus once the particular nucleus is observed, whether the nucleus has just been artificially produced in the laboratory or has been sitting in a rock for a billion years. How does a given nucleus "know" when to decay? There is no evidence that the nucleus contains an internal clock that tells it when to decay. Because the quantum mechanical description of a single nucleus cannot contain information about what other nuclei are going to do, the only interpretation possible is that the *probability* that a nucleus will last a certain time t is part of the wave function of that nucleus, whereas a determination of precisely when that particular nucleus will decay is not.

It might appear superficially that this is no different from the problem of life expectancy in a population. There is some probability that 100-yr-old people exist in a population, but actuarial tables make no predictions for an individual. There is, however, a profound difference: People do have internal clocks, and an examination of the habits and jobs of individuals can give us more information about their life expectancy. With sufficiently detailed medical information, we could at least *in principle* make a prediction about a given lifetime. But nuclei do not age! If we start with a large initial sample of N_0 radioactive nuclei with lifetime τ, then after a time τ, there will be 0.37 N_0 nuclei left. This sample of surviving nuclei acts as a whole new sample of fresh nuclei, smaller in number, but in no way different from the ones in the initial sample. It will take an additional time τ for this new sample to be reduced to 0.37 times its initial number. This is very different from a human population. Once 100 years have passed with a certain number of people still alive, these people are not in effect reborn, and we can be quite sure that there will be none of them left after an additional 100 years have passed! This effect plays an important role in the applications of radioactivity to radiometric dating.

CONCEPTUAL EXAMPLE 40–10 You are given two samples of pure ^{235}U—one from an ancient cave, the other from a centrifuge used for separating different isotopes of uranium. There are equal numbers of nuclei in the two samples. The two samples get mixed up. Can you use radioactive decay to separate the "old" uranium from the "new" uranium?

Answer Both samples of uranium have the same decay rates. The decay rates are characteristic of the nucleus and its structure and do not depend on the history of the sample. If we currently have one milligram of each sample, the "old" one originally consisted of many more milligrams, but that is the only difference, and we cannot test for this by studying the current decay rate of the sample. One can easily imagine a sample embedded in ore from an ancient deposit—in this case an analysis of the decay products of ^{235}U that have been trapped within the ore sample would give us an idea of how old the sample is.

These concepts are far removed from what we would call "common sense." Remember, however, that common sense about the physical world is developed through observation, and there is no reason why the microscopic world should conform to what observation of the macroscopic world has established for us as sensible.

Summary

The phenomena that comprise quantum physics are most important in microscopic systems such as atoms, molecules, and nuclei. These phenomena are rather unintuitive, because our experience is based on classical physics. We have learned that what we think of as particles behave in some respects like waves, and what we think of as waves (electromagnetic radiation, for example) behave in some respects like particles. Quantum mechanics provides us with a unified explanation of all these phenomena.

When we look closely, we find that electromagnetic "waves" have particle properties. Electromagnetic radiation of frequency f behaves as though it consists of particles (photons) with energy

$$E = hf, \tag{40–1}$$

and momentum of magnitude

$$p = hf/c, \tag{40–2}$$

where $h = 6.63 \times 10^{-34}$ J · s is Planck's constant. Radiation exhibits its particle-like properties in the spectrum of blackbody radiation, in the photoelectric effect, in which electrons absorb incident photons and are ejected with specific energies from metals, and in the Compton effect, in which the wavelengths of photons scattered by electrons change in a manner dictated by the classical collisions of particles.

Just as electromagnetic radiation exhibits particle-like properties, a classical particle of momentum p has properties of a wave of de Broglie wavelength

$$\lambda = h/p. \tag{40–6}$$

The frequency associated with a particle can similarly be related to the particle's energy. The wavelike properties of particles include interference, which has been observed for particles such as electrons and neutrons in diffraction experiments, as well as in the phenomenon of tunneling. The wave properties of matter are not evident on a macroscopic scale because h is so small.

Quantum mechanics sets limits on the use of classical variables such as position and momentum. The Heisenberg uncertainty relations state that any attempt to specify the x-position with a precision Δx implies a limit with which the x-component of momentum can be measured,

$$\Delta x \, \Delta p_x > \hbar, \tag{40–12}$$

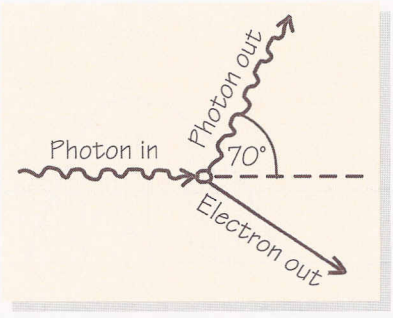
where $\hbar = h/2\pi = 1.05 \times 10^{-34}$ J · s. Similarly, there are limits on the precision of measurements of energy and time. An energy measurement is limited to a precision ΔE by the duration of time Δt that the measurement takes:

$$\Delta E \, \Delta t > \hbar. \tag{40–13}$$

These limitations are intrinsic to the quantum mechanical world, not improvable through the improvement of an experiment. They resolve potential inconsistencies between a simultaneous particle and wave description; for example, interference phenomena intrinsic to waves require a wave to be spread out in space and time, while particle-like properties demand that a particle have a definite, well-defined location. They are also useful in making estimates of ground state energies. In particular, a particle cannot be at rest at the minimum level of potential energy, so the lowest energy of a quantum system (the ground state energy) is always larger than what is expected by classical reasoning.

The difference between classical physics and quantum mechanics is most pronounced in the different types of predictions that can be made from each viewpoint. Classical physics makes direct cause-and-effect predictions of the consequences that follow from forces acting in different situations. Quantum mechanics, the paradigm that supercedes the classical picture, makes only predictions about the probabilities of different possible outcomes of a given dynamical situation.

Understanding the Concepts

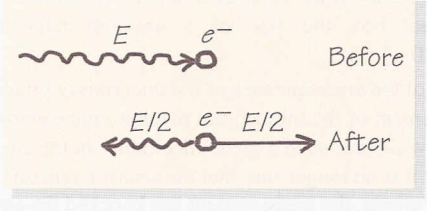


1. The shorter the wavelength of a photon, the more the photon behaves like a particle. Why?
2. The uncertainty relations provide a reason why the temperature $T = 0$ cannot be reached. What is that reason?
3. A lit cigarette can be seen at a distance of 500 m on a dark night. Outline how you would estimate the rate at which photons from the cigarette hit the retina of a night-adapted eye.
4. To probe very tiny regions of space (such as the inside of a proton) with electron beams, you need electron beams of very high energy. Why? Can you estimate the kind of energy needed to study a region of diameter d?
5. Given that electrons behave like waves, how is a Doppler shift described in terms of momentum?
6. Why do we use ^{14}C for radiometric dating—why not something more plentiful, such as ^{16}O or ^{208}Pb?
7. Suppose the charge on the electron were twice its value of 1.602×10^{-19} C. Would you expect the minimum frequency for the photoelectric effect to change? If so, why?
8. Before the Planck formula was discovered Rayleigh and Jeans had obtained the expression $u(f, T) = (8\pi f^2/c^3)kT$. How could we tell that something is wrong with this expression, even with no experimental data on the subject of blackbody radiation?
9. Suppose that half of a sample of radioactive nuclei has decayed in a given time T. How long will it be before half the remaining nuclei will have decayed?
10. You start with a large sample of radioactive nuclei; how much time will elapse before you can be sure that all the radioactivity has died away to zero?
11. The lifetime τ that measures the decay rate of a sample of radioactive particles is affected by the considerations of special relativity; that is, moving radioactive particles decay more slowly than stationary ones. How do the particles "know" that they are moving and that they should decay more slowly?
12. One electron is sent through a double-slit apparatus. In what sense, if any, can we say that there is an interference pattern on the screen?
13. Consider the one-dimensional box of length L treated in Example 40–8. Is there a connection between the ground state energy and the number of wavelengths of the particle that fit the box?
14. You don't have an X-ray machine in your lab, and you want to do an experiment on the Compton effect. Is there a difficulty with using ordinary light ($\lambda = 450$ nm, say) for your purposes?
15. Does the fact that all particles, however large, have wavelike properties mean that there is some probability that a baseball can tunnel through a catcher's mitt?

16. In discussing blackbody radiation, we spoke of a cavity. What does the cavity provide? Do we mean a real cavity in bulk material?
17. Do the uncertainty relations taken together imply that there are restrictions on the simultaneous measurement of position and time?
18. An electron microscope operates by the reflection of electrons, rather than by the reflection of light, from an object. Does the use of particles such as electrons eliminate the problems associated with diffraction through the viewing aperture of the microscope?
19. Some people claim that the conservation of energy principle can be violated. How might this happen in light of the Heisenberg uncertainty principle of Eq. (40–13)? Is it really a violation of the conservation of energy?
20. In the search for a site for the disposal of radioactive waste, a stringent requirement has been imposed, which is that the waste should not have a chance to leak out for at least 10,000 years. What do you think sets this age scale?
21. Does the fact that the speed of light is a definite, predictable quantity conflict with the uncertainty relations?
22. What increases the probability of tunneling the most: halving the energy difference between U and E or halving the barrier width?

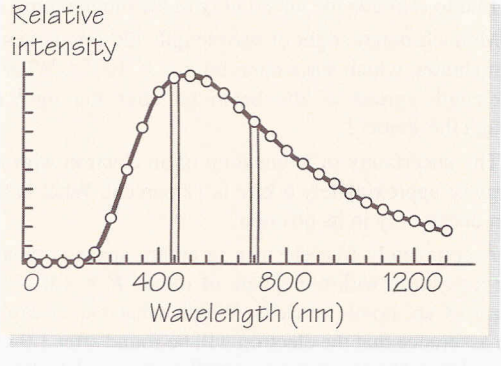
Problems

40–1 The Particle Nature of Radiation



1. (I) For what kinetic energy is the de Broglie wavelength of an electron equal to its Compton wavelength? Express your answer in units of $m_e c^2$ in doing the calculation, and then use $m_e c^2 = 0.5$ MeV.
2. (I) What are the energy and momentum of a photon in He-Ne laser light of wavelength 633 nm?
3. (I) Find the energy of a photon for each of the following cases: (a) a microwave of wavelength 1.5 cm: (b) red light of wavelength 660 nm; (c) a radio wave of frequency 96 MHz; (d) an X ray of wavelength 0.17 nm.
4. (I) Use the fact that the human eye can detect as few as 15 photons per second of red light to *estimate* the minimum power needed to trigger the optic nerve.
5. (I) The work function of cesium is 2.14 eV and that of iron is 4.31 eV. What is the largest wavelength of light that will produce photoelectrons from both of these materials? If you wanted to produce a photocell that operated with visible light, would either of these materials be useful?
6. (I) A light source at $\lambda = 600$ nm emits radiation at a rate of 0.01 W. How many photons per second are emitted by that source?
7. (I) Light of frequency 0.85×10^{15} Hz falls on a metal surface. If the maximum kinetic energy of the photoelectrons is 1.7 eV, what is the work function of the metal?
8. (I) The work function of sodium is 2.75 eV. What is the energy of electrons emitted in the photoelectric effect, if any, when light of wavelength 668 nm bombards sodium?
9. (I) Calculate the maximum wavelength for the initiation of a photoelectric current in the following elements: aluminum (work function $W = 4.28$ eV), cesium (2.14 eV), nickel (5.15 eV), and lead (4.25 eV).
10. (I) A metal has a work function of 1.6 eV. What is the maximum kinetic energy of a photoelectron if radiation of 450 nm wavelength falls on the surface?
11. (II) Estimate the energy of a photon of each of the following radiation types: (a) visible light; (b) X rays; (c) microwaves; (d) television signals; (e) AM radio.
12. (II) Calculate the number of photons from an FM radio station broadcasting at a frequency of 98 MHz that is required to equal the energy contained in one photon of visible light at a wavelength of 510 nm.
13. (II) The power generated by the Sun is 4.0×10^{26} W. Assuming that it is emitted entirely at an average wavelength of 500 nm, calculate the number of photons emitted per second.
14. (II) The energy density of electromagnetic radiation in some region of space is 3.2×10^{-8} J/m^3. Assume that the radiation has a wavelength 610 nm. What is the photon density?
15. (II) Show that the Planck distribution reduces to the classical Rayleigh–Jeans distribution for high temperatures.
16. (II) Derive the Compton effect formula (Eq. 40–5) by following the steps below:
    (a) Show that if the incident photon momentum is $\vec{p}$, the final photon momentum is $\vec{p}'$ and the electron momentum is $\vec{p}_e$, then momentum conservation implies that the magnitudes are related to the angular deflection of the outgoing photon θ by $p^2 - 2pp' \cos\theta + p'^2 = p_e^2$.
    (b) Show that energy conservation, $pc + m_e c^2 = p'c + \sqrt{m_e^2 c^4 + p_e^2 c^2}$, combined with the result of (a) leads to $2pp'(1 - \cos\theta) = 2mc(p - p')$. Then use the relation between the momentum and the wavelength.
17. (II) Use the fact that the human eye can pick up as few as 5 photons/s in the visible range to estimate the intensity of the dimmest star that can be detected by a night-adapted eye. What is the ratio of this intensity to the intensity of noon sunlight, some 1400 W/m^2? This large intensity range means that the eye is indeed a very adaptable instrument.
18. (II) Show that the total energy density in a cavity filled with blackbody radiation at temperature T in degrees kelvin—that is, of energy density $u(f, T)$, given by the Planck radiation law, Eq. (17–16)—is $U(T) = aT^4$. This result is the *Stefan–Boltzmann law*. Calculate the value of the constant a, given the integral
$$\int_0^\infty \frac{x^3}{e^x - 1}\,dx = \frac{\pi^4}{15}.$$
19. (II) Use the Stefan–Boltzmann law [see Eq. (17–14)] to calculate the temperature of the Sun, given that the Sun has a radius of 0.70×10^9 m, it is 1.5×10^{11} m from Earth, and the rate at which the total solar radiation reaches Earth is 1.36×10^3 J/m · s.
20. (II) The maximum energy of photoelectrons from aluminum is 2.3 eV for radiation of wavelength 200 nm and 0.90 eV for radiation of 216 nm. Use these data to calculate Planck's constant and the work function of aluminum.
21. (II) The threshold wavelength for the photoelectric effect in tungsten is 270 nm. Calculate the work function of tungsten, and calculate the maximum kinetic energy that a photoelectron can have when radiation of 120 nm falls on tungsten.
22. (II) A photon of energy 580×10^3 eV (580 keV) collides with an electron at rest. The photon is scattered through 70° (Fig. 40–19, see next page). What is its energy after the collision? What is the kinetic energy of the electron after the collision?

▲ **FIGURE 40–19** Problem 22.



23. (II) The wavelength of the incoming X rays in a Compton scattering experiment is 7.078×10^{-2} nm, and the wavelength of the outgoing X rays is 7.314×10^{-2} nm. At what angle was the scattered radiation measured?

24. (II) Consider a case of Compton scattering in which a photon collides with a free electron and scatters backward while it gives up half its energy to the electron (Fig. 40–20). (a) What are the frequency and energy of the incident photon? (b) What is the electron's velocity after the collision?

▲ **FIGURE 40–20** Problem 24.

25. (III) Consider a cavity that contains blackbody radiation at 6000°C. Calculate the energy density for radiation in the wavelength range 690 nm to 710 nm, and compare it with the energy density for radiation in the range 440 nm to 460 nm (Fig. 40–21). [*Hint*: To calculate energy density as a function of wavelength, use $u(f,T)\,df = u(f,T)\,d\lambda \times df/d\lambda$ and calculate the factor $df/d\lambda$. You must substitute $\lambda f = c$ in $u(f,T)$.]

▲ **FIGURE 40–21** Problem 25.

26. (III) The Sun's radiation peaks at a wavelength of 500 nm. How much less is the radiation intensity at 450 nm and at 550 nm? Use the approach of Problem 25.

27. (III) A consequence of the Stefan–Boltzmann law (see Problem 18) is that a blackbody at a temperature T emits radiation at a rate $P(T) = \sigma T^4$, where $\sigma = 5.68 \times 10^{-8}\ \mathrm{W/m^2 \cdot K^4}$. Suppose we have two large plates, one maintained at a temperature of 300K and the other at a temperature of 6000K, and that we place a small black plate in between these two. The fact that it is black implies that it absorbs all the radiant energy falling on its surface. Assuming that at equilibrium this plate emits as much energy as it absorbs, what temperature will it acquire on reaching equilibrium?

40–2 The Wave Nature of Matter

28. (I) What is the kinetic energy of an electron whose de Broglie wavelength is that of visible red light, 620 nm?

29. (I) What is the de Broglie wavelength of an electron whose kinetic energy is (a) 5.0 eV? (b) 50 eV? (c) 50,000 eV? (d) 5.0×10^8 eV? (e) What size targets would you need in order to observe diffraction of electrons of each of these wavelengths?

30. (I) What is the de Broglie wavelength of a proton (mass 1.7×10^{-27} kg) with kinetic energy (a) 1.0 MeV; (b) 10 MeV; (c) 300 MeV? Neglect relativistic effects.

31. (I) Ultracold neutrons can have speeds as low as 100 m/s. What is the de Broglie wavelength of such neutrons?

32. (I) The spacing between scattering planes in a crystal is 0.45 nm. What is the scattering angle from such a crystal with electrons of energy 22 eV for which a first maximum is observed?

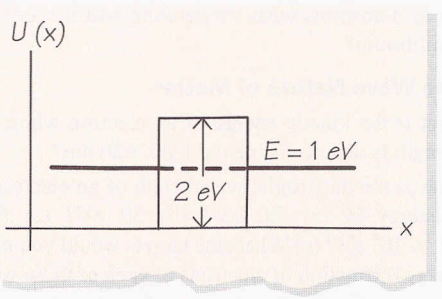
33. (I) Consider a crystal with a planar spacing of 0.074 nm. (a) What energies would electrons need for you to be able to observe up to four interference maxima? (b) Repeat the problem for neutrons.

34. (I) In a neutron two-slit diffraction experiment, the slits are 100 μm apart. If the third diffraction maximum is located at an angle of 2.0×10^{-7} rad, what is the kinetic energy of the neutrons?

35. (I) Express the de Broglie wavelength of a particle of mass m and kinetic energy E in terms of m and E. Suppose that the particle moves at a speed close to the speed of light. How is that relationship modified?

36. (I) You are thinking of testing de Broglie's conjecture by shooting raisins (m about 1 g) at a set of slits that are suitable for microwave interference experiments (λ about 1 cm). Accordingly you adjust the momenta of the raisins so that their wavelength is about 1 cm. Estimate the time it takes for a raisin to get from the raisin gun to the screen with the slits 1 m away from the gun.

37. (II) Suppose that you want to carry out diffraction experiments with the protons of Problem 30. What spacing of scatterers would you need in each of the three cases of energy 1.0 MeV, 10 MeV, and 300 MeV?

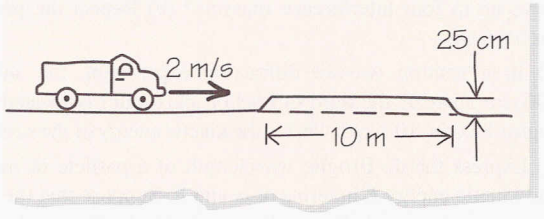


38. (II) What is the de Broglie wavelength of a neutron whose kinetic energy is equal to the average kinetic energy of a gas of neutrons of temperature $T = 85$K?

39. (II) Crystals are studied by means of electron and neutron diffraction as well as by X-ray diffraction. Recall that the typical interatomic distance in a crystal is 10^{-8} cm. Estimate the energy an electron must have to be useful for diffraction experiments on crystals. Repeat the exercise for neutrons.

40. (II) Although the working of an electron microscope does not depend on the wave nature of matter, the waves associated with electrons do set a limit on the resolving power of such instruments. (a) If the electrons in an electron microscope have a kinetic energy of 2.5×10^4 eV and the aperture of the microscope is 3.5×10^{-4} m, estimate the smallest angle that can be resolved.

(b) How much energy would electrons need so that two objects separated by 5 nm could be resolved? Give your answer in electron-volts.



41. (II) A beam of electrons with energy 1.0 eV approaches a potential barrier with $\langle U \rangle = 2.0$ eV, whose width is 0.10 nm (Fig. 40–22). Estimate the fraction of electrons that tunnel through the barrier.

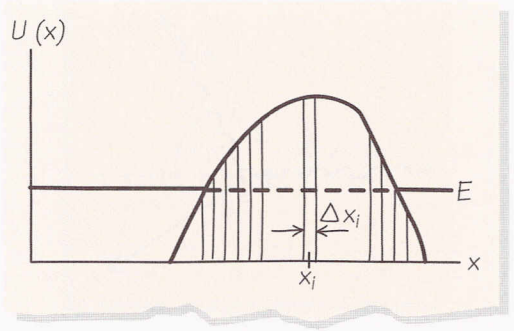
▲ FIGURE 40–22 Problem 41.

42. (II) Suppose that the barrier in Problem 41 is 0.25 nm thick. What fraction of electrons tunnel through the barrier?

43. (II) A truck of mass 3000 kg rolls, with its transmission in neutral, at 2.0 m/s and approaches a smooth bump whose average height is 25 cm and whose average width is 10 m (Fig. 40–23). Estimate the tunneling factor for the truck from Eq. (40–11).

▲ FIGURE 40–23 Problem 43.

44. (II) An electron in a semiconductor device is contained by a potential barrier of width 2.5 nm. The difference between the average potential energy and the energy of the electron is 1.4 eV. By what factor is the probability of tunneling changed if (a) the barrier width is halved? (b) The energy of the electron is increased by 1.2 eV? (c) The barrier width is halved and E is increased by 1.2 eV?



45. (III) The fraction F_n of particles of mass m and energy E that tunnel through a barrier whose potential energy is $U(x_n)$ and (minimal) thickness is Δx_n is given by Eq. (40–11).

$$F_n = e^{(-2/\hbar)\Delta x_n \sqrt{2m[U(x_n)-E]}}.$$

Suppose that a sequence of adjacent barriers at positions x_1, $x_2, \ldots$ have potential energy $U(x_1)$, $U(x_2), \ldots$ and thickness $\Delta x_1, \Delta x_2, \ldots$ respectively (Fig. 40–24). The fraction of particles that penetrate these barriers is given by the product of probabilities $F(x_1), F(x_2), \ldots$ that the particle can penetrate the individual barriers independently, namely $F = F(x_1)F(x_2), \ldots$ Show that in the limit that each barrier is infinitesimally thin, we get

$$e^{(-2/\hbar)\int dx \sqrt{2m[U(x_n)-E]}}$$

for the fraction of particles that penetrate the barrier. Note that Eq. (40–11) is an approximation to this result.

▲ FIGURE 40–24 Problem 45.

40–3 The Heisenberg Uncertainty Relations

46. (I) An electron is localized inside a cubic region of sides 1.5 nm. What is the uncertainty in its kinetic energy?

47. You are given a detector that can time the arrival of a particle to within an accuracy of 10^{-15} s. What is the accuracy of the energy determination possible with such a detector?

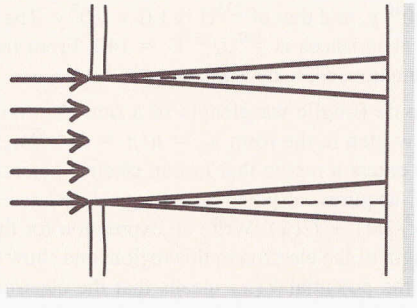
48. (I) The speed of an electron emitted from an atom is measured to a precision of ± 0.08 cm/s. What is the smallest uncertainty possible in the electron's position?

49. (I) Estimate the lowest energy of a neutron confined in a one-dimensional box the size of a uranium nucleus (diameter 1.5×10^{-14} m).

50. (I) One of the consequences of the uncertainty principle is that a measurement of the momentum of an atomic electron that is too precise will force such a great uncertainty in the electron's position that it is no longer sure that the electron remains in the atom. In other words, the measurement has knocked the electron out of the atom. Estimate that precision. Compare your estimate of Δp with the typical momentum of an atomic electron, which corresponds to a kinetic energy on the order of 27 eV.

51. (I) A proton in a tin nucleus is known to lie within a sphere whose diameter is about 1.2×10^{-14} m. What are the uncertainties in the momentum and kinetic energy of the proton?

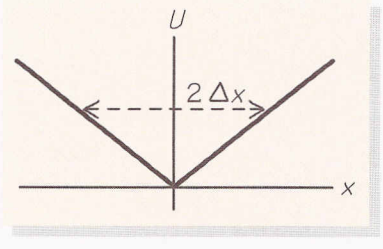
52. (I) One measure of the uncertainty in the position of a particle in a simple harmonic oscillator is to set that uncertainty equal to the amplitude of the motion. In turn, we find the amplitude by writing the energy in terms of the classical amplitude $E = m^2\omega^2 A^2/2$ and setting E equal to $n\hbar\omega$. Use the amplitude you find to *estimate* the uncertainty in the momentum.



53. (II) Monochromatic light of wavelength 720 nm passes through a fast shutter, which stays open for 1.0×10^{-9} s. What will the wavelength spread of the beam be after the light emerges through the shutter?

54. (II) The uncertainty in momentum of an electron with a kinetic energy of approximately 6 keV is 12 percent. What is the minimum uncertainty in its position?

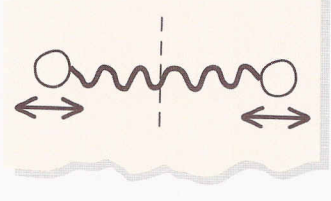
55. (II) A completely free electron in empty space is measured to have a position within a sphere of radius $R = 1.0 \times 10^{-14}$ m, typical of an atomic nucleus. Within what radius can you say with assurance that the electron will be found after 1.0 s? Repeat the problem for an electron initially measured to lie within a sphere of radius $R = 1.0 \times 10^{-10}$ m, the radius of an atom.



56. (II) A radar gun measures the speed of a projectile, mass 28 g, to be 450 mi/h, to an accuracy of 0.5 percent. How well can the position of the projectile be determined in principle? Such accuracy cannot be achieved in practice.

57. (II) A wide beam of electrons of momentum p impinges on a slit of width a. Classically, the width of the beam of electrons passing through the slit and impinging on a screen that is a distance D from the slit would be a (Fig. 40–25). Even if we continue to treat electrons as particles, quantum effects operating through the uncertainty principle will modify this result. Using the uncertainty relations, find the spread of the beam on the screen. For what value of a will the width of the beam be a minimum?

▲ FIGURE 40–25 Problem 57.

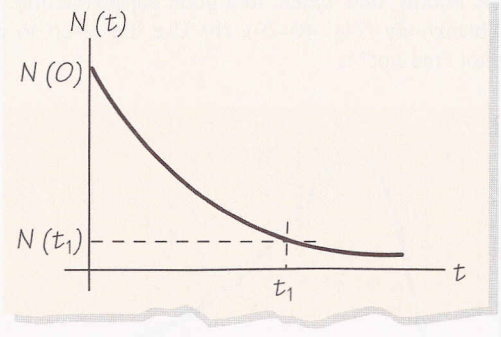


58. (II) Consider a particle of mass m with potential energy of the form $U = -U_0(x/a)$ for $x < 0$ and $U = +U_0(x/a)$ for $x > 0$ (Fig. 40–26). Use the uncertainty relations to estimate the lowest energy the particle can have.

▲ FIGURE 40–26 Problem 58.

59. (II) A neutron, mass $m = 1.6 \times 10^{-27}$ kg, is localized inside a carbon nucleus, of radius 6.0 fm (1 fm $\equiv 10^{-15}$ m). Use the uncertainty relations to calculate a minimum (negative) potential energy for neutrons inside heavy nuclei.

60. (II) A hydrogen molecule can be modeled as a dumbbell in which the two masses—the hydrogen atoms—are connected by a spring whose unextended length is 0.074 nm (Fig. 40–27). The hydrogen molecule can vibrate along its axis with frequency 1.32×10^{14} Hz. (a) Calculate the minimum energy of this vibration. (b) A deuterium molecule D_2 differs from the picture we describe only in the masses of the atoms, which are twice that of hydrogen. Estimate the vibration frequency and zero point energy of the deuterium molecule.



▲ FIGURE 40–27 Problem 60.

40–4 Quantum Mechanics and Probability

61. (I) A beam of light is sent along the $+z$-axis through a polarizer so that it is polarized in the direction of the $+x$-axis. This beam impinges on a second polarizer that makes a 55° angle with the x-axis. What is the probability that a photon will get through the second polarizer?

62. (I) The number of atoms in an excited state whose mean lifetime for single-photon decay is τ is given by $N(t) = N(0)e^{-t/\tau}$. What is the number of photons emitted per second?

63. (II) The half-life of ^{14}C is about 5730 yr (see Problem 64). Organisms accumulate this isotope from the atmosphere while they live but cease doing so upon dying. The skeleton of a mammoth is found to have a concentration of ^{14}C that is 15 percent of the atmospheric value (Fig. 40–28). When did the mammoth live? Assume that the concentration of atmospheric ^{14}C does not change.

▲ FIGURE 40–28 Problem 63.

64. (II) The *half-life* of a set of radioactive nuclei is the time in which half of the nuclei decay. Express the half-life in terms of the lifetime, τ, that appears in Eq. (40–17).

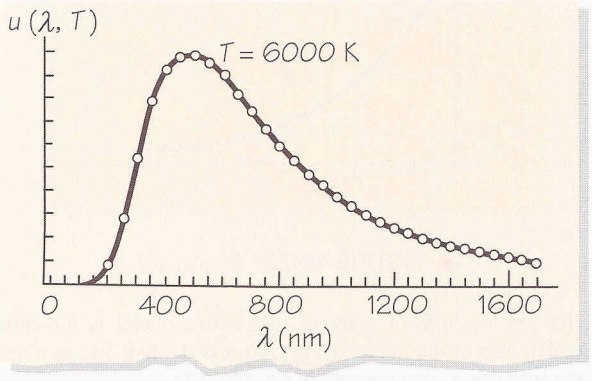
65. (II) Equation (40–17) may be written in the form $dN = -(N/\tau)\,dt$. Interpret this equation, including the sign. Does your interpretation support the assertion that the decay of any one radioactive nucleus is unaffected by the presence of others?

66. (II) Volcanic eruptions can be dated by analyzing the potassium and argon contents of rocks from the eruption. Most rocks contain potassium (K), 0.012 percent of which is ^{40}K, a radioactive isotope that decays to ^{40}Ar (argon) with a half-life of 1.3×10^9 years. Since argon is an inert gas, it is likely that all of the argon in the rock originates from the decay of ^{40}K. Suppose that a test of a rock shows that the ratio of the number of non-decayed ^{40}K and ^{40}Ar isotopes is found to be 24 : 1. When did the eruption happen?

67. (II) What is the activity of 1 g of ^{232}Th (thorium), whose lifetime is 1.4×10^{10} y? (See Problem 68.)

68. (II) A sample of radioactive material undergoing 3.7×10^{10} disintegrations/s is said to have an activity of 1 *curie* (Ci), where the activity is the rate at which decays occur. The activity of 1 g of Ra (radium) is 1 Ci. Given that $A = 226$ for radium, estimate the lifetime of ^{226}Ra.

General Problems



69. (I) What is the fractional energy loss of a photon in the Compton effect for a scattering angle of 60°, given an initial photon energy 2×10^3 eV?

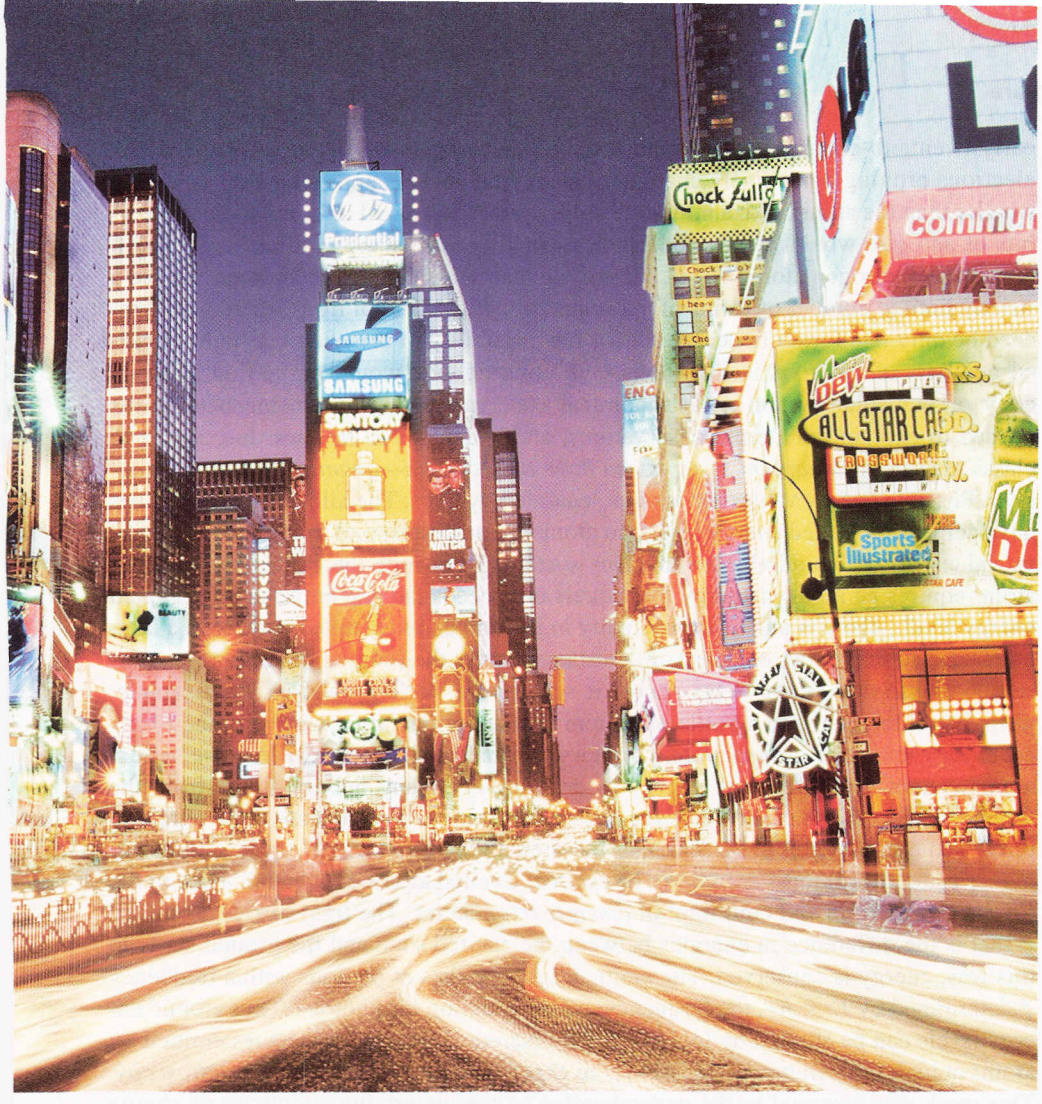
70. (II) When high resolution is needed in biological microscopy, electron microscopes rather than light microscopes are used. Compare the resolution limit of an electron microscope that uses electrons of energy 12 keV with that of a light microscope.

71. (II) Find the average de Broglie wavelength of a gas of nitrogen molecules (each of mass 4.7×10^{-26} kg) at a temperature of 300K. Assume that the gas is ideal and is at 1 atm of pressure. Calculate the interatomic spacing. What would the temperature have to be for the same amount of nitrogen gas in the same volume to have a de Broglie wavelength equal to the interatomic spacing?

72. (II) *Estimate* the rate at which photons in the visible range are emitted by a flashlight. Assume that 50 percent of the energy is emitted in the visible range and that the average wavelength in this range is 550 nm.

73. (II) It is a consequence of the Planck radiation law that the energy density expressed as a function of wavelength and temperature, $u(\lambda, T)$, peaks at $\lambda = \lambda_{max}$, where $\lambda_{max} = 2.9 \times 10^{-3}\ (\text{m} \cdot \text{K})/T$, and T is the absolute temperature (see Problem 25). (a) Use this result to calculate λ_{max} for the radiation emitted by the Sun, whose surface temperature is approximately 6000K, and which, to a good approximation, radiates as a blackbody (Fig. 40–29). (b) Use the result to estimate how hot "red-hot" is.

▲ **FIGURE 40–29** Problem 73.



74. (II) Show that, in the simple process of photon absorption by a free electron, without anything else occurring, energy and momentum cannot be conserved simultaneously.

75. (III) A tungsten block contains a microcrack of width 1 nm. What is the probability that an electron will tunnel from one side of the crack to the other, if the work function of tungsten is 4.6 eV?

76. (III) The abundances of ^{238}U and ^{235}U are assumed to have been equal when Earth formed. The mean life of ^{238}U is 0.6×10^{10} y, and that of ^{235}U is 1.0×10^{9} y. The present ratio of their abundances is $^{238}\text{U}/^{235}\text{U} = 140$. From these data and the assumption, estimate Earth's age.

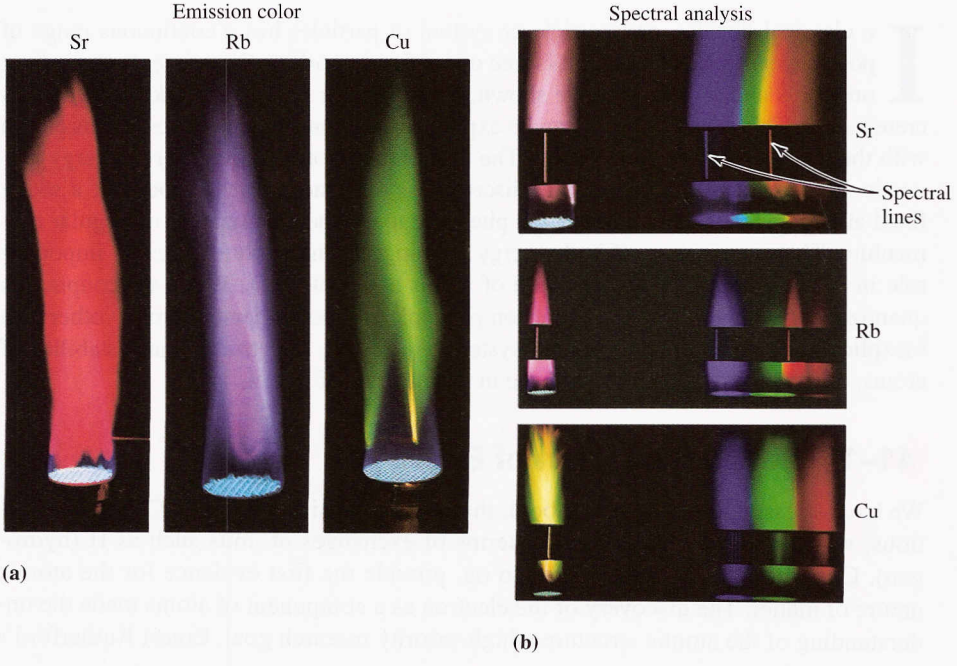
77. (III) The de Broglie wavelength of a free electron of energy E may be written in the form $\lambda_0 = h/p = h/\sqrt{2m_eE}$. When the electron enters a region that has an electric potential $V(x)$, the electron acquires a potential energy $U(x) = -eV(x)$, and $E = (p^2/2m) + U(x)$. Write an expression for the de Broglie wavelength of the electron in this region, and show that the presence of the potential $V(x)$ means that the electron behaves as though it were moving in a region of refractive index $n(x) = \sqrt{[E - U(x)]/E}$.

78. (III) A copper crystal emits 8.3×10^{10} photoelectrons/m$^2 \cdot$s. Given that the atomic weight of copper is $A = 64$ and the mass density of the crystal is 8900 kg/m^3, and assuming that the photoelectrons are supplied by the five layers of copper atoms nearest the surface of the crystal, how many atoms, on average, furnish one photoelectron/s? Assume that the atoms form a cubic lattice.

Chapter 41

◀ The light emitted by the various sources in this picture have colors that are associated with electromagnetic radiation of various wavelengths. These wavelengths are emitted by different species of atoms in characteristic patterns that depend among other things on the energy levels of those atoms.

Atomic and Molecular Structure



In classical physics, any particle or system of particles has a continuous range of possible energies—whether it is free or confined to orbits. Experiments carried out on atoms and molecules have shown, however, that energy can take on only discrete values. This surprising fact can be explained by quantum mechanics and has to do with the wavelike behavior of matter. The discreteness (or quantization) of energy values is mathematically similar to the discreteness of standing-wave modes of a string fixed at two ends. Another unexpected phenomenon is the quantization of angular momentum. The quantization of both energy and angular momentum plays an important role in the description of the structure of atoms and molecules. When we couple this quantization with the so-called exclusion principle, we can understand many otherwise inexplicable features of microscopic systems, including the structure and stability of atoms, of molecules, and as we will see in Chapter 44, of nuclei.

41–1 The Quantization of Energy

We have stressed throughout this book that matter consists of atoms. Chemical reactions, which could be understood in terms of exchanges of units such as H (hydrogen), C (carbon), N (nitrogen), and so on, provide the first evidence for the atomic nature of matter. The discovery of the electron as a component of atoms made the understanding of the atomic structure a high-priority research goal. Ernest Rutherford's

early-twentieth-century experiments revealed an atom made of negatively charged electrons orbiting a positively charged nucleus (the nucleus approximately 10^5 times smaller than the atom), like a miniature solar system; elliptical or circular electron orbits of any size would be allowed. Such variability is in sharp conflict with experiment. One hydrogen atom (^{1}H) is, *literally*, indistinguishable from another. We see a strictly limited number of forms of hydrogen, of helium, and of iron—there would indeed be only one form of each, if not for the possibility of differing but highly limited numbers of neutrons in the nucleus. In contrast, one would never find an exact copy of our solar system in astronomical observations. Quantum mechanics was needed to explain the atomic observations, and it did this as follows: In contrast to classical systems, *quantum systems can have only certain—quantized—values of energy*. Possible energy values are always separated by gaps. The allowed energy values have come to be called *energy levels*. In atoms, these correspond to the possible energy values of the bound electron-nucleus system. To change the configuration of an atom requires an input of energy that equals or exceeds the gap between an *occupied* energy level—there is an electron actually in it—and an unoccupied level with a larger energy, so that under ordinary circumstances, only the (unique) configuration corresponding to this *ground-level energy* is seen in the world around us. For example, virtually all the atoms in a bottle of helium at room temperature will be in their lowest energy level, the *ground state*. Ordinary thermal collisions between these helium atoms cannot supply enough energy to change very many helium atoms from the ground state to the next allowed state (an *excited state*). At sufficiently high temperatures, some non-negligible fraction of the atoms may be "kicked" up into the next, higher state; these atoms are said to be *excited*. Excited atoms can "jump" back to the lowest energy level and emit light of *discrete frequencies*. The light carries an energy E that is the difference in energies between the excited state and the ground state. In this way, energy is conserved. The emitted light consists of photons with a frequency f determined by $E = hf$, the frequency–energy relation for photons. Thus atomic energy levels can be studied by looking at the discrete radiation frequencies emitted by atoms at high temperatures (Fig. 41–1), an experimental field known as *spectroscopy*. This work was essential to the understanding of the underlying simplicity of atomic structure.

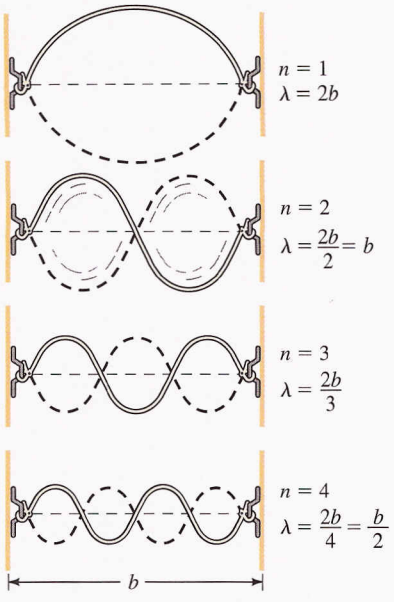
We should emphasize that the energies of all microscopic systems, including molecules, nuclei, and—as far as we understand their structure—elementary particles, are known to be quantized.

▶ **FIGURE 41–1** (a) The color emitted by atoms after they have been excited by heat is characteristic of the particular element they comprise: strontium, rubidium, and copper. (b) When the color of each element in part (a) is analyzed spectrally, it is seen to contain discrete frequencies (lines).

The Wave Nature of Matter and Energy Quantization

The wave properties of matter suggest how energy quantization might come about. Let's consider a particle confined to a one-dimensional box of length b. If the particle inside the box behaves like a standing wave on a string of length b that is fixed at its ends, then the wavelengths are constrained by the condition

$$\lambda = \frac{2b}{n}$$



[Eq. (14–8)], where $n = 1, 2, 3, \ldots$ (Fig. 41–2). The wavelength is related to the momentum p by the de Broglie relation, $\lambda = h/p$ (Eq. 40–6), so the particle's momentum has the form

$$p = \frac{nh}{2b}.$$

The energy of the particle in the box then takes on only the discrete values

$$E = \frac{p^2}{2m} = \frac{n^2h^2}{8mb^2}. \tag{41–1}$$

This expression gives us both the ground-state energy ($n = 1$) and the gaps between the allowed energies. Our more precise calculation improves the estimate we made in Chapter 40 with the help of the position–momentum uncertainty relation (see Example 40–8).

▲ **FIGURE 41–2** The wavelengths of standing waves on a string fixed at both ends are given by the length of the string divided by half-integers.

The Bohr Model of Hydrogen

In the description above, the key step is the de Broglie relation, which links intrinsically wavelike properties, including the quantization of standing waves, to the behavior of particles. But in 1913, more than a decade before de Broglie's deep insight, Niels Bohr (Fig. 41–3) daringly proposed a set of postulates to cure the difficulties of the Rutherford model of the atom. Although these postulates violated the laws of classical physics, they proved very successful in explaining many details of atomic structure.

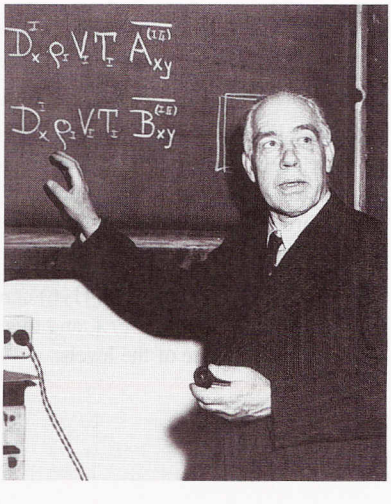
We start with a classical description of the hydrogen atom, consisting of one electron of mass m_e and charge $-e$, and a nucleus that usually consists of a single proton,[†] of mass $m_p \gg m_e$ and charge $+e$. The classical configuration is that of the electron in circular (or elliptical) orbits with the proton at the center (or a focus), in analogy to planetary orbits (Chapter 12). For a circular orbit of radius r, Newton's second law, $F = ma$, becomes

$$\frac{e^2}{4\pi\varepsilon_0 r^2} = m_e a = \frac{m_e v^2}{r}. \tag{41–2}$$

The left side of this equation is the Coulomb force. The total energy is

$$E = K + U = \frac{p^2}{2m_e} - \frac{e^2}{4\pi\varepsilon_0 r}, \tag{41–3}$$

where zero potential energy has been chosen to be at $r = \infty$. Newton's second law, Eq. (41–2), implies that



$$\frac{p^2}{2m_e} = \frac{1}{2}m_e v^2 = \frac{e^2}{8\pi\varepsilon_0 r}.$$

When this result is inserted into Eq. (41–3), we find

$$E = \frac{e^2}{8\pi\varepsilon_0 r} - \frac{e^2}{4\pi\varepsilon_0 r} = -\frac{e^2}{8\pi\varepsilon_0 r}. \tag{41–4}$$

The energy is negative, as we would expect.

[†]Deuterium is hydrogen-like in that it only has one electron, but the nucleus consists of a proton and a neutron; tritium has a nucleus consisting of one proton and two neutrons.

▲ **FIGURE 41–3** Niels Bohr.

So far all of this is classical, and because of that the model as it stands has a fatal flaw. A charge moving in a circular orbit has a constant acceleration, and we saw in Chapter 35 that an accelerating charge radiates energy. Consequently, an orbiting electron would steadily lose energy by radiation; as it did so, the radius would decrease [see Eq. (41–4)] until the proton swallowed up the electron. Detailed estimates (see Problem 18) show that this would happen in only 10^{-10} s!

To fix the flaw, Bohr incorporated an energy quantization condition. Here are the assumptions Bohr made:

1. The classical orbits, whose parameters can take on any values, are replaced by *stationary states*, so called because the energies of those states are fixed, and hence electrons in these states cannot radiate classically. The energies of these stationary states take on only discrete values.
2. The energy values of stationary states are determined by a well-defined set of rules. For circular orbits, the rules reduce to the condition that the angular momentum, $L = mvr$, is quantized in integer units of $\hbar$:

$$L = n\hbar, \quad \text{where } n = 1,2,3,\ldots. \tag{41–5}$$

BOHR QUANTIZATION CONDITION

The integer n is the *principal quantum number* for the orbit. Equation (41–5) is called the *Bohr quantization condition*.

3. Atomic electrons can make transitions (jumps) from one allowed level with an initial energy E_i to another allowed level with a final energy E_f. When $E_i > E_f$, energy is released. The released energy can manifest itself in the appearance of a photon that carries off the excess energy $E_i - E_f$. Because a photon of energy E has frequency f given by $E = hf$, the frequency of the emitted photon is determined by

$$hf = E_i - E_f. \tag{41–6}$$

POSSIBLE ATOMIC EMISSION FREQUENCIES

An electron in an excited state, a state with energy above the ground-state energy, will undergo a *spontaneous* transition to a lower state. An electron can also make a transition to a higher energy state, but to do so it must absorb energy. This may be provided by collisions or by the absorption of a photon. In the latter case the transition is said to be *induced*. The Bohr theory made no predictions about when the transition would take place, and it explicitly ruled out the possibility of catching an electron in the middle of a transition.

EXAMPLE 41–1 A certain laser radiates with a wavelength of 3390 nm. What is the energy difference, in electron volts, between the two energy levels involved in producing this light?

Setting It Up Although we don't know the actual energy values of the levels involved in the transition, Bohr's third postulate, Eq. (41–6), brings in only the energy difference of these levels, and that is directly related to the frequency, and hence to the wavelength of the radiation emitted.

Strategy The use of Eq. (41–6) can be rewritten in terms of the wavelength by using $f = c/\lambda$, and this expression then gives us the the energy difference of the levels.

Working It Out We have immediately

$$\Delta E = hf = \frac{hc}{\lambda} = \frac{(6.63 \times 10^{-34}\ \text{J}\cdot\text{s})(3.00 \times 10^{8}\ \text{m/s})}{(3390 \times 10^{-9}\ \text{m})(1.60 \times 10^{-19}\ \text{J/eV})}$$
$$= 0.367\ \text{eV}.$$

What Do You Think? Suppose light is emitted in two steps: first a transition from E_{initial} to $E_{\text{intermediate}}$ and then a transition from $E_{\text{intermediate}}$ to E_{final}, with $E_{\text{intermediate}}$ lying between E_{initial} and E_{final}. Are the wavelengths of the light emitted greater than, less than, or equal to 3390 nm? *Answers to **What Do You Think?** questions are given in the back of the book.*

To see how the Bohr quantization condition determines the energy values, we start with Newton's second law $\vec{F} = m\vec{a}$, which for an electron in a circular orbit of radius r reads $\dfrac{e^2}{4\pi\varepsilon_0 r^2} = m\dfrac{v^2}{r}$. (A unit vector pointing to the center has been dropped here.)

When we multiply this equation by $m_e r^3$, we find

$$m_e(e^2/4\pi\varepsilon_0)r = m_e^2 v^2 r^2 = L^2. \tag{41–7}$$

We have recognized that the right side of this equation is the square of the electron's angular momentum, so that *for circular orbits* the Bohr condition yields $m_e(e^2/4\pi\varepsilon_0)r = n^2\hbar^2$. We can solve this for r to find the allowed values of the orbit radius:

$$r_n = \frac{n^2\hbar^2}{m_e e^2/4\pi\varepsilon_0} = n^2 a_0, \tag{41–8}$$

where the *Bohr radius* a_0 is the radius corresponding to $n = 1$:

$$a_0 = \frac{\hbar^2}{m_e e^2/4\pi\varepsilon_0} = 0.53 \times 10^{-10}\ \text{m}. \tag{41–9}$$

The allowed radii are discrete, with an index n corresponding to the quantum number n for L.

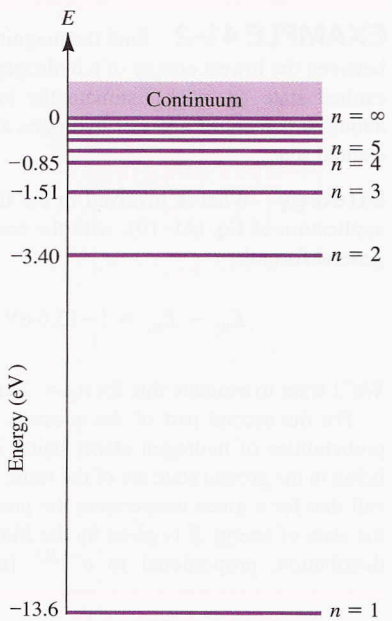
Once the radii can take on only certain discrete values, Eq. (41–4) shows that the energy also has certain discrete values. When the allowed values of r from Eq. (41–8) are inserted into Eq. (41–4) for the energy, we obtain the allowed energy values of a hydrogen atom in the Bohr model:

$$\begin{aligned} E_n &= -\frac{e^2}{8\pi\varepsilon_0 r_n} = -\frac{e^2}{8\pi\varepsilon_0}\frac{1}{[(n^2\hbar^2)/(m_e e^2/4\pi\varepsilon_0)]} \\ &= -\frac{m_e}{2n^2}\left(\frac{e^2}{4\pi\varepsilon_0\hbar}\right)^2 = -\frac{21.8 \times 10^{-19}\ \text{J}}{n^2} = -\frac{13.6\ \text{eV}}{n^2}. \end{aligned} \tag{41–10}$$

The ground-state energy ($n = 1$) is $E_1 = -13.6$ eV.

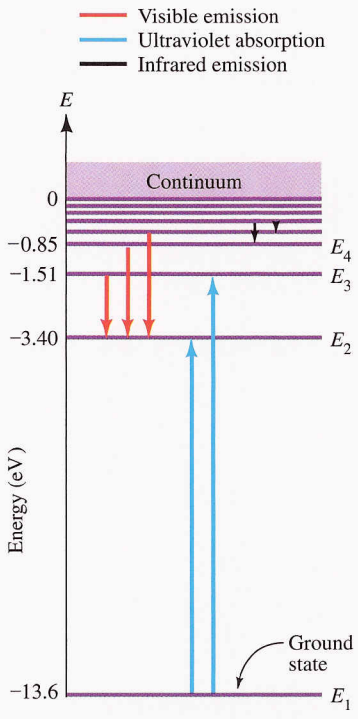
Figure 41–4 illustrates the energy values predicted by Eq. (41–10). The excited-state energies get closer and closer together as n increases, and the energy approaches zero as $n \to \infty$. Positive energies correspond to the situation in which the electron is not bound to the proton. There the energy can take on continuous values because the electron can have any kinetic energy, even though it still feels an attractive force due to the positive nucleus. The minimum energy required to remove an electron in the ground state from the atom is called the *ionization energy*. For hydrogen, this energy is $(0\ \text{eV}) - (-13.6\ \text{eV}) = 13.6\ \text{eV}$.

We can show by analogy with our discussion of the energy quantization in a one-dimensional box that the Bohr condition emerges from the fitting of de Broglie waves into circular orbits. The circumference of a circular orbit is $2\pi r$, and we would require that n de Broglie wavelengths fit into this length. This is a condition that sets allowed discrete radii: $2\pi r_n = n\lambda$, where λ is the de Broglie wavelength, or



$$\frac{2\pi r_n}{\lambda} = n. \tag{41–11}$$

But the wavelength itself should have an index n, because it is given generally by $\lambda = h/p$, and for a given orbit radius r_n the momentum is determined, $p = p_n$. Thus Eq. (41–11) takes the form



$$\frac{2\pi r_n}{h/p_n} = \frac{r_n p_n}{h/2\pi} = \frac{L}{\hbar} = n,$$

which is identical to Eq. (41–5).

This result was noted by de Broglie in his original work. We should stress, however, that the Bohr approach is much more closely related to what quantum mechanics ultimately says about atoms, as we shall see in Section 41–2.

▲ **FIGURE 41–4** The energy levels in a hydrogen atom for circular orbits in the Bohr model, obtained from Eq. (41–9). The energy levels (here, not to scale) bunch up as the quantum number n increases. Above the ionization point $E = 0$, the electron and the proton are no longer bound together.

▲ **FIGURE 41–5** An atomic electron may jump down from one level to another with the emission of a photon or jump up with the absorption of a photon. The frequency of the photon is determined by the energy change.

Emission and Absorption of Photons from Atoms

Bohr's approach gave a concrete rule for the frequencies of the light, or more generally the electromagnetic radiation, emitted by atoms, namely Eq. (41–6). Because of how they appear in a spectrographic separation, one refers to these discrete frequencies as *lines*. In the special case of hydrogen, we have a formula for the possible values of the electron energies, and thus the predictions of the theory are tested experimentally by the observation of the light frequencies that hydrogen atoms emit after they have been excited (see Fig. 41–5).

For hydrogen, the possible energies E_i and E_f are given by Eq. (41–10). We may rewrite Eq. (41–11) in terms of the wavelength λ rather than the frequency by using the relation $f = c/\lambda$. Then the wavelengths of the photons emitted when an electron jumps down from an initial excited state to a lower-energy final state ($E_i > E_f$) are restricted to the values

$$\frac{1}{\lambda} = \frac{E_i - E_f}{hc} = -R_\infty\left(\frac{1}{n_i^2} - \frac{1}{n_f^2}\right), \tag{41–12}$$

where n_i and n_f are the quantum numbers of the initial and final energies, respectively, and $R_\infty \equiv (m_e/2hc)(e^2/4\pi\varepsilon_0\hbar)^2 = 1.0974 \times 10^7\ \text{m}^{-1}$ is the *Rydberg constant*, named for the spectroscopist Johannes Rydberg. Note the sign: With $n_i > n_f$ this expression is properly positive. The predicted wavelengths are in good agreement with the measured wavelengths of the spectral lines of hydrogen. In fact, by 1885 Johannes Balmer had already made a purely empirical fit to the four frequencies of the emission spectrum of hydrogen known at the time, using a formula like that of Eq. (41–12). In Bohr's time, frequencies corresponding to many values of n_f and $n_i (n_f > n_i)$ could be closely approximated by this formula, and new frequencies were correctly predicted on its basis. Bohr was on the right track.

EXAMPLE 41–2 Find the magnitude of the energy difference between the lowest energy of a hydrogen atom ($n = 1$) and the first excited state ($n = 2$). Estimate the lowest temperature at which about 20 percent of a gas of hydrogen atoms would occupy the first excited state.

Strategy What is involved in the first part is a straightforward application of Eq. (41–10), with the energy difference given by the general formula

$$E_{n_2} - E_{n_1} = (-13.6\ \text{eV})\left(\frac{1}{n_2^2} - \frac{1}{n_1^2}\right).$$

We'll want to evaluate this for $n_2 = 2$ and $n_1 = 1$.

For the second part of the question, we require that the relative probabilities of hydrogen atoms being in the first excited state and being in the ground state are of the same order of magnitude. If we recall that for a given temperature the probability for finding atoms in the state of energy E is given by the Maxwell-Boltzmann probability distribution, proportional to $e^{-E/kT}$ [see Eq. (19–35)], then our requirement is that the ratio $e^{-E_2/kT}/e^{-E_1/kT} = e^{-(E_2-E_1)/kT} = e^{-\Delta E/kT}$ should be of the order of (20 percent)/(80 percent) = 0.25. In making this estimate we ignore excitations to higher levels. For conversion purposes we note that 1 eV is equivalent to roughly 1.2×10^4 K of temperature.

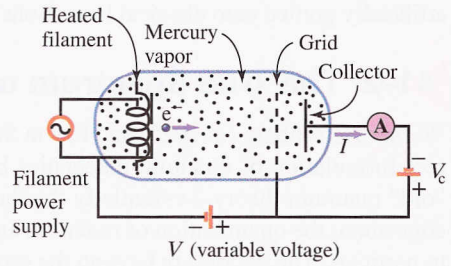
Working It Out For the first part we evaluate

$$E_2 - E_1 = E_1\left[\frac{1}{(2)^2} - \frac{1}{(1)^2}\right] = (-13.6\ \text{eV})\left(\frac{1}{4} - 1\right)$$
$$= 10.2\ \text{eV}.$$

For the second part we want $\exp(-\Delta E/kT) = 0.25$. Taking the natural log of both sides and using $\ln(0.25) = -1.4$, we solve for kT:

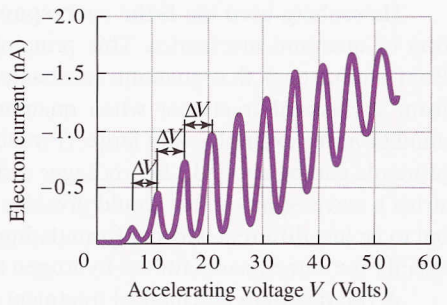
$$kT = (10.2\ \text{eV})/(1.4) \cong 7.3\ \text{eV}, \quad \text{or} \quad T \cong 8.8 \times 10^4\ \text{K}.$$

What Do You Think? How would the numbers change if instead of dealing with hydrogen you were dealing with twice-ionized lithium, i.e. a $Z = 3$ nucleus with only one electron present?



The estimate in Example 41–2 dramatically confirms our earlier assertion that, under normal circumstances, matter will be in its ground state. We can nevertheless study the spectra of elements in the laboratory because a small fraction of atoms is excited, even at low temperatures.

The principles on which the Bohr model is based can be applied to any classical system. Example 41–3 presents another use of Bohr-model techniques.



THINK ABOUT THIS. . .

ARE THERE OTHER WAYS TO VERIFY THAT ATOMIC ENERGY LEVELS ARE DISCRETE?

In 1914, shortly after Bohr proposed his theory of the atom, James Franck and Gustav Hertz performed an important experiment (Fig. 41–6a). They constructed a tube containing a filament that, on heating, emitted electrons. These electrons were attracted to a grid held at a higher potential. On passing through the grid they went on to a collector plate, which measured the current as a function of the potential. When mercury vapor was introduced into the tube, the plot of current as a function of potential showed sharp breaks at well-defined intervals of about 4.9 V (Fig. 41–6b). The interpretation of these results required the basic picture of the Bohr atom. As the potential increases, electrons accelerate and their kinetic energy increases, leading to an increase in the current. When the free electron has enough energy to excite an atomic electron from its ground level to an excited state in an inelastic collision with a mercury atom, the free electron loses energy, and the measured current drops. The free electron reaccelerates until it again reaches the threshold for the excitation of an atomic electron from its ground state to its first excited state. Franck and Hertz also observed that above the 4.9-V threshold energy, light of a discrete wavelength was emitted from the mercury vapor. This wavelength, 253.6 nm, corresponds to the 4.9 eV energy difference between the lowest and first excited state of the mercury atom, reemitted when the atom decayed from the excited state back to the ground state. The Franck–Hertz experiment provided an immediate and dramatic confirmation of the Bohr picture.

(a)

(b)

▲ **FIGURE 41–6** (a) Schematic sketch of apparatus for the Franck–Hertz experiment. (b) Current as a function of voltage in a Franck–Hertz experiment.

EXAMPLE 41–3 Consider a particle of mass m moving in a circular orbit about a fixed center under the influence of the radial force $\vec{F} = (-kr)\hat{r}$, a specific orbit for a two-dimensional harmonic oscillator. Calculate the energy spectrum of this system.

Strategy We start with the classical expression for the energy of a system, composed of a kinetic and a potential energy term. The latter is of the form $\frac{1}{2}kr^2$, and with the notation $k = m\omega_0^2$, the energy takes the form

$$E = \frac{1}{2}mv^2 + \frac{1}{2}kr^2 = \frac{m}{2}(v^2 + \omega_0^2 r^2).$$

We note here that the angular momentum, magnitude $L = mvr$, is conserved, because the force is central.

Our expression for the energy is a function of both v and r, whereas the quantized energy analogous to Eq. (41–10) contains neither. We have two additional tools to eliminate v and r. One is Newton's second law, the dynamical equation. The other is the essential quantum ingredient, the quantization of angular momentum. Once we know v and r, we can use these in the expression for the energy to find its quantized values.

Working It Out We start with Newton's second law. Both the force and the acceleration are centripetal, and the magnitude of the law reads $\frac{mv^2}{r} = kr = m\omega_0^2 r$. We solve for the speed:

$$v = \omega_0 r.$$

As the next step, we apply the angular momentum quantization condition, $L = mvr = n\hbar$, where $n = 0, 1, 2\ldots$ When we insert $v = \omega_0 r$ into this expression, we have $m\omega_0 r^2 = n\hbar$, or

$$r^2 = \frac{n\hbar}{m\omega_0} \quad \text{and} \quad v^2 = \frac{n^2\hbar^2}{m^2 r^2} = \frac{n\hbar\omega_0}{m}.$$

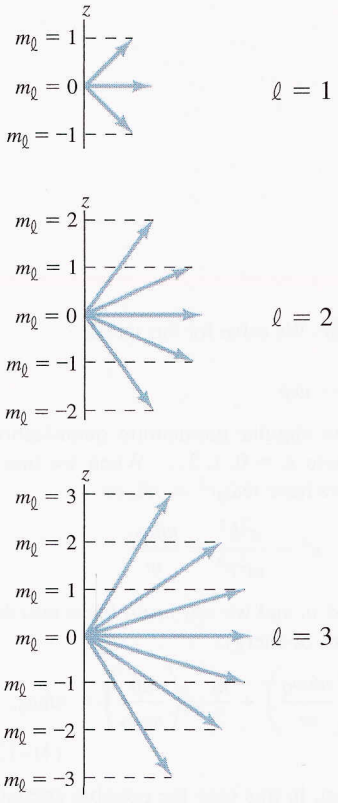
At this point we have both r and v, and we can insert these into the expression for the possible values of energy:

$$E_n = \frac{m}{2}(v^2 + \omega_0^2 r^2) = \frac{m}{2}\left(\frac{n\hbar\omega_0}{m}\right) + \frac{m}{2}\omega_0^2\left(\frac{n\hbar}{m\omega_0}\right) = n\hbar\omega_0,$$

where $n = 1, 2, 3, \ldots$ (41–13)

In contrast to the hydrogen atom, in this case the possible energies are equally spaced.

What Do You Think? Suppose we had a collection of harmonic oscillators in equilibrium at a given high temperature, what we might call a gas of harmonic oscillators. Assuming that the only transitions allowed are those that occur between neighboring levels, what would a spectroscopist see when examining the spectrum of such a gas?



Despite the successes of Bohr's quantization rules, which work well for single-electron atoms, the rules cannot be successfully applied to multi-electron atoms. Among additional problems that the Bohr rules raised was that there was no understanding of when an electron would decide to "jump" from one orbit to another, nor of where the electron was during its jumps. Moreover, the spectrum displays some features that are not accounted for in Bohr's predictions. Perhaps most unsatisfying of all was the fact that the rules were rather artificially grafted onto classical laws. Bohr's efforts were only provisional.

41–2 The True Spectrum of Hydrogen

Werner Heisenberg (in 1925) and Erwin Schrodinger (in 1926) made the leap to the correct formulation of quantum mechanics by generalizing their extensive studies of the "old" quantum theory—essentially the theory proposed by Bohr, together with knowledge about the quantization of radiation and de Broglie's assignment of wave properties to particles. The details are beyond the scope of this book; we simply quote some of the results of quantum mechanics without attempting to derive them. The complete hydrogen spectrum is one of the topics that must be treated in this way.

Heisenberg used the **Bohr correspondence principle** as a guide for his construction of quantum mechanics. This principle, which grew out of work on the original Bohr atom, states that quantum mechanical results should reduce to those that follow from a classical treatment when quantum numbers—the principal atomic quantum number n, for example—are large. (Problems 19, 20 illustrate how the correspondence principle can be applied.) Schrodinger arrived at his formulation by attempting to construct a wave equation that would give rise to de Broglie waves. Both approaches turned out to be just different ways of formulating the same quantum mechanics, and both gave exactly the same results for the hydrogen atom, as well as for all other problems.

A full quantum mechanical treatment applied to the hydrogen atom contains several noteworthy features. We cite in particular the discarding of classical concepts in favor of a probabilistic description, a more elaborate angular momentum quantization than the Bohr quantization rule, and a more complex set of allowed energy levels. Let us discuss these features in sequence.

▲ **FIGURE 41–7** The directions of angular momentum vectors for $\ell = 1, 2,$ and 3 allowed by the vector angular-momentum quantization conditions. The attempt to depict a quantum phenomenon with a classical model of restricted motion is successful only in that it indicates that not all spatial orientations are allowed.

The Wave Function

In quantum mechanics the concept of orbits disappears completely. When an electron is bound to a nucleus, it is described by a *wave function* (see Chapter 40). The wave function is a solution of the **Schrodinger equation**, whose form depends on the potential energy of the electron in the presence of the nucleus. The square of the wave function at a given point is the probability distribution function—in the sense described in Chapter 19—of finding the electron at that point. The electron can exist in one of a number of *states*, each of which is described by a solution of the Schrodinger equation. These solutions, like the solutions of a wave equation for a rope with both ends fixed, are characterized by the quantization of certain physical quantities. For hydrogen, which is a three-dimensional system, these are the energy, the total angular momentum, and the projection of angular momentum along some axis. All of these variables are quantized through their dependence on a set of *quantum numbers*, numbers that take on integer values. Once the quantum numbers are specified, the wave function (and hence all the properties of the atom) is determined.

Angular Momentum

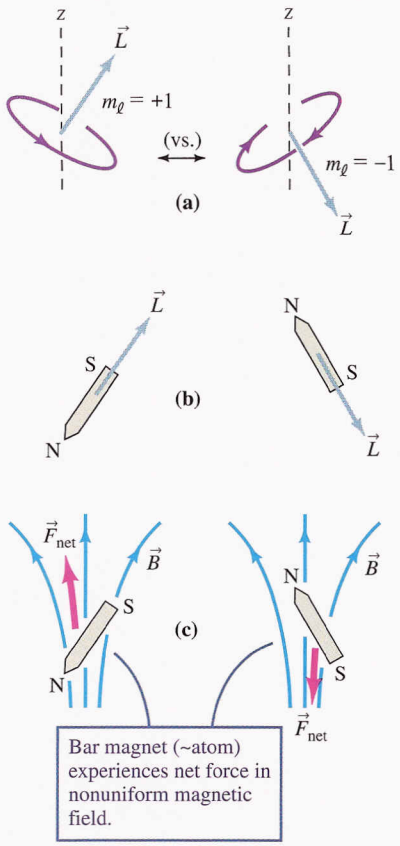
The electron's total angular momentum in the atom is quantized, but not in the way that Bohr's hypothesis specifies. In quantum mechanics it is the *square* of the angular momentum that takes on discrete values, with L^2 taking on the values $\ell(\ell + 1)\hbar^2$, where $\ell = 0,1,2,3,\ldots$ In addition, only one component of angular momentum, along a definite but arbitrary axis (which we shall call the z-axis), can be specified, and for a given value of ℓ it can only take on the values $m\hbar$, with $m = \ell, \ell - 1, \ell - 2, \ldots 1, 0, -1, \ldots -(\ell - 1), -\ell$. In other words, the z-component L_z of the angular momentum vector is itself quantized. Figure 41–7 shows the angular momentum ℓ and its allowed projections for $\ell = 1$, $\ell = 2$, and $\ell = 3$. This behavior is totally at variance with classical mechanics, although for very large L (such that $\ell\hbar$ is some macroscopic number such as 1 g · cm^2/s), the deviations from the classical description are negligibly small.

It is important to note that the specification of the integer ℓ does not give us all of the angular momentum information, since the z-component can take on a total of $(2\ell + 1)$ different m-values, corresponding to $m = \ell, \ell - 1, \ldots, -\ell$.

In 1921, Otto Stern and Walter Gerlach observed the quantization of angular momentum directly by seeing how atoms react in a magnetic field. Their experiment depends on the fact that the magnetic dipole moment of an atom is proportional to the angular momentum. Equation (31–12) gives the classical result, and there is a quantum-mechanical equivalent in which the z-component of the magnetic moment $\vec{\mu}$ is proportional to the z-component of the angular momentum, so that $\mu_z = \text{constant} \times m$. Figure 41–8 uses a classical analogy to illustrate that the atoms will experience a force if the magnetic field is not uniform. The Stern–Gerlach experiment makes direct use of this fact. In this experiment (Fig. 41–9), a beam of atoms is passed through a region of thickness D in which there is a magnetic field $\vec{B}$ oriented in the z-direction.The atoms are characterized by a magnetic dipole moment $\vec{\mu}$, and the potential energy of the atoms in the magnetic field is given by Eq. (28–26):

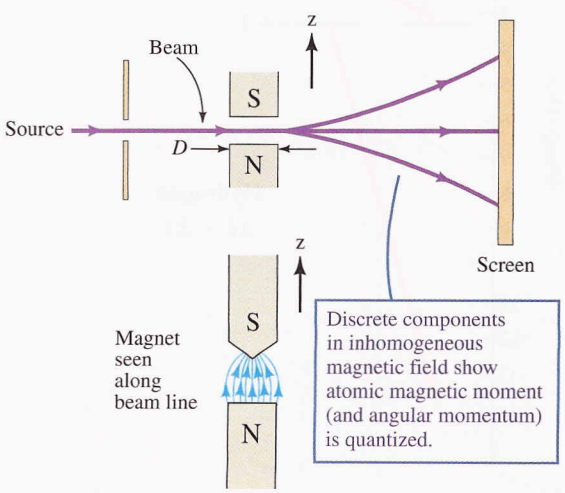
$$U_{\text{mag}} = -\vec{\mu} \cdot \vec{B} = -\mu_z B.$$

If $\vec{B}$ varies with z, then there is a force on the atom proportional to its magnetic dipole moment, in the z-direction:



$$F_z = -\frac{dU_{\text{mag}}}{dz} = \mu_z \frac{dB}{dz}. \tag{41–14}$$

Classically, μ_z, which is proportional to the angular momentum component of the atom in the z-direction [see Eq. (31–12)], is not quantized. From the classical point of view, therefore, the atoms would reach the far side of the apparatus distributed in the z-direction with a uniform spread. The maximum deflection angle θ characterizing this spread would be given approximately by



$$\theta \cong \frac{\Delta p}{p} = \frac{(\text{force})(\text{time in region containing the field})}{mv}$$
$$= \mu_z \frac{dB}{dz}\frac{1}{mv}\frac{D}{v} = \frac{D}{mv^2}\mu_z \frac{dB}{dz}, \tag{41–15}$$

where $p = mv$ is the momentum of an atom of the beam.

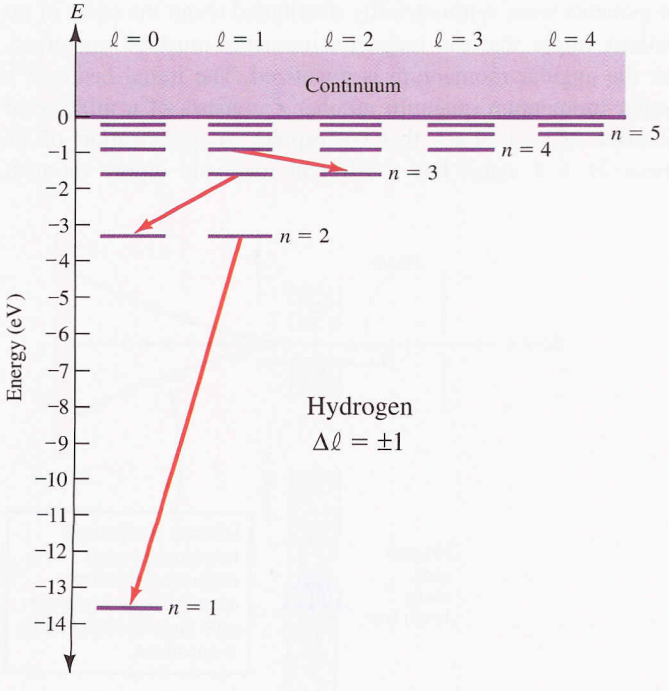
Rather than seeing a uniform spread, Stern and Gerlach saw that their beams were split into components at specific angles. The number of components varied with the species of atom. For helium, there was only one (undeflected) component; a beam of oxygen atoms split into five components; and a beam of silver atoms split into two components. In all cases, the components were symmetrically distributed about the point of no deflection. These observations imply that the magnetic moments must be quantized, which in turn implies that the angular momentum is quantized. The initial beam of a species of atom with angular momentum quantum number ℓ consists of a mixture of atoms in each of the allowed $2\ell + 1$ states that correspond to quantization of its z-component. Each of these $2\ell + 1$ states has a different magnetic dipole moment

▲ **FIGURE 41–8** (a) The atom with oriented angular momentum is analogous to (b) an oriented bar magnet. (c) The bar magnet will experience a net force whose direction depends on the bar magnet's orientation if it is placed in a nonuniform magnetic field. There is a net force because the force on one end of the magnet is different from the force on the other end; in a uniform field, there is a torque but no net force.

◀ **FIGURE 41–9** A Stern–Gerlach experiment. The magnetic field is not uniform. In this case, the beam is split into three components.

z-projection, proportional to $\ell, \ell - 1, \ldots, -\ell$. Thus the single component of helium corresponds to $\ell = 0$, and the five components of oxygen correspond to $\ell = 2$. We shall discuss the case of silver, for which two components are observed, in Section 41–3.

The Spectrum of Hydrogen



In quantum mechanics, the energy values of the hydrogen atom are quantized according to

$$E_n = -\frac{13.6\text{ eV}}{(n_r + \ell + 1)^2} \equiv -\frac{13.6\text{ eV}}{n^2}. \tag{41–16}$$

This is close to the prediction of the Bohr model, but in a generalized form. The original integer n of Bohr's model is replaced by $n_r + \ell + 1$, where $n_r = 0, 1, 2, 3, \ldots$ and ℓ is restricted to the integer values $0, 1, 2, 3, \ldots$ Note, however, that because n_r takes only non-negative values, $n \geq \ell + 1$; in other words, $\ell \leq n - 1$ for a given n. In addition, a state with a given ℓ really refers to the collection of $2\ell + 1$ different states—all of which have the same value of angular momentum squared.

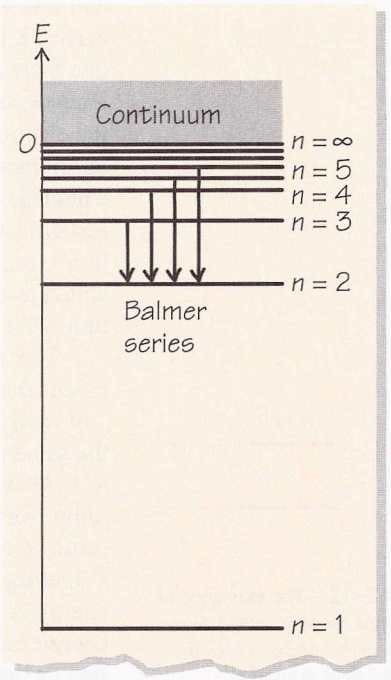
Equation (41–16) leads to a series of energy levels that are more complex than the naïve Bohr model in that each energy level contains several states. The lowest state—the state with the lowest energy value—has $n_r = 0$ and $\ell = 0$ (or $n = 1$), and it corresponds to a single state. The next level, corresponding to $n = 2$, consists of one state for which $n_r = 1$ and $\ell = 0$, and $2\ell + 1 = 3$ states with $n_r = 0$ and $\ell = 1$; that is, there are four states for $n = 2$. The next level, corresponding to $n = 3$, consists of 1 state for which $n_r = 2$ and $\ell = 0$, 3 states with $n_r = 1$ and $\ell = 1$, and 5 states with $n_r = 0$ and $\ell = 2$—a total of 9 states. These results generalize in a straightforward way, with the total number of states labeled by n equal to n^2.

There is one more aspect of the emission spectrum of hydrogen that requires comment: The spectrum is limited by the constraint of angular momentum conservation. We have already noted that the conservation of energy and linear momentum continue to hold in quantum mechanics. The same is true of angular momentum conservation in the absence of external torques. This affects the state in which a given electron will end up when it makes a jump with the emission of a photon. Electromagnetic radiation carries angular momentum, and the angular momentum of a photon is for our purposes $L_{\text{photon}} = \hbar$. As a result, the initial and final angular momenta of the electron states must differ by one unit of $\hbar$. The set of restrictions imposed by angular momentum conservation are known as *selection rules*. Some of the possible transitions are sketched in Fig. 41–10. All the results described here are in extremely good agreement with experiment.

▶ **FIGURE 41–10** Some possible transitions of electrons in the quantum mechanical view of a hydrogen atom.

EXAMPLE 41–4 The *Balmer series* is a series of spectral lines that correspond to atomic transitions in hydrogen that end with a principal quantum number $n = 2$. Sketch the allowed emission transitions that lead to this series, and compute the longest and shortest wavelengths in this series.

Setting It Up An emission transition is one in which the final atomic state is at a lower energy than that of the initial state. The sketch in Fig. 41–11 shows the transitions from states with energies above the level with $n = 2$ that end up at the $n = 2$ level, each transition originating at levels characterized by $n = 3, 4, 5, \ldots$ In each case ℓ will change by 1.



Strategy We can find the wavelengths of the light emitted in the transitions from the Rydberg formula, Eq. (41–12), with the final index set to $n_f = 2$ and the initial index $n_i = 3, 4, 5, \ldots$ Thus the set of wavelengths are given by

$$\frac{1}{\lambda_{n_i,2}} = \frac{E_i - E_f}{hc} = -R_\infty\left(\frac{1}{n_i^2} - \frac{1}{2^2}\right).$$

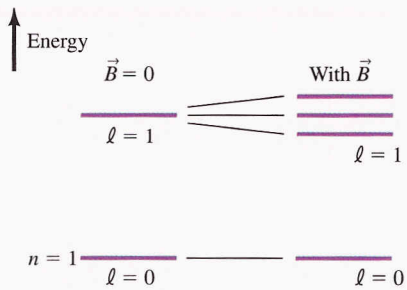
Working It Out We have

$$\lambda_{n_i,2} = \frac{1}{R_\infty}\frac{4n_i^2}{n_i^2 - 4} = 365 \times 10^{-9}\left(\frac{n_i^2}{n_i^2 - 4}\right) \text{m}.$$

The shortest wavelength, corresponding to $n_i = \infty$, is 365 nm; the longest wavelength, corresponding to $n_i = 3$, is 656 nm.

▲ **FIGURE 41–11** This series of transitions is known as the Balmer series.

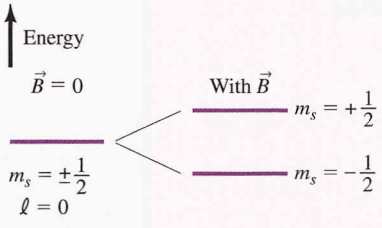
CONCEPTUAL EXAMPLE 41–5 In principle we can imagine hydrogen atoms in states with very large quantum numbers, for example $n = 30$. Under what circumstances could a gas of such atoms exist?



Answer In a gas of such atoms, it would not take much energy to ionize the atoms, since the ionization energy is just $(13.6 \text{ eV})\frac{1}{30^2} = 0.015$ eV. To maintain such a gas, it is necessary that any collisions with other atoms should be gentle, and this can be accomplished only if the temperature of the gas is low enough. We could estimate the temperature T be such that $kT \ll 0.015$ eV or equivalently that $T \ll 180$ K. There is moreover a second requirement and more restrictive condition. According to Eq. (41–8), the radius of an atom with $n = 30$ is $(30)^2 = 900$ times larger than the Bohr radius, and hence the volume taken up by the atom is $(900)^2 \cong 800{,}000$ times larger than the atom in its bound state. These atoms will always be in each other's way unless the gas is very dilute. You can use the techniques of Chapter 19 to make a calculation as to just how dilute the gas must be—for example, you may want the mean separation to be a factor of 10 or 20 times larger than the atomic radius, as is typical for a normal ideal gas at STP.

41–3 The Exclusion Principle and Atomic Structure

The Spin of the Electron



When an atom with a magnetic dipole moment is placed in an external magnetic field, it has a potential energy $U_{\text{mag}} = -\vec{\mu} \cdot \vec{B}$ [Eq. (28–26)]. As we already saw in our discussion of the Stern–Gerlach experiment, each one of the $2\ell + 1$ orientations of an atom with angular momentum quantum number ℓ has a magnetic dipole moment with a different z-component. When such an atom is placed in a magnetic field, the $2\ell + 1$ orientations no longer have the same energy. If hydrogen is placed in an external magnetic field, the energies of the first excited state with $\ell = 1$ are therefore slightly *split* (Fig. 41–12). The frequencies of the radiation emitted (or absorbed) in a transition to or from one of the three (now split) levels are accordingly not quite the same, and this is detectable by experiment.

States of a given ℓ that have a common energy in the absence of a magnetic field break up into $(2\ell + 1)$-member *multiplets* with slightly different energies in the presence of a magnetic field. Because $\ell = 0, 1, 2, 3, \ldots$, only odd-valued multiplets were expected. This was not, however, what was seen: For some atoms—silver, for example—*doublets* appear; that is, there are two components, as we mentioned in our discussion

▲ **FIGURE 41–12** When a hydrogen atom is subject to an external magnetic field, the three states corresponding to $\ell = 1$, which all have the same energy in no magnetic field, have slightly different energies—the levels are split. The amount of splitting depends on the strength of the magnetic field. Note that the $\ell = 0$ state consists of only one level and is therefore not split.

of the Stern–Gerlach experiment. For a doublet, $2\ell + 1 = 2$, so $\ell = \frac{1}{2}$ for these atoms, and this was forbidden by the rules of quantum theory as they were understood in the early 1920s. In 1924, Wolfgang Pauli decided that the electron had to be described by one more quantum number, which could take only two values. A year later, George Uhlenbeck and Samuel Goudsmit explained the Pauli quantum number by proposing that the electron has an *intrinsic angular momentum*, or *spin*, $\hbar/2 \equiv s\hbar$. Whereas the angular momentum L discussed thus far is associated with the motion of an electron around a nucleus, the spin is an *internal* property of the electron. This means that an electron at rest will still have its intrinsic angular momentum. Even though there is no orbital motion associated with the spin, we know that it is an angular momentum because it can be added to the orbital angular momentum of an electron to give a total angular momentum, with its various characteristics.

▲ **FIGURE 41–13** The existence of electron spin explains why some states are split into an even number of levels when a magnetic field is applied.

The fact that electrons have an intrinsic angular momentum $s\hbar$, with $s = {}^1/_2$, means that $2s + 1 = 2$, and an electron can appear in two states. We call these states "up" and "down." In the absence of a magnetic field, the energy of an "up" electron is the same as that of a "down" electron in the hydrogen atom. However, when a magnetic field is present, the energies of these two states differ slightly. When the electrons jump from these two states, the frequencies of the photons emitted differ slightly. As a result of electron spin, the number of possible electron states that correspond to a given ℓ doubles from $2\ell + 1$ to $2(2\ell + 1)$. When $\ell = 0$, the number of states with the same energy is 2 (Fig. 41–13). For $\ell = 1$, there are $2 \times 3 = 6$ states, and so on. When the energies are observed closely in the presence of a magnetic field, the $\ell = 0$ state is always a doublet, the $\ell = 1$ state contains 6 levels, and so forth.

EXAMPLE 41–6 Given that the magnetic dipole moment of an electron is $\vec{\mu} = -\frac{e}{m_e}\vec{S}$, where $\vec{S}$ is the spin angular momentum of the electron, what is the energy difference between the "up" and the "down" states of an electron in a magnetic field of 1.0 T?

Strategy We start with the energy of a magnetic dipole in a magnetic field. We define the z-axis by the direction of $\vec{B}$ and then make use of the fact that the two possible values of S_z are $\pm\hbar/2$. Therefore

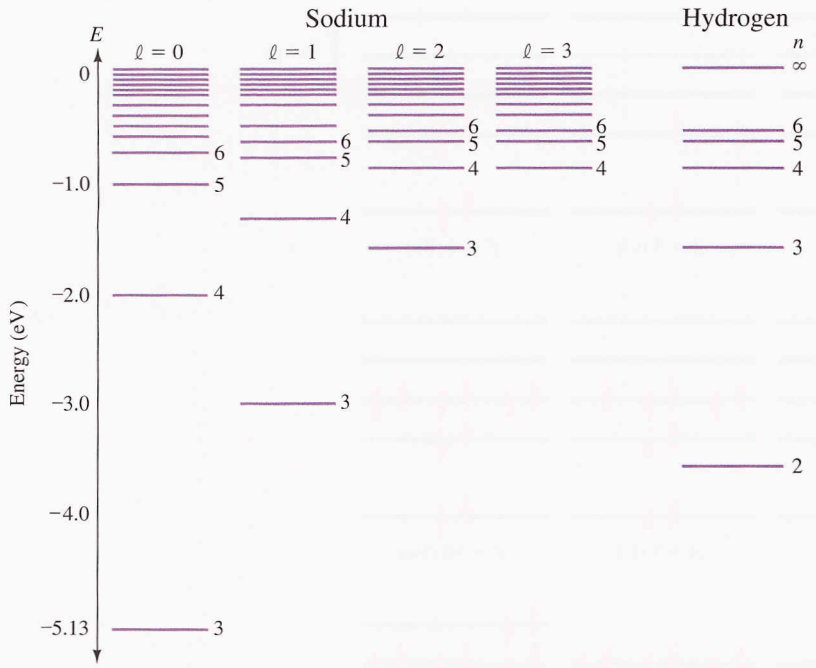
$$U = -\vec{\mu}\cdot\vec{B} = -\mu_z B = \frac{e}{m_e}S_z B = \frac{e\hbar B}{m_e}\left(\pm\frac{1}{2}\right).$$

The desired energy difference ΔE is the difference between these two values.

Working It Out We have

$$\Delta E = \frac{eB\hbar}{m_e}.$$

Numerically,



$$\Delta E = \frac{(1.6 \times 10^{-19}\,\text{C})(1.0\,\text{T})(1.05 \times 10^{-34}\,\text{J}\cdot\text{s})}{(0.91 \times 10^{-30}\,\text{kg})(1.6 \times 10^{-19}\,\text{J/eV})} = 1.2 \times 10^{-4}\,\text{eV}.$$

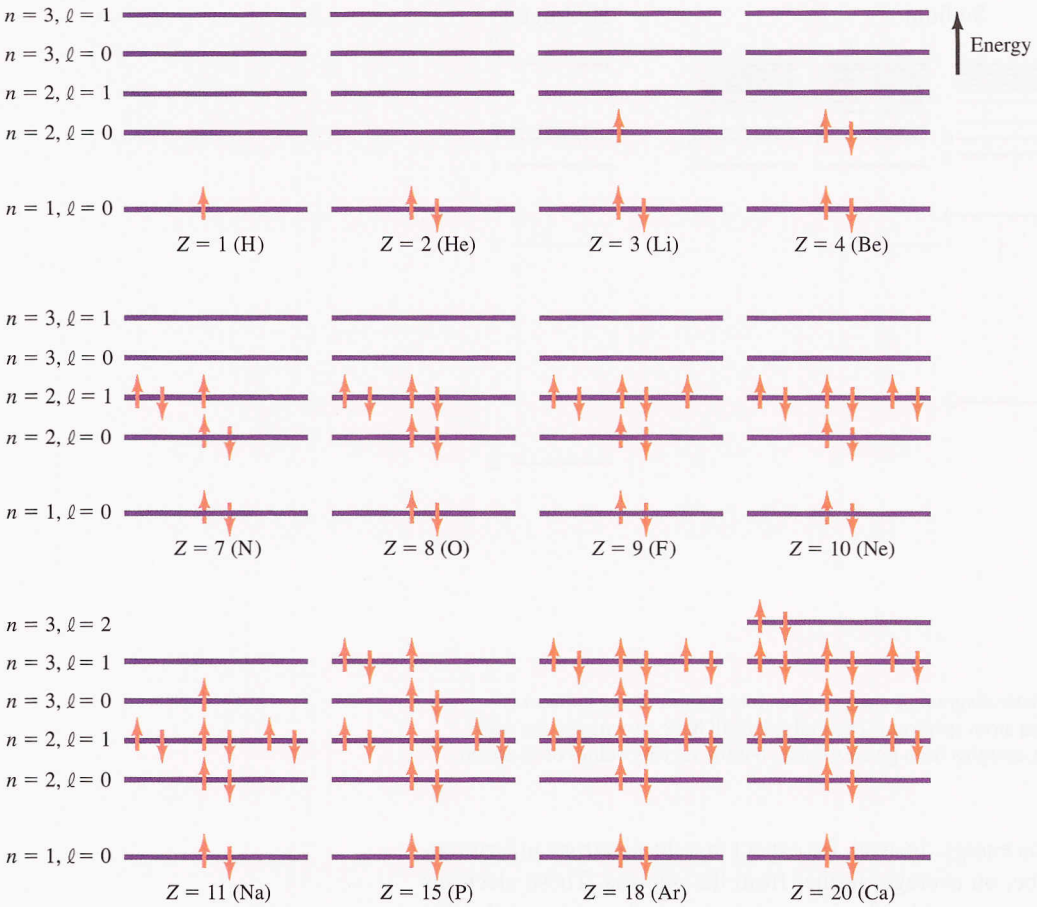
This number is small but not negligible on the atomic scale, and the effect of the energy modifications is quite visible in spectroscopic studies.

What Do You Think? It is believed that magnetic fields on the surface of a neutron star can be as large as 10^8 T. What spin state would electrons occupy in that environment?

Multi-Electron Atoms and the Exclusion Principle

Here is a naïve picture of multi-electron atoms. We have a central charge Ze and Z electrons, where Z is the atomic number. The nucleus is several thousand times more massive than the electrons, and we can treat it as fixed. We are therefore concerned only with a description of the electrons. Each electron moves in the attractive Coulomb potential of the nucleus plus a repulsive potential due to the presence of the other $(Z - 1)$ electrons. Treating the electrons as single particles in a potential is a good approximation. The electrons close to the nucleus experience the full charge Ze of the nucleus. The ones that are far away experience a smaller charge, because the inner electrons superimpose a negative charge on the positive nuclear charge. We can also assume that the modified force acting on the outer electrons remains central, so that angular momentum is conserved. The energy-level structure is accordingly the same as that of the hydrogen atom in many respects. There will still be an n-quantum number, which labels the total energy, and an ℓ-quantum number, which labels the angular momentum of the electron in that energy level. But it would no longer be true that, for a given n, the $\ell = 0$,

▲ **FIGURE 41–14** The schematic diagram of energy levels for an atom (here, sodium) is qualitatively similar to the hydrogen atom spectrum. The multiplets all have very nearly the same energy. For atoms with $Z \geq 2$, the energies for a given n value, but for varying values of ℓ, are no longer equal.



$\ell = 1, \ldots$ levels have the same energy. Instead, we expect that the electrons in large angular momentum states will be, on average, farther from the nucleus. These electrons are therefore more effectively screened by the inner electrons, and we expect that for fixed n, the electrons with larger ℓ will have higher energy values (Fig. 41–14).

The trouble with the description above is that its predictions are essentially all wrong. For example, it predicts that in the ground state of any atom, all the electrons would be in the lowest energy level. The radiation spectrum from such an atom would be qualitatively the same as that of hydrogen, although the numbers would be different because the central charge is Ze and the chemistry of the elements would all resemble that of hydrogen to some extent. Such a spectrum, and such chemistry, would bear little resemblance to what we know.

Pauli (Fig. 41–15) pointed out that an entirely new ingredient was needed to understand the structure of multi-electron atoms ($Z \geq 2$). He proposed the **exclusion principle**, according to which *each quantum state can accommodate only two electrons, one in the "up" state and one in the "down" state.*

◀ **FIGURE 41–15** Wolfgang Pauli.

▲ **FIGURE 41–16** Pattern of electron energy-level occupation for elements from $Z = 1$ to $Z = 20$. The level splittings are not to scale. Each arrow represents an electron with its spin orientation.

Let's examine what emerges when we start filling energy levels according to the exclusion principle, a process that we can follow on Fig. 41–16. Helium, $Z = 2$, has two electrons; both can fit into the $n = 1$, $\ell = 0$ state. There is no room for another electron in the lowest state. Helium is said to form a *closed shell*. Next let's consider lithium, $Z = 3$. Two electrons fit into the $n = 1$, $\ell = 0$ state, and the third electron has to go into the next lowest energy state, which is the $n = 2$, $\ell = 0$ state. The third electron is farther from the nucleus than the other two electrons are (remember that $r \propto n^2$), and the positive charge $+3e$ of that nucleus is partly screened by the negative charge of the two electrons in the $n = 1$ orbit. As a result, the third electron is less tightly bound to the nucleus and can therefore be pulled more easily from the atom and into the orbit of another atom. Thus a lithium atom can bind with another atom to form a molecule and, like other atoms that have one electron outside a closed shell, lithium atoms are chemically very active.

For beryllium, $Z = 4$, we again fill a shell, the $n = 2$, $\ell = 0$ shell, and we expect beryllium to lose its electron less easily and be less chemically active than lithium. This is indeed the case. For $Z = 5$ through $Z = 10$, the $n = 2$, $\ell = 1$ levels are successively filled. The element $Z = 10$ is neon, which corresponds to another major closed shell, the $n = 2$ shell; it is an inert gas, one of a group of elements noted for their chemical inactivity. Fluorine, $Z = 9$, is one electron short of having a filled shell. Elements such as fluorine, which have a *hole* in a shell, react particularly strongly with atoms such as lithium, which have one electron outside a filled shell. Fluorine has the lowest Z value of the *halogens* (atoms with a single hole in a shell), just as lithium has the lowest Z value of the *alkali metals* (atoms with one electron outside a filled shell).

All the details of the periodic table (see Appendix V) can be understood both qualitatively and quantitatively in a quantum mechanical description. Note that the existence of discrete energy levels, spin, and the exclusion principle are purely quantum mechanical phenomena. There is no classical hint of their existence.

EXAMPLE 41–7 An atom has $Z = 37$ electrons. What are the values of n and ℓ for the electron that is least tightly bound?

Strategy The problem is one of systematically counting states and, starting with the states of lowest energy, occupying each of them with a maximum of 2 electrons. The states, again starting with the lowest ones, have n values 1, 2, 3, ... For a given n value, there are states corresponding to the ℓ-values 0, 1, 2, ..., $n - 1$, and each ℓ state is itself subdivided into $2\ell + 1$ different states corresponding to the angular momentum projections.

Working It Out The simplest way to proceed is to make a table in which the states are enumerated, counting two electrons for each state. The first entry corresponds to the lowest level.

Thus the thirty-seventh electron is expected to lie in the $n = 4$, $\ell = 2$ shell.

n	ℓ	Number of Electrons	Cumulative Total of Electrons
1	0	2	2
2	0	2	4
2	1	6	10
3	0	2	12
3	1	6	18
3	2	10	28
4	0	2	30
4	1	6	36
4	2	10	46

What Do You Think? Would you call the atom described above inert, halogen, or alkali?

In Example 41–7, we applied simple counting rules to determine the quantum numbers of the outermost electron in an atom with a certain number of electrons. As Z increases, these simple rules fail, because new effects enter. For example, the dynamics of the orbital motion leads to a tendency for an electron to align its spin with or against the orbital angular momentum. There is then a term in the energy that depends on the alignment of the spin and the orbital angular momentum, a so-called spin–orbit term. These effects may lead to slight differences in the order in which the levels are filled; deviations from our simple rules start at $Z = 19$.

Do All Particles Obey the Exclusion Principle?

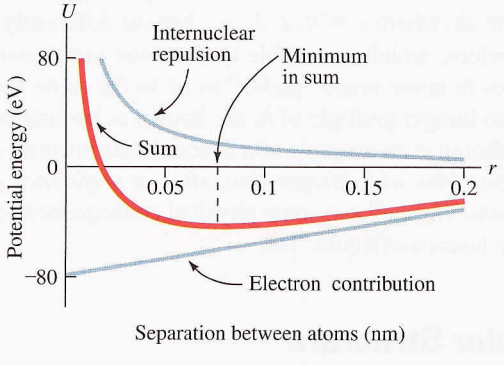
Electrons have spin $\hbar/2$. Nuclear physics experiments have shown that protons and neutrons also have spin $\hbar/2$, and according to a very general theorem, *all particles with spins* $\hbar/2$, $3\hbar/2$, $5\hbar/2$, ... *obey the exclusion principle*. This only means that no two *identical* particles can be in the same state, including the same spin state. The exclusion principle does not apply to a neutron and a proton, for example, which can perfectly well be in the same state. We call particles with half-integral spins **fermions**, named after Enrico Fermi. This has an important bearing on the structure of nuclei, which are made up of protons and neutrons. Nuclei have a shell structure analogous to that of atomic electrons. In nuclei, the average potential energy is the result of the mutual attraction of all the protons and neutrons by a *nuclear force*, with some effects from the coulomb repulsion of the protons.

There are particles that do not obey the exclusion principle. Those particles with intrinsic spin of the form $s\hbar$, where $s = 0, 1, 2, \ldots$, behave differently from particles with spin $\hbar/2$. Unlike fermions, which are unable to share the same quantum state with one another, such particles in some sense "prefer" to be in the same state. Particles in this class, whose spin is an integer multiple of $\hbar$, are known as **bosons**, named after Satyendra Nath Bose. The photon is an example of a boson; it has intrinsic angular momentum $\hbar$. *Photons, like all particles with integer spin, show a preference for congregating in the same quantum state*. We shall see some physical consequences of this congregation effect when we study lasers and liquid ^{4}He.

41–4 Molecular Structure

The Formation of Molecules

Molecules are bound combinations of two or more atoms. Even the lightest nucleus is some 2000 times more massive than an electron, so the nuclei in a molecule move much more slowly than their electrons. It is thus a good approximation to take the nuclei to be



fixed, and this fact leads to considerable simplification in the description of molecules. The electrons move rapidly around the nuclei and effectively create a smear of negative charge in which the nuclei are embedded.

Many of the important properties of simple molecules can be understood by focusing on a particular example. Let's consider the molecule H_2, which consists of two hydrogen atoms. We'll study the energy as a function of R, the separation between the two hydrogen nuclei. There are several contributions to the energy. First, there is the electrostatic repulsion between the positively charged nuclei. For the H_2 molecule, this contribution to the potential energy is $U(R) = e^2/(4\pi\varepsilon_0 R)$.

We must also include the attraction of each of the two electrons to each nucleus and the electron–electron repulsion. Although a precise calculation requires quantum mechanics, we can estimate these contributions to the energy (the "electron contribution"). When R is large, the energy is lowest when one electron is close to one of the H nuclei and the other is close to the other H nucleus. In other words, for large nuclear separation, the system of two hydrogens is just two independent hydrogen atoms. On the other hand, when the separation of the nuclei is small, so that the two H nuclei are directly on top of one another, the electrons see a nucleus of charge $2e$, which, for atomic purposes, is like a helium nucleus. Thus, the system looks like a helium atom for small nuclear separation.

We take these facts into account by pulling together some numbers. The energy of a single hydrogen atom in its ground state is -13.6 eV, so for two widely separated atoms, the total electron contribution for molecular hydrogen is twice this value, -27.2 eV. At small separation, the electron contribution is that of a helium atom, and this energy can be evaluated by noting that it has two components. First, there is the electron interaction with the nuclei: Each electron sees a nucleus of charge Ze, with $Z = 2$. The electron–nucleus energy is then $Z^2(-13.6\text{ eV}) = -54.4$ eV for each electron, a total of -108.8 eV. Second, there is the mutual repulsion of the two electrons, which are separated by roughly half a Bohr radius. In that case the energy associated with the electron–electron repulsion is about double 13.6 eV and positive. When we put these two pieces together, the electron contribution at small nuclear separation is $(-108.8\text{ eV}) + (27.2\text{ eV}) \cong -80$ eV. This is quite a good estimate; a correct quantum mechanical calculation of the binding energy of helium, and experiment, gives the binding energy of helium as -78.5 eV.

We now have estimated the electronic contribution to the energy for large and small nuclear separation R. To estimate it for other values of R, we draw a smooth line between the small-R result (-78.5 eV) and the large-R result (-27.2 eV). Figure 41–17 shows the internuclear repulsion term, $e^2/(4\pi\varepsilon_0 R)$; the electron contribution; and the sum of these two terms. *This sum has a minimum* at a nuclear separation of approximately 0.07 nm, and this is a stable equilibrium point. The experimental value of the separation of the H atoms in the H_2 molecule is very close to this value. This pattern

▲ **FIGURE 41–17** Energy diagram for the formation of the H_2 molecule. The upper curve is the potential energy associated with internuclear repulsion; the lower curve is an estimate of the potential energy associated with the electrons; the middle curve is the sum of these two terms. The sum has a minimum at $r \cong 0.07$ nm, very close to the observed nuclear separation in the H_2 molecule.

holds for other stable diatomic molecules. Most simply stated, *the forces of attraction between the electrons and nuclei cancel the forces of repulsion between the electrons and between the nuclei at the position of stable equilibrium.*

Only certain combinations of atoms can form molecules. Qualitatively, molecules can form under the following circumstances:

1. The two atoms have *paired* electrons outside closed shells, and the orbits of those electrons overlap. Here, "paired" means that one electron has spin-up while the other has spin-down. Because the electrons have opposite spin orientations, the Pauli exclusion principle does not prevent them from moving close to one another, into the region between the nuclei. In that region, the attraction of each electron to the "opposite" nucleus more than compensates for their mutual repulsion, and there is a net attraction. Each pair of electrons of this type form a *bond*: Their interaction binds the two atoms together. The larger the number of bonds, the stronger the binding of the atoms.
2. Only electrons that are not in closed shells can form bonds. An electron in a closed shell already has a second electron acting as its "partner" within its own shell. Thus only electrons in outer shells determine chemical properties.
3. An electron may not be in a closed shell but may nevertheless already be paired within its own, partly filled shell. Such electrons cannot pair up with an electron from another atom. More precisely, whether electrons pair up with partners from their own or from another atom is a matter of which configuration has the lower energy. This is not easily calculated, but chemists have developed a set of useful empirical rules for this question.

The H_2 or CH_4 (methane) molecules are examples of bonding between atoms that have unfilled shells. We say that such molecules are formed by *valence bonding*. *Ionic bonding* occurs when an atom with an electron outside a closed shell combines with an atom in which the outermost shell has one vacancy (a "hole"). As an example, consider sodium fluoride (NaF). Sodium has one electron outside a closed shell, and fluorine has a hole in its outer shell. Energy must be expended for the outermost electron of a sodium atom to be freed. This energy is the ionization energy of sodium. Its value is 5.1 eV, which is compensated by energy released if the free electron occupies the hole in a fluorine atom's outer shell. This released energy is the negative of the energy it would take to remove that electron from a now filled shell of fluorine, −3.5 eV. The net energy cost to move the electron from the sodium atom to the fluorine atom is 5.1 eV − 3.5 eV = 1.6 eV. However, we now have a positive (Na^+) ion and a negative (F^-) ion. These ions attract one another, and the energy associated with this attraction more than makes up for the 1.6 eV, so NaF has a lower energy than the separated Na and F atoms.

Van der Waals Forces

The conditions that we listed for the formation of molecules are not hard and fast. Under special circumstances, the inert gases—whose atoms have no electrons outside of closed shells—*do* form molecules. Ar_2 (diatomic argon) is an example. These molecules form because there is a residual electromagnetic force between (neutral) atoms, the *van der Waals force*. This force falls off much more rapidly than does the Coulomb force with distance. Despite the fact that the van der Waals force is rather weak, it is always attractive and thus can bind atoms. The van der Waals force arises for the same reason that a comb attracts uncharged bits of paper. When one atom approaches another, its charge distribution affects the other by giving rise to a small displacement of charges, such that an electric dipole structure is created. This electric dipole has an electric field, which interacts with the electric dipole of the first atom. The two dipoles attract with a force proportional to $1/r^7$ (see Problem 45).

Although very weak, van der Waals forces are responsible for a number of additional phenomena, such as the adhesion between a liquid and the sides of its container, and the departure of a gas from ideal gas behavior (see Chapter 17).

▲ **FIGURE 41–18** Comparison of the spectra of (a) molecular hydrogen and (b) atomic hydrogen. The far richer structure of the molecular spectrum is evident even in this case, where the molecule is as simple as can be imagined.

Molecular Spectra

In molecules, nuclei separated by roughly 0.1 nm form nearly fixed centers of attraction for electrons. We may expect from the general ideas about quantum mechanics in Section 41–1 that molecules will have a series of electron energy levels separated by the kinds of energies that characterize atomic levels; that is, gaps on the order of 1 eV to 10 eV. Experiments, however, reveal a far richer spectrum—even for simple diatomic molecules (Fig. 41–18). The additional structure is due to quantized motions not seen in the hydrogen atom: vibrational and rotational motion.

Vibrational Motion: For diatomic molecules, we saw that the potential energy curve has a minimum (Fig. 41–17). The minimum point is a point of stable equilibrium. Moreover, as we learned in Chapter 7, the potential energy curve can normally be approximated near the minimum by a parabolic curve; that is, by a harmonic oscillator potential. As a consequence, there will be energy levels associated with the vibrational motion of the nuclei in this harmonic oscillator potential. We saw in Example 41–3 by using Bohr's techniques that these energy levels are given by $E_{\text{vib}} = n\hbar\omega$, where n is an integer and ω is a characteristic frequency given by $\sqrt{k/M}$. Here, k is the "spring constant" and M is the *reduced mass* of the two nuclei in vibrational motion, given by $M = M_1M_2/(M_1 + M_2)$, where M_1 and M_2 are the two nuclear masses.

We have seen that the minimum in the potential energy (the "spring") is created by the electron cloud in which the two nuclei are embedded, and we might therefore expect that it is parameters such as the size of the atomic orbits that determine the value of k. We can *estimate* the value of k by dimensional analysis. The dimensions of any spring constant such as k are $[k] = [EL^{-2}]$, where $[E]$ is the dimension of energy, $[ML^2T^{-2}]$. To estimate k, we use this relation with typical atomic energies and distances, $E \cong e^2/(8\pi\varepsilon_0 a_0)$ and $L \cong a_0$, where a_0 is the Bohr radius. Then

$$k \cong \frac{e^2}{8\pi\varepsilon_0 a_0^3} = \frac{e^2}{8\pi\varepsilon_0}\left(\frac{e^2 m_e}{4\pi\varepsilon_0\hbar^2}\right)^3 = \frac{1}{2}\frac{(m_e)^3}{\hbar^2}\left(\frac{e^2}{4\pi\varepsilon_0\hbar}\right)^4. \tag{41–17}$$

Dimensional analysis cannot specify any additional numerical factors and we must add a little additional physical reasoning to improve our estimate. In particular, because molecules are somewhat larger than atoms, we could replace a_0 by a somewhat larger radius—take $2a_0$ just for illustration. This leads to the estimate

$$k \cong \frac{1}{16}\frac{(m_e)^3}{\hbar^2}\left(\frac{e^2}{4\pi\varepsilon_0\hbar}\right)^4. \tag{41–18}$$

Once we know the effective spring constant, we can find the allowed energies of oscillation from Eq. (41–13):

$$E_{\text{vib}} = n\hbar\omega = n\hbar\sqrt{\frac{k}{M}} = \frac{n}{2}m_e\left(\frac{e^2}{4\pi\varepsilon_0\hbar}\right)^2\sqrt{Z_1Z_2\frac{m_e}{M}}, \tag{41–19}$$

where n is an integer and M is the reduced mass of the two nuclei.

We have written Eq. (41–19) in this way because it exposes the factor $(m_e/2)(e^2/4\pi\varepsilon_0\hbar)^2$, which we recall from Eq. (41–9) is the magnitude of the ground-state energy of hydrogen, 13.6 eV. Let's call this factor E_0. Then

$$E_{\text{vib}} = nE_0\sqrt{Z_1Z_2\frac{m_e}{M}}. \tag{41–20}$$

Numerically, the factor by which nE_0 is multiplied is on the order of 10^{-2}; that is, we estimate that the vibrational energies are on the order of 10^{-1} eV.

Rotational Motion: Independent of vibrations, the nuclei of a diatomic molecule can rotate like a dumbbell of length r_0. Here r_0 is the separation for which the potential energy has a minimum. Our molecule will then have energy levels associated with these rotations. The classical energy E is given in terms of the angular momentum L by $E = L^2/2I$, and we find the quantized energies when we insist that L be quantized.

We must evaluate the rotational inertia. We are treating a diatomic molecule such as OH as two masses, M_1 and M_2, connected by a massless rigid rod of length r_0. The molecule rotates about an axis perpendicular to the rod and passing through the center of mass of the system. For this system the rotational inertia I is given by (see Chapter 9)

$$I = Mr_0^2,$$

where M is the reduced mass of the system. We now quantize L, $L^2 = \ell(\ell + 1)\hbar^2$. The rotational energy levels are then

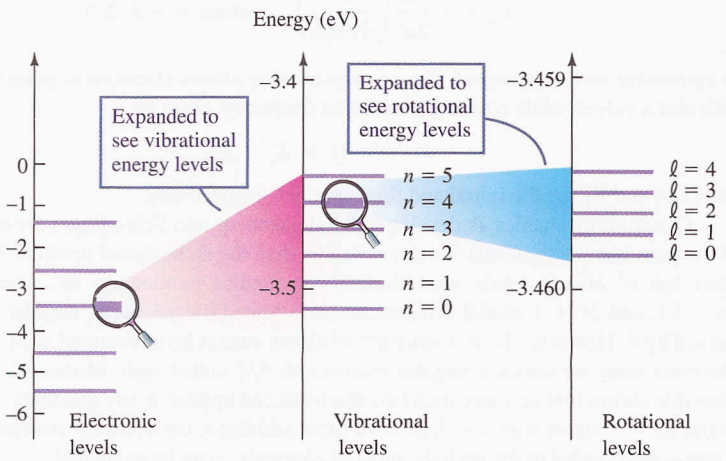
$$E_{\text{rot}} = \frac{L^2}{2I} = \frac{\ell(\ell+1)\hbar^2}{2I} \cong \frac{\ell(\ell+1)\hbar^2}{2Mr_0^2} = \ell(\ell+1)\frac{m_e}{2}\left(\frac{e^2}{4\pi\varepsilon_0\hbar}\right)^2\frac{m_e}{4M}.$$

We have substituted $r_0 = 2a_0 = 8\pi\varepsilon_0\hbar^2/e^2m_e$, as we did in the discussion of the vibrational energy levels. We again recognize the factor E_0, so

$$E_{\text{rot}} = \frac{\ell(\ell+1)E_0m_e}{4M}. \tag{41–21}$$

The energy levels are suppressed by an additional factor $\sqrt{m_e/M}$ from the factors of the vibrational levels and are on the order of 10^{-3} eV.

Let's summarize our results on molecular spectra. There are electronic levels on the order of electron volts apart. Associated with each level is a series of vibrational levels, separated by roughly 10^{-2} of the electronic levels; associated with each of *these* levels is a series of rotational levels, with separations about 10^{-4} of the electronic levels (Fig. 41–19). The latter two sets of levels are described as vibrational bands and rotational bands. The study of rotational bands is important to chemistry because these are most easily excited. Molecular spectra involving transitions between the rotational levels consist of wavelengths on the order of 10^4 times atomic wavelengths and thus involve infrared rather than optical spectroscopy.



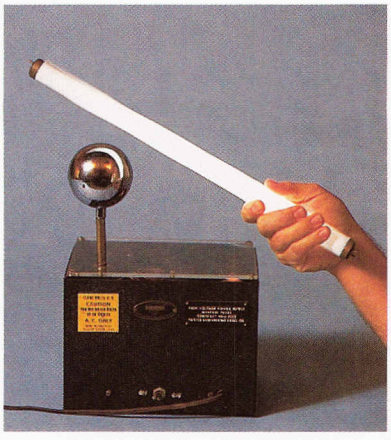


FIGURE 41–19 Molecular levels. The striking feature of these spectra is that the energy levels in each part are separated by energies 100 times finer than the energy-level separations of the previous part. The three parts represent electronic, vibrational, and rotational motions.

▲ **FIGURE 41–20** The high electric field produced by the power supply is enough to ionize the molecules inside the nearby fluorescent tube, which then produces light.

The complex structure of molecular energy levels is responsible for many of the subtleties of organic chemistry and of the chemical reactions that occur in biological systems. A technological application illustrates one consequence of the complexity of molecular structure. The high electric potentials that occur within transformers can cause the electrical breakdown of pockets of air in the transformer. In breakdown, high voltage ionizes air molecules. [A fluorescent tube can be lit simply by holding it near a high-voltage supply (Fig. 41–20).] The electrons liberated are accelerated by the large electric fields. In colliding with successive air molecules, they liberate more electrons, which are accelerated. An avalanche of electrons results, leading to currents that short out the transformer. An excellent method to prevent this type of breakdown is to introduce a gas that allows the liberated electrons to lose energy in ways that do not lead to further ionization. Sulfur hexafluoride (SF_6), which is one gas used in this way, has a very rich molecular structure, and there are many non-ionizing ways in which it can be excited by an electron colliding with it.

THINK ABOUT THIS. . .

WHERE DOES THE STEPLIKE STRUCTURE OF MOLECULAR SPECIFIC HEATS COME FROM?

In Chapter 19 we discussed equipartition, that is, the equal distribution of stored energy in a molecule among all of its degrees of freedom. This led to a prediction that the molar heat capacity for H_2 would be $7R/2$, where R is the universal gas constant. Figure 19–11 shows that this value is finally reached at rather high temperatures, with the molar heat capacity rising in steps from a value of $3R/2$ through $5R/2$ to $7R/2$. Our discussion of molecular excitations readily explains this.

At low temperatures we may think of molecules as inert objects like billiard balls. Thermal energy will be stored in the kinetic energy of these objects, and there the equipartition theorem predicts a heat capacity of $3R/2$. As the temperature increases, molecules can store energy in rotational degrees of freedom. This can only occur when the thermal energy is large enough to excite rotational levels. We argued in the text that these begin at energies of the order of 10^{-3}–10^{-2} eV, which corresponds to a temperature of $T = 10\text{K}–100\text{K}$, with significant contributions occurring at the higher end. There are, at this stage, no contributions from the vibrational degrees of freedom, since the threshold for their onset is at an estimated 0.1 eV, that is, 10^3K. It is above these temperatures that the vibrational excitations begin to share in the storage of energy. These estimates are in good agreement with the data shown in Fig. 19–11.

Summary

One of the important consequences of quantum mechanics is that energies of bound systems can take on only discrete values. In the simplest version of the Bohr model, the quantization of atomic energy levels follows from the restriction of angular momenta to integral multiples of $\hbar$:

$$L = n\hbar, \quad \text{where } n = 1, 2, 3 \ldots \tag{41–5}$$

With this condition the allowed energy values are

$$E_n = -\frac{m_e}{2n^2}\left(\frac{e^2}{4\pi\varepsilon_0\hbar}\right)^2, \quad \text{where } n = 1, 2, 3, \ldots \tag{41–10}$$

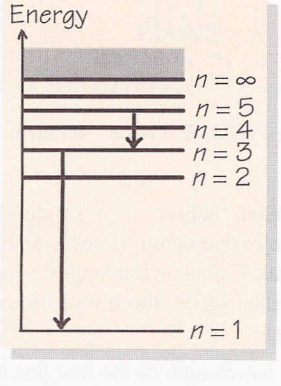
in agreement with experiment. Energy conservation allows electrons to jump between levels with different n values while emitting photons of frequency given by

$$hf = E_i - E_f, \tag{41–6}$$

where E_i and E_f are the initial and final energies, respectively.

Quantum mechanics as developed by Heisenberg and Schrodinger shows that the structure of the possible energy levels is more complex than the Bohr model predicts. For each value of n, there are n^2 energy levels characterized by angular momentum $\ell\hbar$, where $\ell = 0, 1, 2, \ldots, (n-1)$, and $2\ell + 1$ spatial orientations are allowed for the vector angular momentum characterized by ℓ. However, the full structure of atoms cannot be understood until we add the fact that electrons carry an intrinsic angular momentum $\hbar/2$ called spin. Moreover, the Pauli exclusion principle shows that no more than two electrons can appear in any quantum state (corresponding to the $2s + 1$ states with $s = {}^1/_2$). With these additions, the complex structure of multi-electron atoms—as revealed in the periodic table of elements—can be explained.

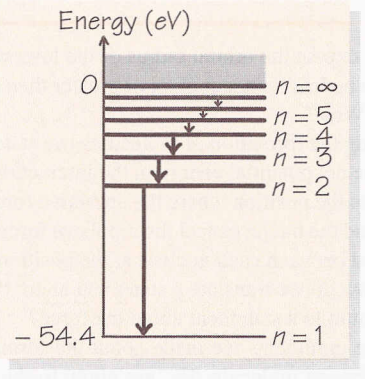
Molecules form when the forces of attraction between the electrons and nuclei cancel the forces of repulsion between the electrons and between the nuclei at the position of stable equilibrium. This can occur if the atoms involved have electrons outside closed shells. Molecular spectra reveal energy levels of a molecule that are associated with vibrations of the atoms and rotations of the entire molecule. The electronic, vibrational, and rotational modes form a hierarchy.



Understanding the Concepts

1. Why is the ground state of a particle confined to a box (Section 41–1) characterized by $n = 1$ rather than $n = 0$?
2. Can we determine the atomic composition of distant objects by studying the wavelengths of their emitted photons?
3. What determines the shortest and longest wavelengths that a hydrogen atom can emit?
4. On the one hand, we say that electrons in atoms have discrete energies; on the other hand, we say that there is inherent uncertainty in our ability to measure energies. Is there a conflict here?
5. We know that metals contain free electrons. Using our illustration of energy quantization in a box, would you expect to be able to measure spectroscopically discrete energy levels for the electrons in a piece of metal of volume 1 cm^3?
6. In the Stern–Gerlach experiment, atoms of silver were observed to have only two components of angular momentum. Does that mean that all the electrons of a silver atom have angular-momentum quantum number ℓ equal to zero?
7. Is it true that all hydrogen atoms are indistinguishable from each other? How is it possible to distinguish between hydrogen with a nucleus consisting of a single proton (^{1}H), hydrogen with a nucleus consisting of a single proton and a single neutron (^{2}H, deuterium), and hydrogen with a nucleus consisting of a single proton and two neutrons (^{3}H, tritium)?
8. Why does an atom with a magnetic dipole moment need a magnetic field that varies spatially in order to deflect an atom? Would a constant magnetic field suffice?
9. Consider a hydrogen atom on Earth and another one on the Moon. Each one of them is in the ground state, and therefore the electrons have the same quantum numbers ($n = 1$, $\ell = 0$). Doesn't the exclusion principle (rather absurdly) tell us that this is impossible?
10. Van de Graaff accelerators, which have terminals at very high voltages inside a pressurized tank, are used to accelerate nuclear particles to high energy for nuclear reactions. Would air or sulfur hexafluoride be better as an insulating gas in a van de Graaff accelerator?
11. Why does it take about twice as much energy to excite an electron from the $n = 1$, $\ell = 0$ state to the $n = 2$, $\ell = 1$ state for He^+ as it does for He (neutral helium)?
12. Would you expect the orbital radius of the lowest orbit in a helium atom to be less than, equal to, or greater than that in a hydrogen atom? Why?
13. In discussing the formation of molecules, we stated that the minimum of the net potential energy in the interaction of two hydrogen atoms is the position where the attractive forces between the electrons and the nuclei cancel the repulsive forces between each electron and between each nucleus at the position of stable equilibrium. How do we translate a statement about the potential energy minimum to a statement about the force?
14. Why do the arguments we made about the formation of the diatomic hydrogen molecule, H_2, not apply to the formation of a diatomic helium molecule, He_2, from two helium atoms?
15. In a H_2 molecule there are two protons, and these have spin $\frac{1}{2}\hbar$, that is, they are fermions. If we just look at the two protons, would you expect their spins to be parallel or antiparallel in the ground state of the H_2 molecule?
16. Suppose that we add an electron to hydrogen. The second electron could be in the same orbit as the first (the spins would then have to point in opposite directions). What might prevent the existence of such a negatively charged atom? Would the existence of an atom consisting of one proton and three electrons be as likely, or unlikely?
17. In the levels of sodium that are described in Fig. 41–14 we have displayed the level with quantum numbers $n = 4$, $\ell = 0$ below the level $n = 3$, $\ell = 2$. Is this necessarily a misprint?
18. The molecules N_2 and CO have the same number of electrons but different binding energies. Why might this be? [*Hint*: Think about the energy levels of the valence electrons.]
19. In Example 41–2, we estimated the temperature at which 20% of the atoms were in their first excited state. If you had used the same method to find the temeprature at which 50% of the atoms were in the first excited state, what temperature would you have found? Why this peculiar result?
20. We stated that electrons under the influence of the nuclear Coulomb force form states whose energy is lowest when the orbital angular momentum is zero. Is this classically possible?

Problems

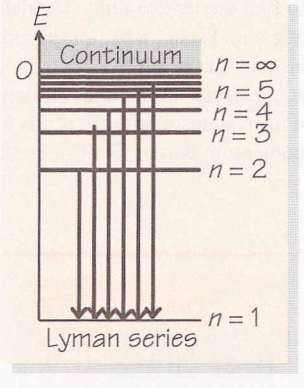


41–1 The Quantization of Energy

1. (I) What wavelength of radiation is necessary to ionize hydrogen? [*Hint*: Recall that to ionize an atom, it is necessary to raise the energy of the electron to be emitted from its ground state to at least $E = 0$.]
2. (I) Consider double ionized lithium (lithium in which two electrons have been removed). How much energy is needed to remove the third electron?
3. (I) What are the energy and wavelength of the photon emitted when a hydrogen atom jumps from its second excited state ($n = 3$) to its ground state ($n = 1$)? From $n = 5$ to $n = 3$ (Fig. 41–21)?

▲ **FIGURE 41–21** Problem 3.

4. (I) Bohr suggested an addition to the model named after him; specifically, that emitted radiation is very faint unless n changes by one unit. For what range of values of n will the radiation from singly ionized helium lie in the visible range; that is, with wavelengths in the range 400 nm to 700 nm (Fig. 41–22)?

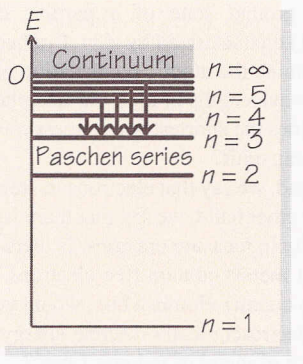


▲ **FIGURE 41–22** Problem 4.

5. (I) The negative muon (symbol μ^-) is a heavy version of the electron; it has a mass $m_\mu = 210m_e$. What is the ground state of the atom formed by a μ^- and a proton atom, assuming the Bohr rules apply?

6. (I) Consider the μ^--proton atom described in Problem 5. What is the energy difference between the first excited state and the ground state?

7. (II) The *Lyman series* is a series of spectral lines for hydrogen whose wavelengths correspond to Eq. (41–12) when $n_1 = 1$ (Fig. 41–23). (a) What are the quantum numbers of the states involved in the three transitions of the Lyman series with the longest wavelengths? (b) Calculate the wavelengths for the transitions of part (a). Are these wavelengths in the visible or ultraviolet regions?



▲ **FIGURE 41–23** Problem 7.

8. (II) Singly ionized helium is a single-electron atom with $Z = 2$ and a nuclear mass four times as large as the mass of the hydrogen nucleus. Calculate the longest wavelength in the analogue of the Lyman series, those transitions that end in $n = 1$ (see Problem 7).

9. (II) What is the wavelength of the first line of the Lyman series (see Problem 7) in triply ionized beryllium ($Z = 4$)?

10. (II) The *Paschen series* is a series of spectral lines for hydrogen whose wavelengths correspond to Eq. (41–12) when $n_1 = 3$ (Fig. 41–24). (a) What are the quantum numbers of the states involved in the three transitions of the Paschen series with the longest wavelengths? (b) Calculate the wavelengths for the transitions of part (a). Are these wavelengths in the visible or infrared regions?

▲ **FIGURE 41–24** Problem 10.

11. (II) Calculate the wavelengths of the *Paschen* ($n_1 = 3$), *Brackett* ($n_1 = 4$), and *Pfund* ($n_1 = 5$) series transitions. (These series all refer to hydrogen.) Sketch the spectrum of atomic hydrogen for the 1000-nm to 5000-nm range of wavelengths. Calculate only wavelengths for values of $n_2 \leq 8$ in the n_2 to n_1 transitions.

12. (II) Derive a formula for the wavelengths of the transitions in single-electron ions whose nuclei have charge $+Ze$. For what range of Z values will radiation for $n = 2$ to $n = 1$ transitions be in the 20-nm range? In the 0.2-nm range?

13. (II) It is useful to introduce the *fine-structure constant* $\alpha \equiv e^2/4\pi\varepsilon_0\hbar c$ in problems that involve atoms. (a) What are the dimensions and value of α? What is the value of $1/\alpha$, to the nearest integer? (This is a useful number to remember.) (b) Express in terms of α the energy of the nth level of the hydrogen atom, E_n. (c) Calculate in terms of α the speed of the electron in the lowest Bohr orbit of hydrogen.

14. (II) What are the orbital radius, speed, momentum, and energy of an electron in the $n = 3$ state of hydrogen? Assume a classical model to calculate the momentum and speed of the electron.

15. (II) The most strongly bound $n = 1$ electrons of a large atom are closer to the nucleus than the other electrons. As a consequence, their energy is primarily determined by their interaction with the nucleus, without much influence from the other electrons. Use this idea to *estimate* the energy required to remove an electron from the lowest energy state of copper ($Z = 29$) and tungsten ($Z = 74$) atoms. (Experiments by Moseley showed that the nucleus is somewhat shielded by the other electrons, an effect that can be taken into account for $n = 1$ electrons by replacing Z of the nucleus by $Z - 1$.)

16. (II) Consider the Rutherford planetary model of circular orbits. (a) Use the expression for the radius given in Eq. (41–7) to calculate the speed of an electron in terms of $e^2/4\pi\varepsilon_0$, the angular momentum L and m_e. (b) Use the result of part (a) to calculate the electron's acceleration. (c) Calculate the period of the electron's orbital motion.

17. (II) According to classical electromagnetism, the power radiated by a particle of charge e that undergoes an acceleration a is

$$P = \frac{2}{3}\frac{e^2}{4\pi\varepsilon_0 c^3}a^2.$$

Use this formula and the results of Problem 16 to calculate the energy radiated by an electron per unit time for a circular orbit of angular momentum L.

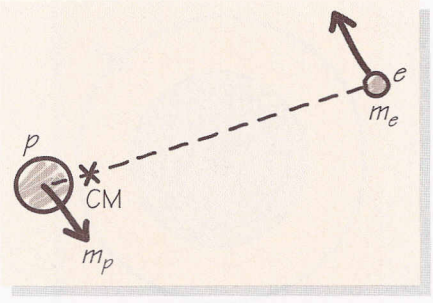
18. (II) (a) Use the results of Problem 17 to show that the fraction of energy radiated by an electron in a single period T is given by

$$\frac{\Delta E}{E} = \frac{8\pi}{3}\left(\frac{e^2}{4\pi\varepsilon_0 Lc}\right)^3.$$

(b) Use your result to find the number of periods over which the electron would lose all its energy, and the time over which this would take place. Evaluate this result numerically for L when the orbital radius is 0.05 nm. (Your result should be on the order of 10^{-10} s.)

19. (II) Calculate the frequency of the radiation emitted by an electron in a hydrogen atom when it jumps from a level of quantum number $n + k$ to a level of quantum number n. Find a simple expression for it when $n \gg k$. Express your result in terms of $L = n\hbar$, and compare it with the classical frequency $f_{cl} = 1/T$, where T is the period calculated in Problem 16. Show that the two will be equal only for $k = 1$, so the requirement that the results of quantum mechanics coincide with classical results for very large values of n (the Bohr correspondence principle) means that only transitions with changes in n of value $\Delta n = 1$ are allowed.

20. (III) (a) Express the power ($P = \Delta E/\Delta t$) radiated by an accelerating electron (see Problem 17) in terms of $L = n\hbar$. The energy will be radiated in the form of a photon of energy hf, where f is the frequency that corresponds to a transition $\Delta n = 1$. (b) Find $\Delta t = \Delta E/P$ in terms of n. Use this formula to calculate a numerical value for Δt when $n = 1$. This time interval may be viewed as the time constant for the $n = 2$ state of the hydrogen atom to jump to the $n = 1$ (ground) state. (c) Compare your time constant with the period of an electron in the $n = 2$ orbit. From your comparison, could you argue that the $n = 2$ orbit is almost stable? (d) Roughly, Δt is the longest time you have available for measuring the energy of the $n = 2$ state. Use the time–energy uncertainty relation to estimate the spread in energy of the $n = 2$ state, and compare this spread with the transition energy $E_2 - E_1$.



21. (III) *Estimate* the deflection of a beam of electrons in a Stern–Gerlach experiment. Assume that the kinetic energy of the electrons are 100 eV each, and that they travel through a region of length 0.20 m, in which there is a magnetic field gradient of 1.0 T/cm.

41–2 The True Spectrum of Hydrogen

22. (I) What are the possible values for the quantum numbers ℓ and its corresponding m-value for an atomic electron in a state labeled with $n = 3$?

23. (II) A correction should be supplied to the formulas for the energy levels of hydrogen-like atoms: The electron orbits about the center of mass of the electron–proton system rather than about the proton itself (Fig. 41–25). This correction, known as the *reduced-mass effect*, is small because the proton, of mass m_p, is much more massive than the electron, of mass m_e. The result is that the energy levels of hydrogen should be corrected to

$$E_n = -\frac{m_e}{1 + (m_e/m_P)}\frac{1}{2n^2}\frac{e^2}{(4\pi\varepsilon_0\hbar)^2}.$$

▲ **FIGURE 41–25** Problem 23.

The energy levels for deuterium, an atom with a nucleus whose charge is that of the hydrogen nucleus but whose mass is about twice that of hydrogen, obey the same formula. Find the difference in the wavelengths of radiation emitted in the transition between the $n = 2$ and $n = 1$ states for the two atoms. It was the observation of this difference that led to the discovery of deuterium by Harold Urey in 1931.

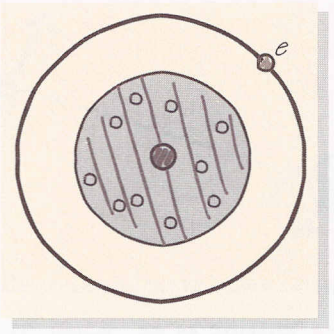
24. (II) A heavy version of the electron, called the *muon*, μ, differs from the electron only in that its mass is $m_\mu \cong 207m_e$. In the muonic hydrogen atom (a proton–muon atom), the reduced-mass effect of Problem 23 is much more important than in ordinary hydrogen. (a) What is the radius of the muonic hydrogen atom in its ground state? (b) Calculate the wavelength of radiation emitted in the transition of a muonic hydrogen atom from the $n = 2$ state to the $n = 1$ state.

25. (II) When an electron and a positron get close together at very low energies, they can form a bound state. This $e^- - e^+$ "positronium atom" lasts for a relatively long time before the electron and the positron annihilate. What are the energy levels of the positronium atom, assuming that the potential energy results from a pure Coulomb attraction? Which transitions are in the ultraviolet, the visible, and the infrared ranges?

41–3 The Exclusion Principle and Atomic Structure

26. (I) For what value of Z is the $n = 3$ level filled?

27. (I) Give the n and ℓ quantum numbers of the levels that are filled in the ground state of an atom of phosphorus, $Z = 15$.



28. (I) An atom has $Z = 34$ electrons. What are the n and ℓ values for the electron that is least tightly bound?

29. (I) What is the lightest element with a single electron in an $n = 3$ level?

30. (I) Sketch the pattern of electron energy-level occupation for the elements $Z = 13$ and 16 (see Fig. 41–16).

31. (II) In multi-electron atoms, the ordering of levels does not coincide with hydrogen-like atoms. In a particularly stable multi-electron atom, the following states are fully occupied: $n = 1, \ell = 0$; $n = 2, \ell = 0, 1$; $n = 3, \ell = 0, 1, 2$; $n = 4, \ell = 0, 1, 2$; $n = 5, \ell = 0, 1$. What is the Z value of this atom?

32. (II) An atom with $Z = 10$ has a closed shell; an atom with $Z = 11$ (sodium) may be viewed as a "nucleus" with a net charge of $+e$ and one electron on the outside (Fig. 41–26). In terms of this simplistic depiction, what would you expect sodium's ionization energy to be? [*Hint*: What levels are filled in the "nucleus"?]

▲ FIGURE 41–26 Problem 32.

33. (II) When an electron in an atomic state characterized by the quantum numbers (n, ℓ) is placed in a magnetic field, then the $(2\ell + 1)$ possible states no longer have the same energy $E_{n,\ell}$. The magnetic field *splits the degenerate levels* so the energy levels have the values $E_{n,\ell} + \kappa\ell B$, $E_{n,\ell} + \kappa(\ell - 1)B, \ldots$, $E_{n,\ell} - \kappa(\ell - 1)B$, $E_{n,\ell} - \kappa\ell B$, where κ is a constant. (a) In the presence of a magnetic field, how many different spectral lines are there in the transition $(n = 2, \ell = 1) \rightarrow (n = 1, \ell = 0)$? (b) in the transition $(n = 3, \ell = 2) \rightarrow (n = 2, \ell = 1)$? [*Hint*: Different transitions in which the energy change ΔE is the same give a single spectral line of frequency $f = \Delta E/h$.]

34. (II) The potential energy U of a magnetic dipole with magnetic dipole moment μ in a magnetic field $\vec{B}$ is $U = -\vec{\mu} \cdot \vec{B}$. The magnetic dipole moment of an electron has magnitude $\mu = (e/m_e)S$. How much more (or less) energy does an electron with spin up have than an electron with spin down in the presence of an external magnetic field with magnitude $B = 0.3$ T, assuming that the field is parallel to the "up" direction?

35. (II) The halogens are a set of elements whose outermost shells of a given n are filled, except for one electron. Find the Z values of all the halogens for which $Z < 100$. [The approximation of successive filling of levels in the order $n = 1, 2, 3, \ldots$, $\ell = 0, 1, 2, \ldots$, $(n - 1)$ is incorrect for Z greater than about 20. Thus your numbers will not agree with the periodic table at the high end.]

36. (III) The binding energy of the $n = 1$ electron in an atom for which the nuclear electric charge is $+Ze$ is obtained by taking the hydrogen atom results and replacing e^2 by $(Ze)(e) = Ze^2$. The ionization energies of the least-tightly bound electrons for some atoms with Z values from 1 to 29 (that is, through the $n = 3$ levels) are as follows:

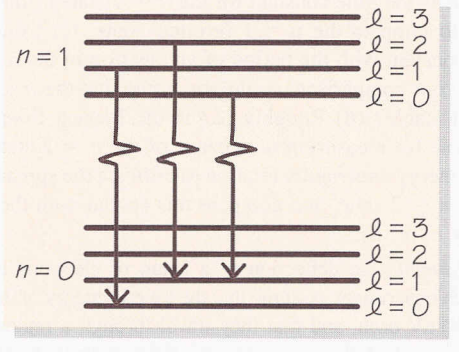
Z:	2	10	11	18	19	28	29
Ionization energy (eV):	24.6	21.6	5.1	15.8	4.3	7.6	7.7

Compare these values with those that you would obtain for the removal of an $n = 1$ electron. To what do you ascribe the huge discrepancy in most cases?

41–4 Molecular Structure

37. (I) What is the minimum (nonzero) rotational energy of the hydrogen molecule?

38. (I) Use the Boltzmann factor $e^{-E/kT}$ to estimate the temperature at which 15 percent of a gas of harmonic oscillators with angular frequency 10^{15} Hz will be excited from the ground state to the first excited state.



39. (I) Use the Boltzmann factor $e^{-E/kT}$ to estimate the temperature at which 25 percent of a gas of diatomic molecules in the ground state $(\ell = 0)$ will be excited to the $\ell = 1$ rotational state, given that the rotational inertia of the molecule is 3×10^{-47} kg · m^2.

40. (II) What are the energies of the three lowest levels in the vibrational spectrum of the HCl molecule (containing ^{35}Cl)? Assuming that the allowed transitions correspond to $\Delta n = 1$, find the wavelengths of the allowed transitions between these levels.

41. (II) The wavelength of the $n = 1 \rightarrow n = 0$ transition in the vibrational spectrum of NaCl is 2.63×10^{-5} m. Use this to estimate the spring constant k in Eq. (41–18). Approximate the mass of the sodium and chlorine nuclei as 23 and 35 times the mass of a hydrogen nucleus, respectively, to compare your result with a calculation from Eq. (41–18). The discrepancy that you will find between the two numbers suggests that Eq. (41–18) is a very crude approximation to the spring constant.

42. (II) The $\ell = 1 \rightarrow \ell = 0$ rotational transition in the lowest electronic state of the KCl molecule has a wavelength of 43.4 mm. Estimate the rotational inertia of the KCl molecule and the equilibrium separation of the atoms. Approximate the mass of the K and Cl nuclei as 39 and 35 times the proton mass, respectively.

43. (II) The energy difference between the lowest state in the CN molecule and the first excited electronic state would give rise to a single spectral line at a wavelength near 387.4 nm if there were no rotations (or vibrations). However, the lowest and first excited states actually consist of a series of rotational states with superimposed energies $\ell(\ell + 1)\hbar^2/2I_0$ and $\ell(\ell + 1)\hbar^2/2I_1$, respectively (Fig. 41–27). Calculate I_0 and I_1 from the following data: Transition $(n = 1, \ell = 1) \leftrightarrow (n = 0, \ell = 0)$ gives $\lambda = 387.4608$ nm; transition $(n = 1, \ell = 2) \leftrightarrow (n = 0, \ell = 1)$ gives $\lambda = 387.3998$ nm; transition $(n = 1, \ell = 0) \leftrightarrow (n = 0, \ell = 1)$ gives $\lambda = 387.5763$ nm. Why, physically, should I_0 and I_1 be different?

▲ FIGURE 41–27 Problem 43.

44. (II) (a) Use the data from Problem 43 to find the internuclear separation between the C $(A = 12)$ and N $(A = 14)$ nuclei for the two electronic states $n = 1$ and $n = 0$. (b) Calculate the wavelengths for the transitions $(n = 1, \ell = 3) \rightarrow (n = 0, \ell = 2)$. Compare your results with the measured value, $\lambda = 387.3369$ nm.

45. (II) Suppose that when one atom is separated from another by a distance r, its charge distribution affects the other by giving rise to a small displacement of charges, with separation d less than the atomic radius, thus creating an electric dipole. We know from Eq. (22–14) that the electric field due to such a dipole has magnitude $E \cong ed/4\pi\varepsilon_0 r^3$. (We have ignored angular factors such as sines or cosines.) The charge separation created in the

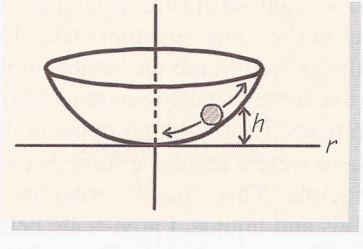
second atom induces a dipole moment of magnitude αE. The coefficient α has the dimensions $4\pi\varepsilon_0(\text{length})^3$, as can be seen from $E \cong ed/4\pi\varepsilon_0 r^3$, and this length turns out to be the charge separation d. Now the induced dipole interacts with the electric field E. Show that the resulting interaction leads to a potential energy in the interaction of the atoms of the general form

$$U(r) = -(\text{a constant})\frac{e^2}{4\pi\varepsilon_0}\frac{d^5}{r^6}.$$

This potential energy is what leads to the van der Waals force between the atoms.

46. (III) The rotational motion of a diatomic molecule affects the equilibrium position of the nuclei. If R_0 is the separation for zero angular momentum and R is the average separation when there is rotation, then the rotational energy is $\ell(\ell + 1)\hbar^2/2MR^2$, where M is the reduced mass of the nuclei. In addition, for a given vibrational frequency ω, the vibrational potential energy in the presence of rotation is $\frac{1}{2}M\omega^2(R - R_0)^2$. Calculate the new equilibrium separation R by minimizing $E(R)$, the sum of the two new terms. Treat $R - R_0$ as small. How is the rotational inertia changed, and what effect does this have on the rotational spectrum of the molecule?

General Problems



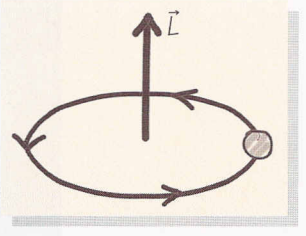
47. (I) For what value of the angular momentum quantum number ℓ does the quantum mechanical angular momentum have the value $1.00\ \text{kg} \cdot \text{m}^2/\text{s}$?

48. (II) Suppose that two electrons are in orbit around one proton (an H^- ion), both in an $n = 1$ level. By listing all the potential energy contributions, make a crude guess of how much energy it would take to ionize one of the electrons.

49. (II) An electron in an atom jumps from the first excited state to the ground state. The mean duration for the transition is 4.5×10^{-11} s. What is the uncertainty in the energy value of the first excited state? Give your answer in electron volts and as a fraction of the energy of the state, which is 2.6 eV.

50. (II) By using the assumptions of the Bohr model, calculate the radius of the ground-state electron orbit for doubly ionized lithium, Li^{2+}.

51. (II) A marble of mass $m = 20$ g moves in a circular orbit near the bottom of a circular bowl (Fig. 41–28). The height of the sides of the bowl is given by $h = \alpha r^2$, where r is the radial distance from the bottom of the bowl. Given that $\alpha = 0.25\ \text{cm}^{-1}$, find the separation between the successive allowed energies of the marble in the bowl. It is not surprising that we have no intuitive feel for quantum mechanical phenomena.



▲ FIGURE 41–28 Problem 51.

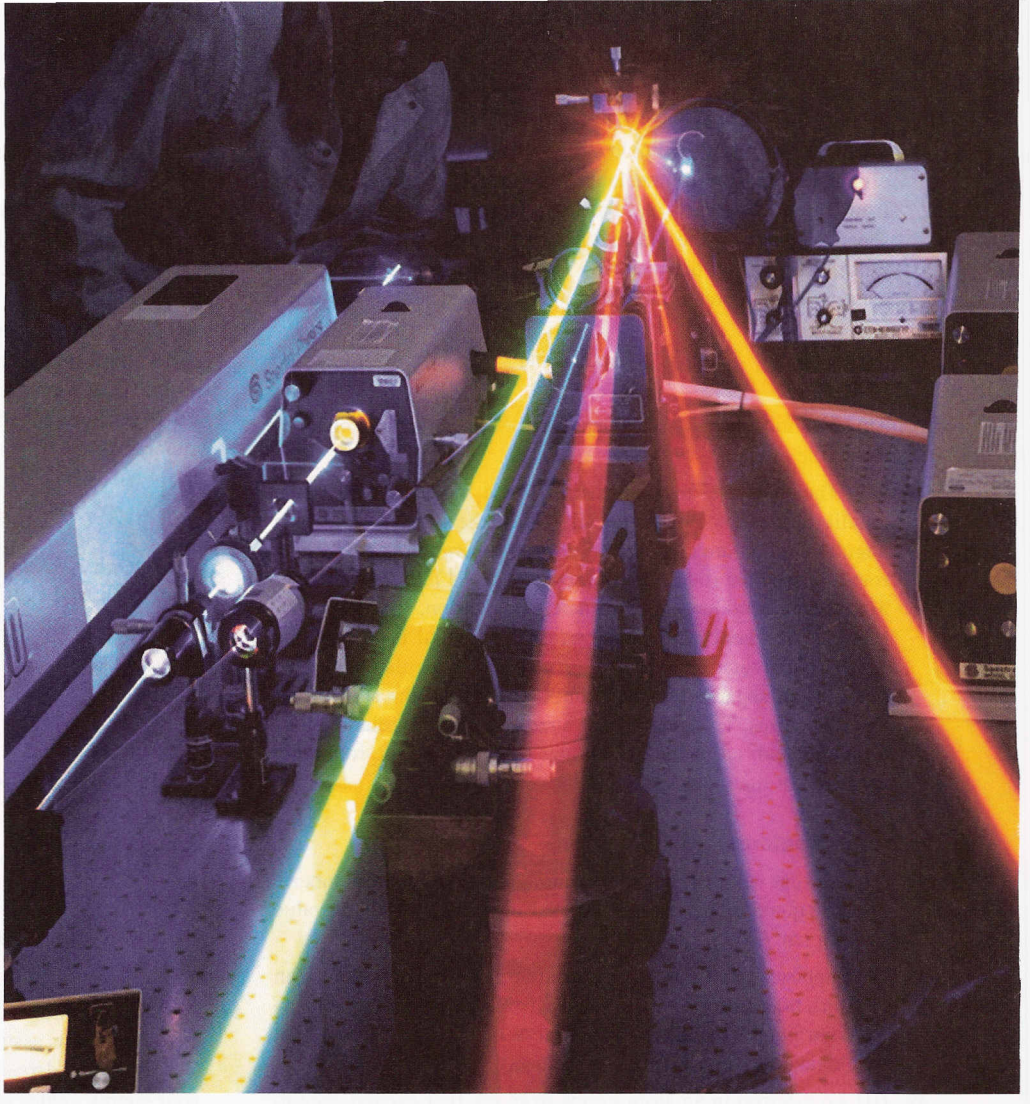
52. (II) All integer values of the principal quantum number n, even very large ones, are allowed in atoms. In practice, it is very hard to excite orbits that correspond to large n values in an atom unless the atom is totally isolated. Estimate the largest value of n that would be possible if you could make a gas of *atomic* hydrogen of density $r = 6.0 \times 10^{-10}\ \text{g/cm}^3$. For practical purposes, we regard an interatomic spacing of at least three times the diameter of the large-n atom as total isolation.

53. (II) By finding the momentum of an electron in a circular orbit with orbital angular momentum L and by using your knowledge of the magnetic dipole moment due to a current loop (Fig. 41–29), show that this orbiting electron has a magnetic dipole moment

$$M = \frac{e\hbar}{2m_e}\frac{L}{\hbar}.$$

The quantity $e\hbar/2m_e$, known as the *Bohr magneton*, is the minimum quantized value for the possible magnetic dipole moments of electrons in their orbits.

▲ FIGURE 41–29 Problem 53.



54. (III) Repeat your calculation of the energy levels of the Bohr atom, but now assume that the potential energy is given by $U(r) = -(e^2/4\pi\varepsilon_0 r) + (\sigma/r^2)$, where σ is a constant. Are your energy values larger or smaller than the corresponding values for the pure Coulomb case? Is your result physically reasonable? Is the effect of the added term more important for large n or for small n, and is that result plausible?

55. (III) According to the Heisenberg uncertainty relations, it is impossible to measure to high precision the position of an atomic electron without making its momentum highly uncertain. By finding the magnitudes of the momentum for the ground state and the first excited state of an electron in a hydrogen atom, calculate just how well the position of an electron in the ground state of hydrogen can be located before you can no longer be sure whether it is in the ground state or the first excited state. It is for the reasons outlined here that it makes little sense to think of an electron as following a classical orbit like those of the planets.

56. (III) Use the position–momentum uncertainty relation to prove that it is not possible to detect orbits in hydrogen, by the following argument: (i) a measurement of the nth orbit must be such that $\Delta x \ll r_{n+1} - r_n$. Calculate Δx. (ii) This gives rise to an uncertainty in the momentum of the electron in the orbit, and hence in the energy. Calculate the uncertainty in the energy. (iii) Show that the energy is larger than the energy difference between adjacent orbits, so an orbit cannot be "photographed."

57. (III) Consider a particle of mass m that moves in a circular orbit of radius r around a center of attraction that exerts a force on the particle. The particle's potential energy is $U = U_0(r/a)^4$, where U_0 is a constant with dimensions of energy, and a is a constant with dimensions of length. (a) Calculate the total energy (including kinetic energy) in terms of r by using the relation $mv^2/r = |F| = |dU/dr|$. (b) Use the Bohr quantization rules to obtain an expression for the quantized energy values of the particle.

Chapter 42

▶ Smoke in the air makes these laser beams visible. Lasers, whose effects are visible on a macroscopic scale, produce intense beams of coherent light through quantum-mechanical effects.

Quantum Effects in Large Systems of Fermions and Bosons

The particles that compose matter are of two types: Fermions have angular momentum $\left(\ell + \frac{1}{2}\right)\hbar$, where $\ell = 0, 1, 2, \ldots$, and bosons have angular momentum $\ell\hbar$. Identical fermions obey the Pauli exclusion principle, which states that at most one fermion can be in a given quantum state (given by n, ℓ, ℓ_z, s, s_z). In contrast, identical bosons obey a kind of "anti-exclusion principle" that translates into a tendency for them to congregate in the same quantum state. The consequent behaviors of systems with many fermions or bosons are the subject of this chapter. In Chapter 41 we saw how the filling of the energy levels in atoms is explained by the exclusion principle as it applies to electrons. Even with no dynamic forces present, identical fermions behave as though there were a repulsive force between them, just because they obey the exclusion principle. This "force" accounts, among other things, for the incompressibility of solids and liquids. Large-scale behavior can also be influenced by the behavior of bosons. The congregating effects of identical bosons explain the laser, Bose-Einstein condensates, and superfluidity. Under the right circumstances, identical fermions may in effect congregate in pairs, such that a large number of them behaves like a large system of bosons. This phenomenon lies behind

the behavior of superconductors and leads to such properties as flux quantization and the Josephson effect—properties that go beyond the mere absence of resistivity in superconductors.

42–1 The Exclusion Principle in Bulk Matter

Electrons in Metals and the Fermi Energy

The classical treatment of the electrical conductivity of metals (Section 26–5) starts with free electrons in metals. These electrons move under the influence of an externally imposed electric field. Resistance to current flow is due to the collisions between the electrons and ions, which leads to a retarding force and an average terminal speed for the electrons called the *drift speed*. The quantum mechanical description of conductivity is also based on the premise of free electrons in metals. The description of the motion of those electrons must be quantum mechanical, however, and this leads to some major differences with the classical estimates.

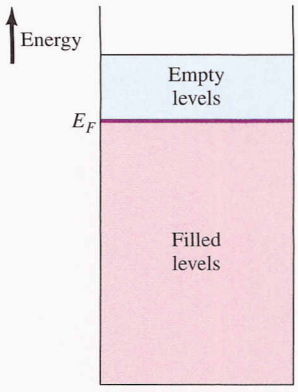
Picture the electrons as being confined to a one-dimensional box of macroscopic length L—several centimeters, for example. From Eq. (41–1), we get the energy levels for a single electron confined to a one-dimensional box:

$$E = \frac{\pi^2\hbar^2 n^2}{2m_e L^2}.$$

In a three-dimensional box, there are three such contributions, corresponding to motion in the x-, y-, and z-directions. The result is that

$$E = \frac{\pi^2\hbar^2(n_1^2 + n_2^2 + n_3^2)}{2m_e L^2}, \tag{42–1}$$

with each of the integers n_1, n_2, and n_3 allowed to take the values 1, 2, 3, ... These integers label a state, and with this in mind it is evident that many states have the same energy. The lowest energy level is the one for which $n_1 = n_2 = n_3 = 1$, and it is composed of a single unique state. The next energy level consists of three states: $(n_1, n_2, n_3) =$ (2, 1, 1), (1, 2, 1), and (1, 1, 2). Different states that have the same energy are said to be *degenerate*; as the n value increases, the degree of degeneracy becomes high.



Suppose that we now start filling the levels described by Eq. (42–1) with electrons—we are now viewing a piece of metal as a three-dimensional box that contains the valence (free) electrons of the metal. According to the Pauli exclusion principle, each state can accommodate a maximum of two electrons, one for each of the two spin states of an electron, "up" and "down." With one or more valence electrons per atom, the "box" is filled with many electrons. *The lowest possible electron energy for a metal "box" that contains N_e electrons corresponds to the states filled from the bottom—the lowest energy level—with two electrons per state.* The values of $n_1^2 + n_2^2 + n_3^2$ under consideration are very large. Suppose that an electron in the metal has energy $1\text{ eV} = 1.6 \times 10^{-19}$ J—a value typical of the energy of electrons in conductors. Let's also take $L = 1$ cm, so that we are dealing with a small but definitely macroscopic piece of metal. It follows from Eq. (42–1) that

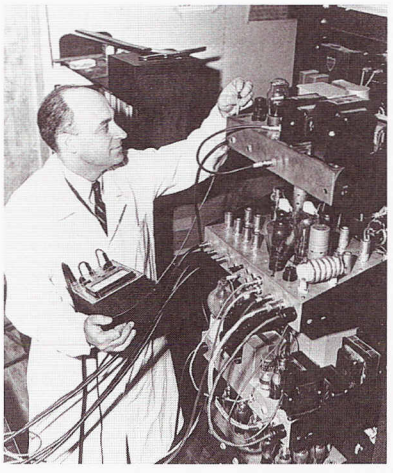
$$(n_1^2 + n_2^2 + n_3^2) = 2m_e\frac{EL^2}{\pi^2\hbar^2} \cong \frac{2(0.9 \times 10^{-30}\,\text{kg})(1.6 \times 10^{-19}\,\text{J})(0.01\,\text{m})^2}{\pi^2(1.05 \times 10^{-34}\,\text{J}\cdot\text{s})^2}$$
$$\cong 2.6 \times 10^{14}.$$

Thus we are dealing with values of n_1, n_2, and n_3 that are very large. If, for example, we let $n_1 = n_2 = n_3 = 10^7$, then the energy *difference* ΔE between the corresponding level and an adjacent level, with n_1 increased by 1 (but n_2 and n_3 unchanged), is determined by

$$\frac{\Delta E}{E} = \frac{(n_1 + 1)^2 - n_1^2}{n_1^2 + n_2^2 + n_3^2} \cong \frac{2n_1}{n_1^2 + n_2^2 + n_3^2} \cong 10^{-7}.$$

The energy levels are so close together that we say they *almost* form a continuum.

▲ **FIGURE 42–1** The energy levels of "free" electrons in a metal at $T = 0$. All the levels are filled to the Fermi energy, E_F, of the material, leaving unoccupied levels above.



When an electron accelerates under the influence of an external field, its energy increases smoothly according to the classical view. In quantum mechanics, the electron energy must jump by a discrete amount. Here, the exclusion principle plays an important role: An electron cannot jump to a state of higher energy if that higher-energy state is fully occupied by other electrons. This means that only electrons at the top of the filled levels—the levels that have energy above this are not fully occupied—can be accelerated by the electric field (Fig. 42–1).

The energy of the *highest* filled energy level is called the **Fermi energy**, E_F, after Enrico Fermi (Fig. 42–2), who with Paul Dirac first clarified the importance of the exclusion principle in many-fermion systems. In general, the de Broglie wavelength of a particle roughly corresponds to the space it occupies. Thus the closest that two electrons with the same energy and angular momentum can get to each other is about half a de Broglie wavelength. Any closer distance would effectively superimpose the electrons, a situation forbidden by the exclusion principle. While this estimate is not precise, it is a useful guide to the qualitative calculation of E_F that follows.

To estimate the Fermi energy, we suppose that the closest possible distance between two electrons is one-half the de Broglie wavelength that corresponds to the *Fermi momentum* $p_F = \sqrt{2m_eE_F}$. If we denote this closest distance by d, then the total number of electrons N_e in a cubical box of sides L is

$$N_e = \left(\frac{L}{d}\right)^3; \tag{42–2}$$

$$d = \left(\frac{N_e}{L^3}\right)^{-1/3} = n_e^{-1/3}. \tag{42–3}$$

▲ **FIGURE 42–2** Enrico Fermi excelled as an experimentalist and as a theorist. Among his other accomplishments, he led the successful effort to build the first controlled nuclear fission reactor, completed in December 1942 in Chicago. His theory of beta decay was a crucial step along the way to a deeper understanding of fundamental interactions.

Here, n_e is the number density of free electrons in the metal. When we equate this closest distance to half the de Broglie wavelength at the Fermi energy, λ_F, we find that

$$d = \frac{\lambda_F}{2} = \frac{h}{2p_F} = \frac{h}{2\sqrt{2m_eE_F}} = \frac{\hbar\pi}{\sqrt{2m_eE_F}}. \tag{42–4}$$

We can combine Eqs. (42–3) and (42–4) and solve for E_F: $E_F = (\hbar^2/2m_e)(\pi^3 n_e)^{2/3}$. A more precise calculation of the number of electrons that can be accommodated with energy $E < E_F$, a calculation that takes into account the presence of degeneracy, leads to the replacement of the factor π^3 by $3\pi^2$, a very minor change:

$$E_F = \frac{\hbar^2}{2m_e}(3\pi^2 n_e)^{2/3}. \tag{42–5}$$

The magnitude of the Fermi energy depends on the density of free electrons. Copper, for example, has one free electron per atom. For copper, then, with an atomic weight of 63.5 g/mol and a mass density of 8.95 g/cm^3,

$$n_e = \left(\frac{1 \text{ electron}}{\text{atom}}\right)\left(\frac{6.02 \times 10^{23} \text{ atoms}}{\text{mol}}\right)\left(\frac{1 \text{ mol}}{63.5 \text{ g}}\right)\left(\frac{8.95 \text{ g}}{\text{cm}^3}\right)\left(\frac{10^6 \text{ cm}^3}{\text{m}^3}\right)$$
$$= 8.48 \times 10^{28} \text{ electrons/m}^3.$$

Substituting this result into Eq. (42–5), we find $E_F = 1.13 \times 10^{-18}$ J $= 7.1$ eV.

EXAMPLE 42–1 Calculate the Fermi energy for *N neutrinos*, particles of spin $\hbar/2$, symbol ν, confined to a cubic volume with sides of length L. The neutrino mass is so small that the relation between energy and momentum is the relativistic relation $E = pc$ rather than the nonrelativistic one $E = p^2/2m$.

Strategy With spin $\hbar/2$, neutrinos are fermions, and the exclusion principle still applies; that is, $\lambda_F = 2d$, where d is the spacing between neutrinos. The only difference between the treatment of neutrinos and our earlier treatment of electrons is that for neutrinos, we use the massless-particle relation $E_F = p_Fc$.

Working It Out We combine the relation $d = \lambda_F/2$ with the energy-momentum relation to get

$$d = \frac{\lambda_F}{2} = \frac{h}{2p_F}.$$

With $E_F = p_F c$, this reads $d = hc/2E_F$, or

$$E_F = \frac{hc}{2d} = \pi\hbar c n_\nu^{1/3} = \pi\hbar c\left(\frac{N}{L^3}\right)^{1/3}.$$

What Do You Think? How would the calculation be modified if we asked for the Fermi energy of neutrinos in a two-dimensional box? *Answers to **What Do You Think?** questions are given in the back of the book.*

With the picture we have sketched in mind, we can ask what happens when a weak electric field is applied to a metal. Only the electrons at the top of the filled levels can accelerate and move to states of higher energies because, as we have already mentioned, only they find empty levels to occupy (see Fig. 42–1). In the expression for electrical conductivity, Eq. (26–25), with the collision time given by Eq. (19–45), the appropriate quantity to use is the Fermi speed v_F, defined by $E_F = \frac{1}{2}m_e v_F^2$, rather than v_{rms} given by the kinetic theory of gases. Recall that the use of v_{rms} gave an incorrect $\sqrt{T}$ temperature dependence for the resistivity (see Section 26–5). The effect of temperature changes on the behavior of electrons with a given Fermi energy is negligible. A 100K change in temperature changes the energy of an electron by $kT = (1.4 \times 10^{-23}\,\text{J/K})(100\text{K}) = (1.4 \times 10^{-21}\,\text{J})/(1.6 \times 10^{-19}\,\text{J/eV}) \cong 10^{-2}\,\text{eV}$. Compared with the Fermi energy of copper—7 eV—the factor kT is negligible. Thus the resistivity will be temperature independent for reasonable temperature changes.

The Incompressibility of Matter

The exclusion principle plays a crucial role in explaining the incompressibility of matter. A measure of this incompressibility is given by the bulk modulus, B, defined by Eq. (11–20),

$$B = -\frac{\Delta p}{\Delta V/V}.$$

Here, Δp is a pressure change that brings about a fractional change $\Delta V/V$ in the volume of some sample of matter. Because an infinitesimal volume change dV is brought about by an infinitesimal pressure change, we rewrite this definition as

$$B = -V\frac{dp}{dV}. \tag{42–6}$$

Suppose now that the sample of material forms a cylinder of cross-sectional area A and that the pressure is applied to the ends. The work done in compressing the material along the cylinder's axis by an amount dL is $dW = -F\,dL$. Work dW is done, so energy $dE = dW$ is added to the sample. We have

$$dE = dW = -F\,dL = -\left(\frac{F}{A}\right)(A\,dL) = -p\,dV,$$

so the pressure p is the negative of the ratio of the energy change to the volume change:

$$p = -\frac{dE}{dV}. \tag{42–7}$$

When the volume of a metal changes, the number density changes, and so does the total energy. Let's calculate the bulk modulus under the assumption that the *only* resistance of a metal to compression is due to this energy change. The total energy of the free electrons in the material is equal to the number of electrons N_e multiplied by an average energy, which is a value somewhere between 0 and E_F. A calculation that we omit because of its length yields the result that the average energy factor is $\frac{3}{5}E_F$ (see Problem 51):

$$E \cong \frac{3}{5}E_F N_e = \frac{3}{5}\frac{\hbar^2}{2m_e}\left(3\pi^2\frac{N_e}{V}\right)^{2/3}N_e. \tag{42–8}$$

Thus, from Eq. (42–7), the pressure, which is called the *degeneracy pressure* of the electrons, is given by

$$p_e^{\text{degen}} = -\frac{dE}{dV} = \frac{2}{5}\frac{\hbar^2}{2m_e}(3\pi^2)^{2/3}\left(\frac{N_e}{V}\right)^{5/3}. \tag{42–9}$$

We emphasize that the exclusion principle, not an explicit repulsive force between the electrons, provides this countering pressure. According to Eq. (42–6), one further derivative of this pressure is necessary to find the corresponding bulk modulus:

$$B = -V\frac{dp_e^{\text{degen}}}{dV} = -V\frac{d}{dV}\left[\frac{2}{5}\frac{\hbar}{2m_e}(3\pi^2)^{2/3}\left(\frac{N_e}{V}\right)^{5/3}\right]$$

$$= -V\left[\frac{2}{5}\frac{\hbar^2}{2m_e}(3\pi^2)^{2/3}(N_e)^{5/3}\right]\left(-\frac{5}{3}\right)\frac{1}{V^{8/3}}.$$

$$= \frac{2}{3}\frac{\hbar^2}{2m_e}(3\pi^2)^{2/3}\left(\frac{N_e}{V}\right)^{5/3} = \frac{2\pi^{4/3}}{3^{1/3}}\frac{\hbar^2}{2m_e}(n_e)^{5/3}. \tag{42–10}$$

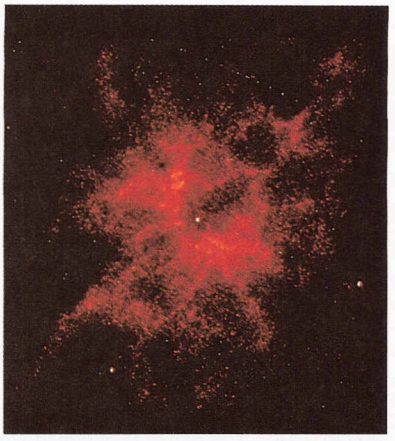
For copper, $n_e = 8.5 \times 10^{28}\ \text{m}^{-3}$, so $B = 6.4 \times 10^{10}\ \text{N/m}^2$. The experimental value of B for copper is $13.4 \times 10^{10}\ \text{N/m}^2$. Given the uncertainties of our estimates, our neglect of interaction between electrons, and the Coulomb repulsion between the ions, the fact that our rough approximation is within a factor of 2 of the experimental result is impressive. The effective repulsion between electrons that is supplied by the exclusion principle plays a major role in the high degree of incompressibility of matter.

White Dwarfs and Neutron Stars

The exclusion principle also plays a critical part in the evolution of stars: It is responsible for preventing a star's collapse under the mutual gravitational attraction of its mass. Stars are generally formed from the clumping together of large clouds of gas through mutual gravitational attraction (mainly hydrogen, which forms most of the raw material of the universe). When the hydrogen atoms fall together, gravitational potential energy is converted into kinetic energy. The density and temperature increase. The hydrogen atoms are ionized, and as further compression occurs, the protons that form the hydrogen nuclei come close enough to undergo a variety of reactions. For example, through a sequence of reactions to be described in Chapter 44, four protons can combine to form a helium nucleus and two positrons (the antimatter of electrons). A great deal of energy is released in the process, which is responsible for the luminosity of many stars and represents a kind of thermonuclear burning. While the reactions occur, the temperature of the star remains high, and an equilibrium is established. Once the hydrogen fuel has burned to the point where the process can no longer occur, there is a substantial fraction of helium nuclei in the star. The gravitational pressure shrinks the size of the star further until the temperature is high enough that the helium nuclei begin to undergo reactions that produce still more energy. In a sequence of processes, heavier and heavier elements, up to iron, are produced. Iron does not take part in further thermonuclear reactions, and the reactions stop. However, the material continues its gravitational contraction.

To estimate the gravitational pressure that acts to compress the matter, we proceed as follows. Suppose that the star contains N nucleons (protons and neutrons), each of mass M. (We can neglect the electron mass here.) A characteristic gravitational force at the star's surface has magnitude $G(NM)^2/R^2$, and thus a characteristic gravitational pressure (force per unit area) at the surface is

$$p_g = \frac{G(NM)^2/R^2}{4\pi R^2} = \frac{G(NM)^2}{4\pi\left(\frac{3}{4}V/\pi\right)^{4/3}} = 0.54\frac{G(NM)^2}{V^{4/3}},$$



where the volume $V = 4/3\ \pi R^3$. Note that the gravitational pressure is directed *inward*. It actually varies through the star; a more rigorous calculation shows that the correct value for our constant is 3/5 of 0.54 and hence

$$p_g = 0.32\frac{G(NM)^2}{V^{4/3}}. \tag{42–11}$$

As V decreases, the pressure grows and, without some countering pressure, the star would collapse. The degeneracy pressure p_e^{degen} of the electrons [Eq. (42–9)], which points outward, provides this counterbalance. (Note that the degeneracy pressure is largest when the mass of the fermion involved is smallest, which is why we use the degeneracy pressure of electrons rather than that of, say, protons.) When the electron degeneracy pressure matches

the gravitational pressure, equilibrium is reached. For less massive stars, the end product is a *white dwarf* (Fig. 42–3). Given that N_e = number of protons $\cong N/2$, we can calculate the radius of the resulting star. We get a radius of some 7000 km for a star the mass of the Sun, 2×10^{30} kg (see Problem 54). This corresponds to a density of 7.5 metric tons/cm^3! Note that the radius of our Sun is about 1.4 million km, and a quick comparison of the densities of the Sun and our white dwarf shows that the difference between ordinary matter and degenerate matter is enormous.

For a more massive star, p_g is larger and, to maintain equilibrium, the factor N_e/V in the degeneracy pressure [Eq. (42–9)] must increase. This means, however, that the Fermi energy of the electrons grows. When the Fermi energy of an electron is comparable to the electron's rest mass, we can no longer use nonrelativistic formulas but instead must treat the electron relativistically. In the extreme relativistic case, the result of Example 42–1 must be used. The total energy of the electron is again N_e multiplied by the average energy; this time, though, p_e^{degen} is proportional to $(N_e/V)^{4/3}$. This implies that the factor V cancels from the balancing equation $p_e^{\text{degen}} = p_g$, which then can no longer be satisfied by a judicious choice of V. The gravitational pressure always exceeds the electron degeneracy pressure when a star is more massive than about 1.4 solar masses (the *Chandrasekhar mass*) and without the possibility of balance, gravitational collapse continues.

▲ **FIGURE 42–3** A white dwarf star is at the center of the gas cloud.

EXAMPLE 42–2 Show that if the electron's energy E in a star is so high that its rest mass can be ignored (see Example 42–1), then the gravitational pressure is on the order of magnitude of the degeneracy pressure for a star of one solar mass. (A star is electrically neutral, and to a good approximation the number of neutrons equals the number of protons when the star is formed.)

Strategy The gravitational pressure is given by Eq. (42–11). We want to compare this to the electron degeneracy pressure, which can be calculated from the relation $p_e^{\text{degen}} = -dE/dV$, Eq. (42–7). We again use $E \cong 3/5\ E_F N_e$, but now we need the expression for the Fermi energy applicable to massless (or highly relativistic) particles, $E_F = \pi\hbar c(N_e)^{1/3}V^{-1/3}$ (see Example 42–1). We must also relate the number of electrons to the mass of the star. We do this as follows: Electrical neutrality gives us $N_e = N_p$. The total mass of the star, $M_\odot$ (one solar mass), is the total number N of neutrons and protons times the mass M of a proton (or neutron), $M_\odot = NM$. Finally, as we stated above, the number of protons equals the number of neutrons, so $N_e \cong N/2 = (NM)/2M = M_\odot/2M$.

Working It Out The degeneracy pressure is

$$p_e^{\text{degen}} = -\frac{dE}{dV} = -\frac{d}{dV}\left[\frac{3}{5}E_F N_e\right] = -0.6N_e^{4/3}\pi\hbar c\frac{d(V^{-1/3})}{dV}$$
$$= +0.2\pi\hbar c N_e^{4/3}V^{-4/3}.$$

We now express the electron number in terms of the solar mass, giving

$$p_e^{\text{degen}} = +0.2\pi\hbar c\left(\frac{M_\odot}{2M}\right)^{4/3}V^{-4/3}.$$

Thus, the ratio of the degeneracy pressure to the gravitational pressure is

$$\frac{p_e^{\text{degen}}}{p_g} = \frac{0.2\pi\hbar c(0.5M_\odot/M)^{4/3}V^{-4/3}}{0.32G(NM)^2/V^{4/3}}$$
$$= \frac{0.2\pi\hbar c(0.5M_\odot/M)^{4/3}}{0.32GM_\odot^2} \cong 1.2.$$

This crude calculation does give the right order of magnitude. Chandrasekhar showed the more general result that if a star has a mass $sM_\odot$, then $p_e^{\text{degen}}/p_g = 1.2s^{-2/3}$.

What Do You Think? Would this calculation apply to the Sun, whose mass is 2×10^{30} kg and radius is 7×10^8 m?

What happens when a star exceeds the Chandrasekhar mass and collapses? The process can crudely be described by the statement that the consequent squeezing forces the electrons in the star to combine with protons into neutrons and neutrinos via the reaction

$$e^- + p \rightarrow n + \nu.$$

As we remarked in Example 42–1, neutrinos are very nearly massless, and more important, they interact so weakly with matter that they immediately escape from the star. What is left is a star made of N neutrons only: a *neutron star* (Fig. 42–4).

Neutrons are fermions and hence also obey the exclusion principle. We have a new equilibrium condition, $p_g = p_n^{\text{degen}}$, where p_n^{degen}, the neutrons' degeneracy pressure, has the same form as that of p_e^{degen} but replaces N_e with N and m_e with M. The balancing relation is then

$$p_g = 0.32\frac{G(NM)^2}{V^{4/3}} = p_n^{\text{degen}} = \frac{2}{5}\frac{\hbar}{2M}(3\pi^2)^{2/3}\left(\frac{N}{V}\right)^{5/3}. \qquad (42\text{–}12)$$

▲ **FIGURE 42–4** At the center of the crab nebula, shown here, is a neutron star, identifiable through its properties as a pulsar.

This equation can be solved for V and thus for R. For a star of a few solar masses, numerical calculation yields R on the order of 10 km! The neutron star is as dense as a nucleus—that is roughly a billion times denser than the white dwarf we talked about above—and the compactness of neutron stars is responsible for the many properties that continue to intrigue astrophysicists. The existence of neutron stars was predicted in 1934 by Walter Baade and Fritz Zwicky. The *pulsars* first discovered by Anthony S. Hewish and Jocelyn Bell Burnell in 1967 were identified by Tom Gold in 1968 as rapidly rotating neutron stars.

EXAMPLE 42–3 Calculate the radius of a neutron star whose mass is three solar masses.

Strategy The radius is obtained when the gravitational pressure is equated to the degeneracy pressure. Since we are dealing with a neutron star, the degeneracy pressure that applies corresponds to a degenerate set of neutrons, p_n^{degen}, as described above.

Working It Out The equation $p_g = p_n^{\text{degen}}$ yields

$$0.32\frac{G(3M_\odot)^2}{V^{4/3}} = \frac{2}{5}\frac{\hbar^2}{2M}(3\pi^2)^{2/3}\left(\frac{3M_\odot}{MV}\right)^{5/3},$$

where we have replaced N, the number of neutrons, by $3M_\odot/M$; $M_\odot$ is the solar mass, and M is the neutron mass. From this expression, we find

$$V^{1/3} = \left(\frac{4\pi}{3}\right)^{1/3} R = \frac{\frac{2}{5}(\hbar^2/2M)(3\pi^2)^{2/3}(3M_\odot/M)^{5/3}}{0.32G(3M_\odot)^2},$$

where R is the radius of the neutron star. Thus,

$$R = \left(\frac{3}{4\pi}\right)^{1/3}\frac{\frac{2}{5}(\hbar^2/2M)(3\pi^2)^{2/3}(3M_\odot/M)^{5/3}}{0.32G(3M_\odot)^2} = 1.0 \times 10^4 \text{ m}.$$

What Do You Think? If the mass of the star is n solar masses, what is the variation of the radius with n?

If the mass of a star is so large that even the pressure due to the Pauli exclusion principle applied to the neutrons proves inadequate to resist collapse, continued gravitational contraction occurs, and this time there is no mechanism to stop it. A black hole forms. It is clear that the exclusion principle is a crucial ingredient in the understanding of matter, from its ordinary terrestrial form to how stellar cores behave.

THINK ABOUT THIS. . .

WHAT IS THE CONNECTION BETWEEN PULSARS AND NEUTRON STARS?

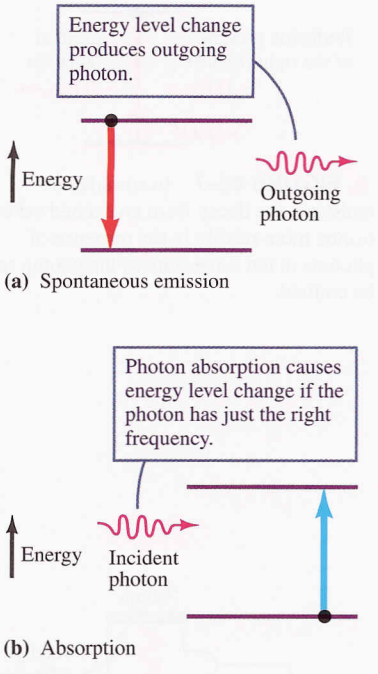
We briefly described above how gravitational pressure in massive stars (two to three solar masses) forces electrons and protons to combine into neutrons and neutrinos, thus forming a neutron star. The star begins its collapse when its primary fuel supply has been exhausted, creating a supernova. As part of the process, a fraction of the mass of the star is blown off, leaving an expanding shell of material surrounding a neutron star at the core. Most of the neutron star is indeed tightly packed neutrons, but on the surface (about 1 km thick) there is an iron crust containing protons and electrons as well. Typically the original star has a radius of the order of 10^6 km and a surface magnetic field of 10^{-2} T. It also has some angular momentum—the Sun, for example, rotates over a nearly 25-day span, $\omega \cong 3 \times 10^{-6}$ radians/s. When a collapsing star contracts in radius by a factor of 10^5, the magnetic flux is conserved, and thus the magnetic field increases to $10^{-2} \times (10^5)^2 = 10^8$ T, while the spin rate grows to a typical value of 10–100 revolutions/s as a result of angular momentum conservation. The rapid motion of magnetic field lines generates an emf that accelerates some of the electrons on the surface. This acceleration gives rise to strong beams of radiation. On Earth a light beam is seen that repeats with the rotation period of the star, like that of some vast and distant lighthouse. The period can be measured to very high precision—the first such example to be discovered had a period of 1.33730113 seconds! The regularity of the emission from these objects led them to be dubbed as pulsars.

An isolated neutron star will very slowly decrease the rate of its rotation due to the effects of general relativity. But the star's shape is correlated with the speed of rotation, and its iron crust is rigid, so that as the star slows, it may be stressed and suddenly develop cracks. The consequent rapid change, what may properly be called a "star-quake," gives rise to sudden changes in the otherwise nearly steady period of rotation. These sudden tiny changes in the period have indeed been observed.

42–2 Lasers and the Behavior of Bosons

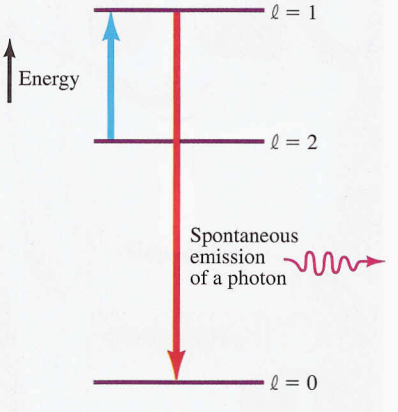
The tendency of identical bosons to cluster into the same quantum mechanical state has its most direct application in the functioning of lasers. To understand lasers, we need some further detail about photon-producing transitions in atoms and molecules.

Transitions Between Energy Levels



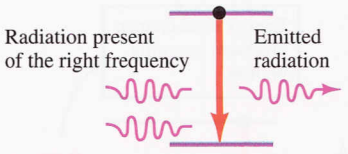
The quantum of electromagnetic radiation—the photon—has a wavelength λ or a frequency f related to λ by $f = c/\lambda$. It also has a momentum vector $\vec{p}$ oriented in the direction of propagation of the photon. The magnitude of this momentum is given by Eq. (40–2):

$$p = \frac{hf}{c}.$$



Photons are emitted (or radiated) when the electrons of atoms (or of molecules) undergo a transition ("jump") from a higher energy level to a lower energy level, as in Fig. 42–5a. Such photons are said to be *spontaneously emitted*. We have already mentioned that transitions in which photons are emitted are subject to the law of conservation of angular momentum; moreover, because photons act as though they have angular momentum quantum number $\ell = 1$ (with small mixtures of $\ell = 2$ and higher values), the most frequent transitions occur between atomic or molecular levels for which $|\ell_i - \ell_f| = 1$.

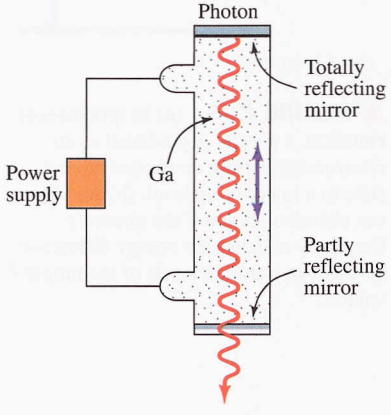
In order for an atom to radiate, it must first be excited into a higher energy level. To excite the atom, an atomic electron must be given the proper energy and angular momentum. One method of doing this is to bombard the atom with photons whose energy is the energy required for the transition. In this case, an atomic electron *absorbs* a photon and jumps into a higher energy state (Fig. 42–5b). If electrons in the ground state have $\ell = 0$, then (to high accuracy) the only states that can be reached in this way are those in which the electrons have $\ell = 1$. It is possible to reach other states—in this case, $\ell = 2, 3, \ldots$—by other mechanisms, such as collisions with other atoms. In fact, the discovery of states with $\ell > 1$ was possible only through these other excitation methods. How does an electron in a state with $\ell = 2$ fall back to the ground state? If an $\ell = 1$ energy level lies between the $\ell = 2$ state and the $\ell = 0$ ground state, which is always the case for low-Z atoms, the electron can jump first to the intermediate $\ell = 1$ state by emitting a photon, then jump to the $\ell = 0$ state by emitting a second photon (Fig. 42–6). What happens, though, if the atomic level structure is complicated enough that there is no intermediate $\ell = 1$ state through which the electron can cascade downward? A jump accompanied by photon emission is still possible, but it is on the order of 10^4 times less probable. If the change in ℓ is 3 rather than 2, then a jump accompanied by photon emission is 10^8 times less probable. These probabilities can be illustrated by thinking of a given excited energy level as a tub filled with water. A large drain that empties it in a short time corresponds to the possibility of transitions in which the angular momentum changes by one unit of $\hbar$. There are two tiny holes that are 10^4 and 10^8 smaller in area than the drain hole. If the drain is open, we can ignore any leakage through the small holes, but if the drain is blocked (if there are no possible $\Delta\ell = 1$ transitions), leakage occurs through the next smallest hole. It takes much longer to empty the tub through the tiny hole. If there are no possible $\Delta\ell = 1$ transitions, then the energy level is called *metastable*, or nearly stable. Metastable states play a critical role in the operation of the laser.



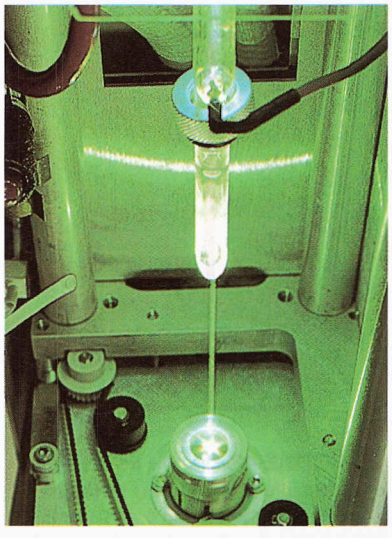
The discussion so far concerns what are known as *spontaneous transitions* in atoms. In 1917, Albert Einstein used thermodynamics together with the rudimentary quantum theory in existence at the time to predict the possibility of *stimulated transitions*. Consider an electron in a metastable state. It will stay in that state for a long time (long on the atomic scale, typically 10^{-8} s) before it decays with the emission of a single photon into the ground state. The energy of the photon will be $hf = E_i - E_f$, where E_i and E_f are the initial and final electron energies. Einstein discovered, however, that if photons of frequency f are present in the vicinity of the atom, then the very presence of these photons will make the transition occur more rapidly, and the rapidity

▲ **FIGURE 42–5** (a) In spontaneous emission, a photon is produced as an electron drops from an excited atomic state to a lower-lying level. (b) An atom can absorb a photon if the photon's frequency matches the energy difference between two atomic levels of the proper ℓ values.

▲ **FIGURE 42–6** The de-excitation of metastable $\ell = 2$ level is by the allowed excitation to the $\ell = 1$ level, followed by the allowed transition to the $\ell = 0$ state. The metastable level is populated by the inverse process: allowed excitation to the $\ell = 1$ state followed by the allowed decay to the ($\ell = 2$) state. Direct excitation from the $\ell = 0$ level to the $\ell = 2$ level is also possible in collisions.



▲ FIGURE 42–7 In stimulated emission, the decay from an excited state occurs more readily in the presence of photons in the same state as the photon to be emitted.



increases as the number of photons grows. We say that there is *stimulated emission* (Fig. 42–7). The more external photons, the more rapidly the stimulated emission occurs. There is another very important effect: *Because they are bosons, the photons emitted by stimulated emission will preferentially be in the same quantum state as the stimulating photons*; that is, they will have the same momentum, frequency, and phase. A *coherent* state of many photons is formed, a state in which the electromagnetic fields associated with the photons reinforce. This coherent state describes a single, intense, monochromatic plane wave, or beam. Moreover, because the photons have the same momentum (both magnitude and direction), the beam is extremely well collimated. The functioning of lasers relies on the existence of such stimulated transitions. The term *laser* is in fact an acronym for "light amplification by stimulated emission of radiation."

Lasers

Suppose that we have a collection of atoms in a cavity, each of which is in a metastable state. The presence of many photons of energy hf will stimulate a very rapid transition to the ground state, where f is the frequency corresponding to the transition to the ground state. Without the presence of these photons, the atoms will remain in the metastable state for a long time. We may then picture the following sequence: After a long time, one atom decays to the ground state and emits a photon of energy hf. The photon (as well as many others to follow) is constrained to stay in the cavity by means of mirrors positioned to reflect the photon back into the cavity (Fig. 42–8a). Other atoms in the metastable state, stimulated by the first photon, undergo a slightly faster transition to the ground state and produce more photons in the same state. The ever increasing number of the "right" photons—those that induce stimulated emission—produces an avalanche of decays. These photons can form a well-collimated, coherent *laser beam* (Fig. 42–8b).

(a)

(b)

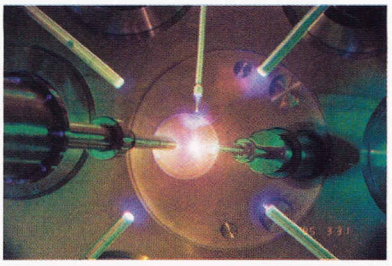
▲ FIGURE 42–8 (a) Schematic diagram of a laser. The mirrors are present to contain photons and provide the conditions necessary for stimulated emission. (b) A krypton laser under test.

The fraction of the radiation reflected back into the tube is over 99 percent, allowing the cascade of stimulated emission to occur rapidly. To form a coherent beam, many of the photons bouncing back and forth between the reflectors must be extracted, so one of the mirrors at the ends of the tube is not a perfect reflector. Photons that emerge from the tube do so as a coherent, monochromatic, and well-collimated beam through the partly reflecting mirror. The coherent state is so intense that even though only 1 percent of the photons emerge, the beam is intense enough to be useful.

In summary, the construction of a laser requires:

1. A collection of atoms that contain a metastable energy level into which many atoms can be excited.
2. A mechanism for holding emitted photons in a cavity containing excited atoms so that there is a massive stimulated deexcitation of the excited atoms (a laser transition).
3. A mechanism for repopulating the excited level after the laser transition has taken place, basically a repeat of step 1.
4. A way for the coherent laser beam to be extracted sufficiently well to be useful.

Some Uses of Lasers



We described in Chapter 35 how the ability to measure time intervals accurately allows us to use lasers to perform *ranging*, or a measurement of distance (see the discussion on corner reflectors on p. 980). The coherence of the laser beam is crucial in *holography*, as we described in Chapter 38. Lasers are an important part of optical readers, found in CD players and checkout counters. They hold promise as a way to manipulate systems as small as individual atoms,[†] and the ability to do this will be of increasing importance in quantum engineering (see Chapter 43).

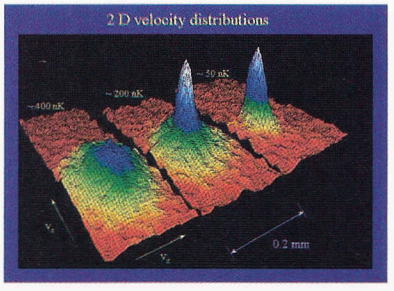
In Chapter 19 we discussed isotope separation and its significance. An application of lasers occurs in a commercially important method of isotope separation that works as follows: The spectra of different isotopes of an element differ slightly because of tiny differences in their nuclear masses and magnetic dipole moments. Both properties affect the

[†]See S. Chu, "Laser Trapping of Neutral Particles," *Scientific American*, Feb. 1992, p. 70.

atomic energy levels. If atoms consisting of a mixture of isotopes are irradiated with a laser beam tuned very precisely to a transition frequency of only one of the isotopes, then the atoms of only those isotopes will be excited. For example, a suitably tuned laser beam can excite atoms of ^{235}U but not atoms of ^{238}U. A second laser beam with enough energy to ionize the already excited ^{235}U atoms but not ^{238}U atoms is then applied. The charged ions of ^{235}U can now be separated by electric fields from the un-ionized atoms of ^{238}U.

Lasers also have important applications in medicine. One of their first uses was to reattach detached retinas. The lens of the eye focuses a laser beam onto a small area of the retina, which fuses to the tissue from which it has become detached. Because the energy is delivered in a short time, there is no need to immobilize the eye. Infections are less likely to occur than with surgical procedures. Lasers can also be used to cauterize internal wounds and stop bleeding. We can mention also the potential application of lasers for controlled thermonuclear fusion reactions (to be discussed further in Chapter 44). Laser beams focused on lightweight nuclei may be able to provide the energy necessary for them to fuse and produce additional energy. Figure 42–9 illustrates an apparatus designed for this job.

▲ **FIGURE 42–9** The intense laser beams of the OMEGA system at the University of Rochester focus simultaneously on a pellet in order to produce a state hot enough and dense enough to cause thermonuclear fusion.



Lasers play an important role in the scientifically interesting process of the slowing down, or *cooling*, of atoms. From our knowledge of the Doppler shift, we can say that an atom moving with speed v toward the source of a laser beam of a certain frequency f sees the frequency shifted upward to $f(1 + v/c)$. If we choose f to be just under the frequency at which a photon is readily absorbed, then if the atom moves toward the source, it absorbs the photon and its momentum and is therefore slowed down. The photon is, of course, reemitted, but the direction in which this happens is not related to the direction of the initial motion. The net effect is that on average the atom is slowed down. If there are two beams, one coming along the $+x$-axis and one along the $-x$-axis, then any atom moving along the x-axis will be slowed down, whether it moves to the right or to the left. A set up of six laser beams, all tuned to a frequency just below the absorption frequency, will slow the atoms down no matter what their direction of motion. The electromagnetic field in the environment of our atom has been described as *optical molasses*. The creation of optical molasses requires a tunable laser with an extremely accurate control of its frequency. This method of cooling atoms was essential to the creation of the first Bose-Einstein condensate.

Bose-Einstein Condensation

As the temperature is lowered in a gas of bosons, a phase transition can occur at a critical temperature T_c. In this transition, a large number of bosons accumulate in a single lowest-energy state composed of large numbers of these bosons. In his original work on this subject, Einstein was able to find an expression for T_c.

Classical kinetic theory (see Chapter 19) shows that for a gas of atoms, the root mean square speed v_{rms} and hence the root mean square momentum is proportional to $T^{1/2}$. The de Broglie wavelength is h/p and therefore increases as the temperature is lowered. Thus it is only at low temperatures, when the de Broglie wavelength becomes comparable to the interparticle spacing, that collective quantum effects can become important. At the same time, we want to work where the density of the atoms is very small in order to avoid the effects of interatomic forces. Most of the time, the atoms condense to a liquid and then to a solid well before the quantum domain is reached. When the gas of atoms is very dilute, however, so that the interparticle forces are almost negligible, then quantum effects become important. In particular, a gas of atoms of integer angular momentum is a gas of bosons, and at a critical temperature the atoms cease their independent existence. As the temperature is lowered, more and more join together to form a single quantum state.

In 1995 Eric Cornell and Carl Wieman cooled a gas of ^{87}Rb atoms to a temperature of only 20×10^{-9} K. This was achieved by a combination of laser cooling (which brought the temperature down to 10^{-4}K) and a technique known as evaporative cooling, in which the more energetic atoms are allowed to leave the collection of atoms, leaving behind only the coldest (least energetic) ones. The condensate, which is held in a kind of magnetic trap, manifests itself as a cloud. When the trap is suddenly switched off, the central part of the cloud expands very slowly, showing that it consists of a coherent object at effectively zero speed. Figure 42–10 shows how the lowering of temperature from 400nK

▲ **FIGURE 42–10** A computer-generated image of the velocity distribution in the first Bose-Einstein condensate created at the University of Colorado. As the temperature is lowered from 400nK to 200nK (corresponding to the leftmost and center image, respectively), the atoms condense to form a single quantum system with zero velocity, the effect of which here is the sharp peak. The peak is stable and is even more prominent in the rightmost image, which is at a temperature of 50nK.

to 200nK produces a peak around zero in the speed plot. Individual atoms will not give such a peak; only a large quantum state consisting of millions of atoms can do it.

The Bose-Einstein condensate produced in this way is a new state of matter—so new, in fact, that its technological usefulness has not yet been explored. If the field is anything like the field of lasers, then given what has happened with lasers since the first one was made in the early 1960s, the potential for Bose-Einstein condensates is enormous.

EXAMPLE 42–4 The expression found by Einstein for the critical temperature T_c at which a Bose-Einstein condensate forms is

$$n = \frac{2.31}{4\pi^2}\left(\frac{2mkT_c}{\hbar^2}\right)^{3/2},$$

where n is the number density and m is the mass of the bosonic atoms. What is the density of ^{87}Rb atoms for a critical temperature of 2×10^{-7} K?

Strategy The calculation is a direct application of the expression above. The mass of an ^{87}Rb atom is, to a good approximation, 87 times a nucleon mass, 1.67×10^{-27} kg.

Working It Out We have

$$n = \frac{2.31}{4\pi^2}\left[\frac{2(87 \times 1.67 \times 10^{-27}\,\text{kg})(1.38 \times 10^{-23}\,\text{J/K})(2 \times 10^{-7}\,\text{K})}{(1.055 \times 10^{-34}\,\text{J}\cdot\text{s})^2}\right]^{3/2}$$
$$= 3.6 \times 10^{19}\,\text{atoms/m}^3.$$

This is a very dilute gas indeed; the density of air at STP is about 3×10^{25} molecules/m^3.

What Do You Think? What is the de Broglie wavelength at T_c, and how does it support our qualitative argument about the onset of quantum phenomena in gases?

CONCEPTUAL EXAMPLE 42–5 Hydrogen atoms are bosons that are composites of fermions: two particles of half-integer spin, an electron and a nucleus composed of a single proton. Does this mean that we can squeeze two hydrogen atoms together until they overlap strongly?

Answer As soon as the electrons or the protons get to within a de Broglie wavelength of each other, the effective repulsion due to the exclusion principle for fermions becomes significant. We know from the previous chapter that the de Broglie wavelength of an electron in hydrogen is of the order of an atomic orbit, so squeezing will become hard due to fermionic "repulsion" once the atoms are immediately adjacent, and this is part of what determines the size of a hydrogen molecule.

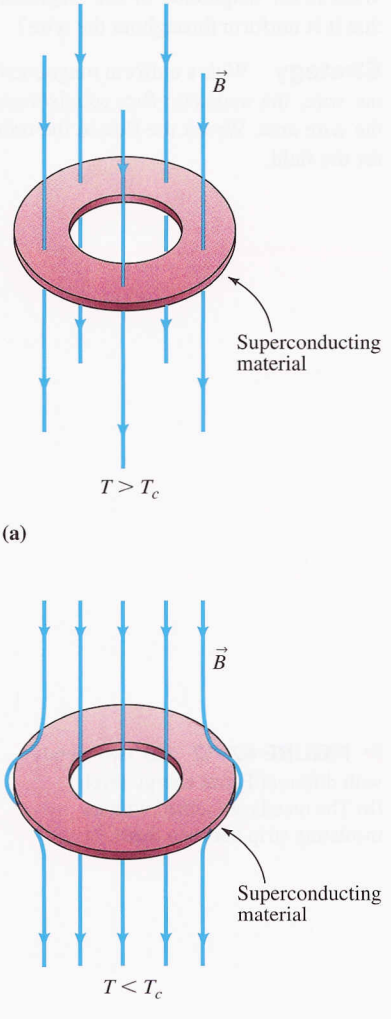
42–3 Superconductivity

In Section 26–6 we described the phenomenon of superconductivity, with a further discussion of the remarkable magnetic properties of superconductors in Section 31–5. Superconducting materials have no resistance at temperatures below a critical temperature, in which case we say they are in the superconducting state. In addition, they either expel magnetic field completely or confine it to filaments when they are in the superconducting state. The phenomenon has technological importance in a number of domains, including the large magnets used in medical resonance imaging—the current flows necessary to produce these magnetic fields would produce an unmanageable amount of thermal energy were they not carried in superconducting wires. We are at this point equipped to understand a little of the physics that lies behind the phenomenon of superconductivity.

Cooper Pairs and the BCS Theory

In our discussion of fermions and the Fermi energy in metals, we ignored all dynamic interactions among the fermions. How can this make sense, given that electrons repel each other because of their electric charges? The exclusion principle explains why electron–electron interactions are not very important in ordinary metals. Consider two electrons in different states. Their interaction would manifest itself in some change of state—that is the only way we would see that something had happened. However, the vast majority of electrons cannot change states because the states above and below their own state are already fully occupied, and the exclusion principle forbids further occupation. Interactions do lead to some modification of the predictions of the free-electron theory, and these modifications are well understood.

The phenomenon of superconductivity also involves interactions, but between the electrons and the vibrating lattices of ions in a metal. For complicated reasons that



were first understood by Leon Cooper, the electron–ion interaction has as a secondary effect a weak *attraction* between electrons with energies that are close to the Fermi energy. This attraction leads to the formation of weakly bound pairs of electrons known as **Cooper pairs**. Their binding is so weak that they can be quite far apart from one another, as much as hundreds of lattice spacings—in quantum-mechanical language this is the statement that the wave function of the bound state is very spread out. (Indeed, this is the only way the pair can exist in the presence of a Coulomb repulsion—the Coulomb force between the electrons is screened by the presence of the lattice when the electrons are far apart.) The spread-out wave function means that many Cooper pairs may overlap each other, and we cannot think of Cooper pairs as "atoms" consisting of two electrons, because such a term implies that the bound system is localized, with each pair well separated. Although different pairs overlap spatially, there is a sense in which two electrons that make up a Cooper pair are tightly correlated, acting as a true pair: The electrons have equal and opposite momenta, and opposite spins. Because the pairs have lower energies than free electrons—it takes some energy to separate the electrons that form a pair—an energy gap of width $2\Delta \cong 10^{-3}$ eV develops about the Fermi energy, meaning that there are no electron states with energies that lie between $E_F - \Delta$ and $E_F + \Delta$. The gap width is small compared to the Fermi energy itself.

John Bardeen, Leon Cooper, and Robert Schrieffer constructed a theory in 1957—the so-called BCS theory—that explained satisfactorily all of the observations about superconductors known at the time. For most superconducting materials a Cooper pair has a total angular momentum of 0. Although, strictly speaking, a pair cannot be treated as a boson such as a helium atom, a pair shares some crucial properties with bosons. In particular, the BCS theory proposed that the Cooper pairs all condense into the same state when the material's temperature drops below a critical temperature T_c that is approximately given by the gap width divided by the Boltzmann constant. This condensation signals an abrupt change in the properties of the metal, a change somewhat analogous to the phase change from liquid to solid.

The BCS Theory and the Electromagnetic Properties of Superconductors

The most striking property of superconductors is that their resistivity is zero below T_c. This phenomenon is explained by the coherence of the superconducting state. In a normal metal, when a current starts and there is no potential difference to maintain it, the electrons scatter from the lattice and give up energy. The energy appears as ohmic (I^2R) heating and the current rapidly decays. In a superconductor, however, a large number of electron pairs move together in a coordinated way. For the superconductor to lose energy, *the entire coherent state would have to be broken up*, and this would require a large amount of energy to be supplied at once. The mechanisms of ordinary electrical resistance cannot work if a macroscopic number of electron–electron pairs (say, 10^{22}) must be slowed down *all at once*. An analogy is the difference between pushing your hand through liquid water (analogous to a "normal" metal) and pushing your hand against an icicle (analagous to a "superconductor"). In the first case, there are easy ways to lose just a little energy: You can form arbitrarily small waves and eddies. In the second case, you can lose a large amount of energy only all at once, when you break the icicle.

The Meissner effect, which as we saw in Chapter 31 states that no magnetic field can penetrate a superconductor and that a magnetic field already present is expelled when a metal is cooled below T_c (Fig. 42–11), is also described by the BCS theory. The inability to establish a magnetic field within a superconductor is once again a consequence of the coherence of the superconducting state. If you were to try to increase a magnetic field inside a superconductor, you would induce an emf within the material by Faraday's law. A current would be induced to oppose the change in magnetic flux. But because all the Cooper pairs act together, even the tiniest change in magnetic flux can generate a current sufficiently large to cancel entirely the inducing field within the superconductor.

▲ **FIGURE 42–11** Magnetic field lines expelled by a ring of material that makes a transition to the superconducting state when the temperature drops below the critical temperature T_c. Flux is trapped by the hole.

Flux Quantization

Suppose that we place into a magnetic field a ring of superconducting material that is above its critical temperature. The ring lies in a plane perpendicular to the field direction. We now lower the temperature of the material below T_c so that the material becomes superconducting. The field is expelled, and all the field lines will be either outside the ring or confined within the ring (Fig. 42–11).

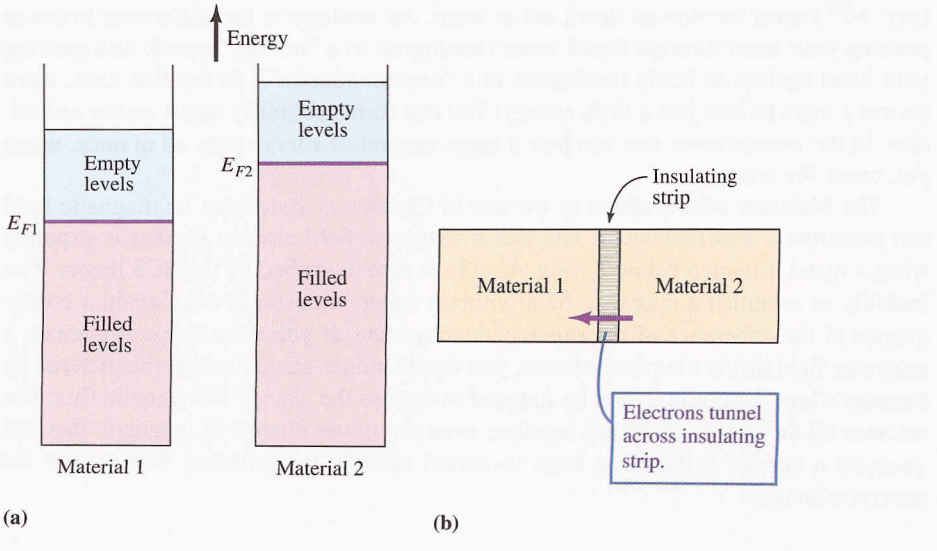
The BCS theory can be used to show that the coherence of the superconducting state implies that *the magnetic flux through the ring is quantized in units of* $h/2e$:

$$\Phi_B = \frac{nh}{2e} \equiv n\Phi_0, \qquad \text{where } n = 1, 2, \ldots. \tag{42–13}$$

The quantity Φ_0 is the *magnetic flux quantum*, with value 2.07×10^{-15} Wb $= 2.07 \times 10^{-15}\ \text{T} \cdot \text{m}^2$. The charge $2e$ that appears here is the charge of a Cooper pair. The prediction that flux is quantized has been successfully tested by experiment.

EXAMPLE 42–6 A single unit of the quantized flux Φ_0 is confined within a cylinder of copper wire of diameter 1.3×10^{-5} m. What is the magnitude of the magnetic field in the wire, assuming that it is uniform throughout the wire?

Strategy With a uniform magnetic field across a cross section of the wire, the magnetic flux equals the magnitude of the field times the wire area. We set the flux to the unit of quantized flux and solve for the field.



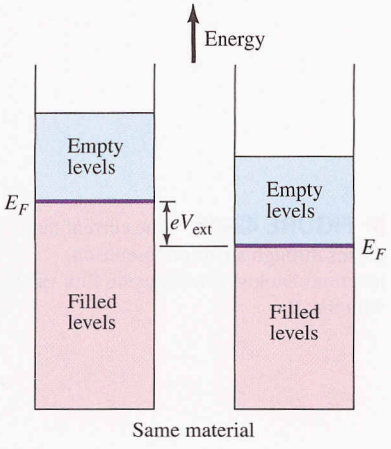
Working It Out The unit of flux is $\Phi_0 = 2.07 \times 10^{-15}\ \text{T} \cdot \text{m}^2$. With the magnetic field magnitude written as B and the wire radius R, the flux is given by the surface integral of the component of the magnetic field perpendicular to the area elements over the total area, $\Phi_0 = \int \vec{B} \cdot d\vec{A} = B \times \pi R^2$. We can solve for B:

$$B = \frac{\Phi_0}{\pi R^2} = \frac{2.07 \times 10^{-15}\ \text{T} \cdot \text{m}^2}{\pi (0.65 \times 10^{-5}\ \text{m})^2} = 1.6 \times 10^{-5}\ \text{T}.$$

This is only about a factor of 6 less than Earth's magnetic field and is quite measurable.

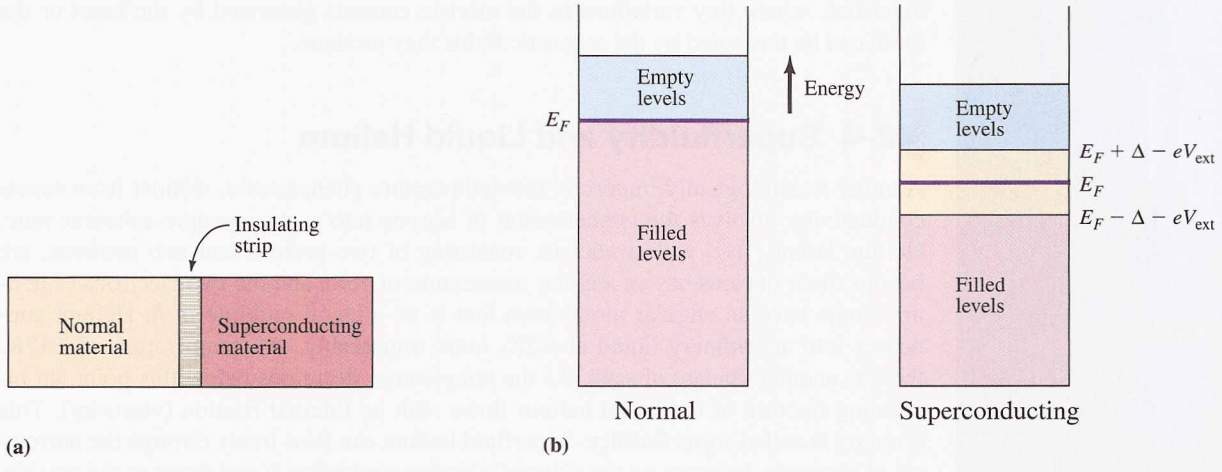
Tunneling of Pairs and the Josephson Effects

We saw in our discussion in Sections 7–2 and 40–2 that quantum-mechanical tunneling, in which particles such as electrons can cross potential barriers—a classically forbidden process—has important technological implications. Tunneling can occur across junctions between normal metals, between normal metals and superconductors, and between superconductors. Here, "junction" refers to a very thin insulating strip between two pieces of metal. The insulating strip is formed from a material that can be evaporated and then deposited in thin, uniform layers. If the strip is thin enough (10 nm to 20 nm), an electron can tunnel across it from one metal to the other. Let's consider two normal metals (materials 1 and 2), with Fermi energies E_{F1} and E_{F2}, respectively. If $E_{F2} > E_{F1}$ (Fig. 42–12a), then, since they find lower energy levels to occupy, electrons can tunnel through the barrier formed by the insulating strip, moving from metal 2 to metal 1 (Fig. 42–12b).

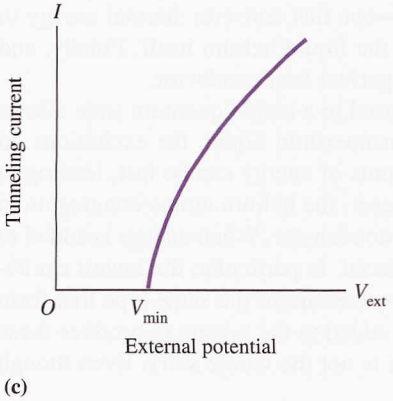


▶ **FIGURE 42–12** (a) Two metals with different Fermi energy levels. (b) The metals are joined with an insulating strip between them.

If the two metals are identical, there will be no tunneling—at least at very low temperatures—because there are no empty states to occupy. However, if an external potential V_{ext} is imposed, the levels on one side of the junction will be lowered relative to those on the other side of the junction, and tunneling is again possible (Fig. 42–13).

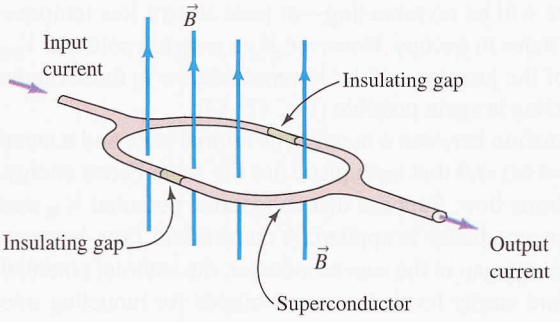


Now suppose that we have a junction between a metal in its normal state and a metal in a superconducting state (Fig. 42–14a) and that each piece has the same Fermi energy. With no external potential, no electrons flow. Suppose that an external potential V_{ext} that lowers the Fermi energy of the superconductor is applied. A current will flow between normal metals, but because of the energy gap in the superconductor, the external potential must exceed a minimum value before empty levels become available for tunneling into (Fig. 42–14b). This minimum value is given by $eV_{min} = \Delta$ and, by varying the external potential and observing the onset of tunneling, it is possible to measure the gap size. Figure 42–14c illustrates the relationship between current and potential in this case.



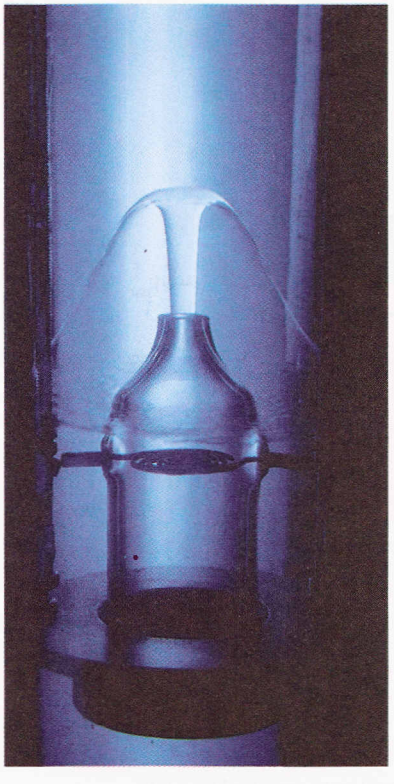
Let's now consider two superconductors separated by a thin insulating strip, an arrangement known as a *Josephson junction*. At first there might appear to be little current across the barrier. If the probability of a single electron tunneling through is very small, then, because the probability of two independent electrons tunneling through is the product of the tunneling probabilities of the individual electrons, there would be very little tunneling for an electron pair. In 1962, Brian Josephson noted that if the barrier is less than 1 nm thick, the two superconductors form a single, coherent quantum system. As a result, what tunnels through the barrier is not two individual electrons, but a pair of electrons as a unit. This has two consequences (we shall prove neither here): First, *even in the absence of a potential difference between two identical superconductors, a tunneling current will flow across a Josephson junction*. This is called the *DC Josephson effect*. Second, *when there is a constant potential difference V across the barrier between two superconductors, the current that flows between them oscillates with angular frequency*

$$\omega = \frac{2e}{\hbar}V. \qquad (42\text{–}14)$$



▲ **FIGURE 42–13** When an electric potential that lowers the levels on the right-hand side compared to those of the left-hand side is applied, a tunneling current flows from left to right across the insulating strip. In this case, the metals on both sides of the strip are the same.

▲ **FIGURE 42–14** (a) A metal in its normal state separated by a thin insulating strip from the same metal in its superconducting state. (b) An energy diagram of this situation, including an external potential, V_{ext}, applied so that the energy levels in the superconducting metal are lowered with respect to those in the normal metal. Because an energy gap is present in the superconductor, the potential must be a certain minimum size before electrons from the normal metal can tunnel into the empty levels of the superconductor. This minimum value of V_{ext} is given by $eV_{min} = \Delta$. (c) The flow of tunneling current in the junction described in Fig. 42–14a as a function of V_{ext}. V_{ext} must have the minimum value V_{min} before current can flow.



▶ **FIGURE 42–15** The current that passes through a pair of Josephson junctions enclosing a magnetic flux varies with that flux.

This phenomenon is called the *AC Josephson effect*. Because frequencies can be measured with great precision, the AC Josephson effect provides physicists and engineers with the most accurate way known of standardizing voltage measurements. Equivalently, it allows the most precise measurement possible of the fundamental ratio $e/\hbar$.

Consider two Josephson junctions connected in parallel (Fig. 42–15). Like the interference pattern produced by an electron passing through a double slit, an interference pattern appears in the net current. The interference pattern is affected by a magnetic flux enclosed by the two arms of the pair of junctions. The flux plays the same role in the pair of Josephson junctions that the slit separation plays in a double-slit experiment. The dependence of the current on the enclosed magnetic flux Φ_B is given by

$$J = J_{\max} \cos\left(\frac{e\Phi_B}{\hbar}\right). \tag{42–15}$$

This phenomenon allows us to measure magnetic flux precisely. The SQUID (Superconducting QUantum Interference Device), which is based on the phenomenon described, is widely used for high-precision measurements of very tiny magnetic fluxes. Magnetic fields as small as 10^{-13} T have been measured. With SQUIDs, an esoteric quantum mechanical phenomenon has become a major technological tool in medical diagnostics, where tiny variations in the electric currents generated by the heart or the brain can be measured by the magnetic fields they produce.

▲ **FIGURE 42–16** The fountain effect of superfluid helium, which flows without viscosity and exhibits a number of phenomena not seen in ordinary fluids—here we see it flowing against gravity through an orifice under the influence of interparticle forces and continuing through to form a type of fountain.

42–4 Superfluidity and Liquid Helium

Another technologically important low-temperature phenomenon, distinct from superconductivity, involves the condensation of bosons into a macroscopic coherent state. Helium atoms, ^{4}He, with a nucleus consisting of two protons and two neutrons, are bosons; their nucleus has an angular momentum of zero, and the two electrons of helium atoms have an angular momentum that is an integral multiple of $\hbar$. Helium condenses into an ordinary liquid at 4.2K; more remarkably, at a temperature of 2.17K, there is another change of state. As the temperature decreases below this point, an increasing fraction of the liquid helium flows with no internal friction (viscosity). This property is called **superfluidity**. Superfluid helium can flow freely through the narrowest of channels. It creeps up the sides of a beaker containing it and flows to the outside, even escaping through a hole to make a fountain (Fig. 42–16). It can be used to make the most nearly perfect (frictionless) heat engine—one that converts thermal energy to kinetic energy with no moving parts save that of the liquid helium itself. Finally, and most important technologically, it makes a nearly perfect heat conductor.

The fact that atoms of ^{4}He are bosons condensed in a single quantum state allows us to explain these properties. In an ordinary, nonsuperfluid liquid, the excitations do not involve the entire fluid. Arbitrarily small amounts of energy can be lost, leading to viscosity at any speed. In superfluid helium, however, the helium atoms congregate in the same (coherent) ground state, a Bose-Einstein condensate. When energy is added to the system, excitations of the entire fluid are produced. In particular, the lowest excitations are compressional, or sound, waves. (These waves are of the same type that form sound waves in solids.) Very little energy must be added to the system to produce these excitations. However, the energy of the excitation is not the whole story. Even though

sound waves are the excitations of lowest energy, it is difficult to excite them mechanically, and this class of excitations is not useful for carrying off mechanical energy; that is, they produce no internal friction. To understand the significance of this remark, let's consider the process by which friction is produced.

When we drag a sphere of mass M through liquid helium, we will create an excitation only if the sphere gives up some energy and momentum to the liquid. Such excitations are discrete quantum mechanical states that correspond to motion of the entire system of liquid helium, and the excitations have a definite momentum $\vec{p}$ and energy E. Momentum conservation states that

$$M\vec{v}_i = \vec{p} + M\vec{v}_f,$$

where $\vec{v}_i$ is the initial velocity of the sphere and $\vec{v}_f$ is its velocity after it has given up some energy. Then $\vec{v}_f = \vec{v}_i - \vec{p}/M$. Similarly, energy conservation gives

$$\frac{1}{2}Mv_i^2 = E + \frac{1}{2}Mv_f^2.$$

We substitute $\vec{v}_f$ into the energy conservation equation:

$$\frac{1}{2}Mv_i^2 = E + \frac{1}{2}\left(Mv_i^2 - 2\vec{v}_i\cdot\vec{p} + \frac{p^2}{M}\right) \cong E + \frac{1}{2}Mv_i^2 - \vec{v}_i\cdot\vec{p}.$$

We dropped the last term on the right because M is large (macroscopic). Solving for E,

$$E = \vec{v}_i\cdot\vec{p}. \tag{42–16}$$

As long as this relation can be satisfied, it will be possible for the sphere to lose kinetic energy by causing excitations in the liquid, and there will therefore be resistance to the motion of the sphere. But if it cannot be satisfied, the sphere has no way to lose energy.

Let's see whether it is possible for sound waves to be excited in this way. Now sound waves themselves obey the rules of quantum mechanics, meaning that if one looks at sound of very low energy, one will see that it comes in quantized packets. The relation between energy and momentum in these packets of sound is given by

$$E = v_s p,$$

where v_s is a constant, the velocity of a sound wave. This is analogous to the relation between energy and momentum for photons. In fact, the quanta of the acoustic field that manifests itself as sound waves are called *phonons*. We see that for $v_i < v_s$, Eq. (42–16) cannot be satisfied, and *there is no way for the sphere to lose energy*. It therefore travels with *no viscosity*—superfluidity.

THINK ABOUT THIS. . .

OF WHAT USE IS SUPERFLUID HELIUM?

The technological importance of the properties of superfluid helium is closely linked to the importance of superconductivity. Superconducting systems such as the large superconducting magnets used in particle accelerators or MRI apparatus must be kept at temperatures below their critical temperature. The failure of superconductivity in such a system can be very destructive, with the large currents suddenly producing large amounts of thermal energy. The only practical superconductors that can be used for such magnets are those for which liquid helium is sufficiently cold to form a coolant. Here, the fact that the liquid ^{4}He is in a single quantum state plays an important role. First, it is a nearly perfect heat conductor—its coefficient of thermal conductivity is hundreds of thousands of times greater than that of copper. That is because a less-than-perfect thermal conductivity is associated with collisions in which whatever carries off the thermal energy (in the case of liquid helium it is carried off by vibrational excitations) can lose small amounts of that energy in collisions, and there is no way to lose only small amounts of thermal energy in a collision with a single quantum state. Moreover, and for similar reasons, boiling cannot occur at any one location, and this offers crucial insurance against any of the magnet coils heating beyond its critical temperature. In other words, no "hot spots" can form. The Large Hadron Collider accelerator, under construction at CERN, headquartered in Geneva, Switzerland, will operate with a large array of magnets cooled by a connected system of superfluid helium.

The creeping of liquid helium up the sides of a beaker depends on the difficulty of dissipating arbitrarily small amounts of energy. In this situation the superfluid can respond vigorously to very small forces such as the van der Waals forces between neighboring helium atoms and between the atoms of helium and of the beaker walls. While the details of the mechanisms that produce these strange properties are more complicated than we can get into here, the phenomena themselves provide another demonstration of quantum effects on a large scale.

Summary

In large systems for which quantum mechanics governs the dynamics, the Pauli exclusion principle plays a crucial role if the system is composed of fermions. This principle states that only one fermion—for our purposes, a particle with spin $\hbar/2$—of a given type can occupy a particular state such as an energy level. In metals, this means that very closely spaced energy levels are filled with electrons up to the Fermi energy, E_F. The Fermi energy of electrons is

$$E_F = \frac{\hbar^2}{2m_e}(3\pi^2 n_e)^{2/3}, \tag{42–5}$$

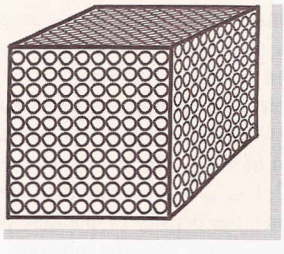
where n_e is the electron number density in the metal. Only electrons near the top of the filled levels take part in dynamic processes such as current flow.

The exclusion principle is responsible for the incompressibility of matter. In ordinary matter the incompressibility can be estimated to within a factor of 2 by assuming that the electrons in the matter are free. The exclusion principle prevents stars that are not too massive from collapsing under the mutual gravitational attraction of their constituents.

A system composed of bosons—particles whose spins are integral multiples of $\hbar$ such as photons and ^{4}He atoms—manifests quantum mechanical effects quite different from those of fermionic systems. Identical bosons have an enhanced probability of aggregating in the same quantum state. As a consequence, there can be stimulated emission of radiation (photons) into states already occupied by other photons. The operation of the laser is based on stimulated emission and on the bosonic properties of photons. To construct a laser, we need a way to populate an excited energy level in a collection of atoms; a way to build up many photons of the "proper" energy to provoke a massive stimulated transition from the excited level; and a way to extract the coherent laser beam formed by the stimulated emission.

Fermions can pair up to form bosons, and those correlated pairs tend to congregate in the same quantum state. This is the mechanism behind superconductivity. Superconductors form when a collection of electron–electron pairs known as Cooper pairs occupy a single, coherent quantum state at low temperatures. Cooper pairs can tunnel, and this phenomenon has advanced our ability to observe very small magnetic fields. Superfluidity, characterized by flow without viscosity in superfluid ^{4}He, is another phenomenon that follows from the tendency of bosons to condense in the same quantum state at low temperatures.

Understanding the Concepts



1. How would the behavior of electrons in materials change if the Pauli exclusion principle were not applicable?
2. Most heavenly bodies rotate and have some angular momentum. Astrophysicists believe that pulsars are rapidly rotating neutron stars, some with periods as short as 0.005 s. Explain how such a small, massive object could rotate so fast.
3. Where does the fact that photons tend to congregate in the same quantum state play a role in our discussion of lasers?
4. You have perhaps heard that neutrinos interact only very slightly with matter and therefore could not be confined in the way that is described here. Does this make the exercise in Example 42–1 totally useless? In thinking about the answer to this question, ask yourself whether there might be highly relativistic systems of fermions in nature in which the constituents are effectively confined.
5. The *Fermi temperature*, T_F, is defined by $E_F \equiv kT_F$. What does it mean if T_F in a given material is much larger or much smaller than the material's temperature?
6. Describe the steps in the evolution of a star that becomes a black hole.
7. Is the neutron star described in Example 42–3 relativistic? That is, do its constituents move relativistically? What is the general criterion for deciding when such a system is relativistic?
8. An electron on the Moon and an electron on Earth both have spin up and are in the ground state of hydrogen. Given that both electrons are in the same state, how is the Pauli exclusion principle bypassed?
9. Suppose that a crystal could be made from the atoms of the inert gases (by going to low temperatures, for example). Would such a crystal be likely to act as a metal?
10. The spins of the two electrons in the ground state of helium can be either parallel or antiparallel. The Pauli exclusion principle does not apply to antiparallel spins, but electrons with parallel spins must avoid each other. Would you expect the two possible spin arrangements to have the same energy? If not, which energy would be lower?

11. How could you tell if electrons in very distant galaxies obey the Pauli exclusion principle?
12. Given our discussion of stellar evolution, why is Jupiter not a star? (Assume that Jupiter is an aggregate of hydrogen atoms held together by gravity.)
13. An electron traveling through a collection of protons in a plasma is slowed down by collisions and captured into an orbit with a large principal quantum number, far from the proton it orbits. Given that radiative transitions are largely those for which $\Delta\ell = \pm 1$, would the electron end up in the ground state through one transition or through a sequence of transitions?
14. The filament of a lightbulb has many atoms that become thermally excited into the same excited states. Why doesn't the bulb act as a laser?
15. What difficulties might you encounter in an attempt to make an X-ray laser?
16. Use the argument as to why the flow of superconducting helium around an obstacle is nonviscous when the flow occurs at a speed less than that of sound to explain why electron waves propagate without energy loss through a rigid crystal lattice at $T = 0$. Why will the electrons experience resistance at finite temperatures?
17. In our treatment of the incompressibility of ordinary matter, we spoke about metals rather than a more general class of solids. Does our discussion apply to insulators? (See Chapter 26 for the difference between conductors and insulators.)

Problems

42–1 The Exclusion Principle in Bulk Matter

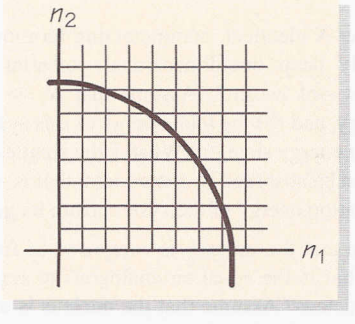
1. (I) What is the value of the Fermi energy of calcium, which has two valence electrons per atom? The gram-atomic weight of calcium is 40.1 g/mol, and its mass density is 2.30 g/cm^3.
2. (I) Find the Fermi temperature (see Question 5) of gold, for which the Fermi energy is 5.51 eV.
3. (I) Calculate the Fermi energies of sodium ($n_e = 2.65 \times 10^{28}$ m^{-3}), potassium ($n_e = 1.40 \times 10^{28}$ m^{-3}), and aluminum ($n_e = 18.1 \times 10^{28}$ m^{-3}). All these metals have a single valence electron per atom.
4. (I) Calculate the bulk moduli, B, of sodium, potassium, and aluminum, using the data given in Problem 3. (The experimental values of B for these materials are 0.64, 0.28, and 7.6, respectively, in units of 10^{10} N/m^2.)
5. (I) Zinc, a metal with two free electrons per atom, has a gram-atomic weight of 65.4 g/mol and a density of 7.13 g/cm^3. What is the density of electrons in zinc?
6. (I) The density of electrons in silver is 5.85×10^{28} electrons/m^3. Calculate the bulk modulus of silver. (The experimental value is 10.1×10^{10} N/m^2.)
7. (I) What values of $n_1 (= n_2 = n_3)$ give an energy close to 1.0 eV for an electron in a cubical box whose sides are precisely 100 nm long? What is the actual energy of this state? Of the state in which n_1 and n_2 are unchanged but n_3 is increased by 1?
8. (I) Consider a copper "nanoparticle," a cube of $10 \times 10 \times 10$ atoms (Fig. 42–17). Given that $n_e = 8.47 \times 10^{28}$ electrons/m^3, what is the energy difference between adjacent energy states in the neighborhood of the Fermi energy? Take the distance between neighboring atoms to be 0.25 nm.

▲ FIGURE 42–17 Problem 8.

9. (I) The Fermi energy of electrons in a metal, E_F, may be used to define the Fermi momentum, p_F, defined by $E_F \equiv p_F^2/(2m_e)$. Express the Fermi momentum in terms of n_e. Use your results to calculate the Fermi speed, v_F, the speed of an electron with the Fermi energy.
10. (I) What is the speed of an electron with the Fermi energy in magnesium, given that $n_e = 8.60 \times 10^{28}$ electrons/m^3?
11. (I) Estimate the gravitational pressure at the surface of the Sun.
12. (II) When the Fermi speed is, say, $0.1c$, where c is the speed of light, it is more appropriate to use a relativistic connection between E_F and p_F rather than the nonrelativistic connection that we used in Problem 9. Estimate the value of n_e for which the relativistic connection is necessary.
13. (II) The conduction electrons of a metal have to be treated relativistically when the Fermi speed is about $0.1c$ or more. Because they are confined to a small volume, the inner-shell electrons may also reach high speeds when Z is large. (a) Derive the condition on the density of conduction electrons that allows a nonrelativistic treatment. (b) Derive the condition on Z for which the innermost electrons can be treated nonrelativistically.
14. (II) Seven electrons are in an infinitely deep one-dimensional potential energy well of width L. (a) What is the lowest possible energy value for this system? (b) What is the next highest energy value? In both parts, ignore Coulomb interactions between the electrons.
15. (II) Consider N identical, noninteracting fermions of mass m in an infinitely deep one-dimensional potential energy square well—a box—of width L. Assume that $N \gg 1$. Find (a) the Fermi energy, and (b) the total energy of this system of particles in its lowest energy state. (c) What is the smallest amount of energy that can be absorbed by the system; that is, what is the minimum excitation energy of the system from its ground state?
16. (II) Assume that the nucleus is composed of free neutrons and protons. What is the equation analogous to Eq. (42–1) for the case of a nucleus? Assume that the nucleus is a cubic box with sides L. L is such that the box volume is the same as a sphere of radius $R = r_0 A^{1/3}$, where A is the total number of neutrons and protons and $r_0 \cong 1.2 \times 10^{-15}$ m.
17. (II) Calculate the Fermi energy for the neutrons confined to the nucleus ^{96}Mo, which roughly forms a sphere of radius 5.5×10^{-15} m. (There are 54 neutrons in the ^{96}Mo nucleus.)

18. (II) The general definition of the pressure in a gas with internal energy U is $p = -(\partial U/\partial V)$, where V is the volume of gas. (This follows from the first law of thermodynamics and from the fact that the infinitesimal work done when a system changes volume by dV is $dW = p\,dV$.) Given the fact that for a gas of identical fermions at $T = 0$, $U = 3/5\ NE_F$, show that at $T = 0$, $p = (2/3)\,(U/V)$ for the fermion gas. This result is the *same* as our result in Chapter 19, where we studied the atomic origin of pressure. (That result did not depend on the precise distribution, so it is not surprising that we recover it here.)

19. (II) Using the result of Problem 18, (a) calculate the pressure of an ideal gas of N identical fermions at $T = 0$ in terms of the volume, and (b) evaluate the pressure of the degenerate electron gas at $T = 0$ in a sample of sodium. The density of free electrons in sodium is 2.65×10^{22} electrons/cm^3.



20. (II) Calculate the ratio of the degeneracy pressure of electrons to that of protons for a star such as our Sun. Assume that the star is electrically neutral.

21. (II) Suppose that electrons are confined to a plane at a density of n_e electrons per unit area. Follow the steps that lead to Eq. (42–5) to calculate the Fermi energy for such a system.

22. (II) An iron nucleus consists of 26 protons and 30 neutrons in a sphere of radius 6.0×10^{-15} m. Assume that none of the particles interact with each other. Calculate the Fermi energies of the protons and the neutrons.

23. (II) (a) Calculate the radius of a neutron star as a function of its mass. (b) Find the Fermi energy and Fermi momentum of a neutron star in terms of its radius and its mass. (c) Estimate the mass for which one should start to use the relativistic expression in part (b). Express your results in solar masses.

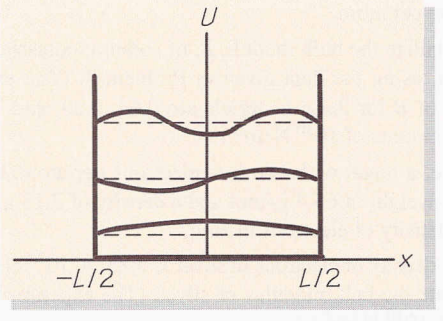
24. (III) A proper calculation of the Fermi energy in a cubical box with sides L amounts to counting the number of electrons that fill all the states up to an energy E_F. There are two states for each set of positive integers $\{n_1, n_2, n_3\}$ that satisfy the condition $n_1^2 + n_2^2 + n_3^2 = 2(m_e E_F L^2/\pi^2\hbar^2) \equiv R^2$. In a "continuum approximation" to the problem of counting the number of states, appropriate to large values of n_1, n_2, and n_3, the number of states is twice the volume of an octant (one-eighth) of a sphere of radius R; that is, $2\left(\frac{1}{8}\right)(4\pi/3)R^3$ (Fig. 42–18 is a two-dimensional version). Compare the answer in terms of the density with the approximate result that we gave in the text, $E_F \cong (\hbar^2/2m_e)(\pi^3 n_e)^{2/3}$.

▲ **FIGURE 42–18** Problems 24, 25.

25. (III) By counting the number of states (that is, by using the techniques described in Problem 24), calculate the Fermi energy for a two-dimensional gas of free, noninteracting electrons (Fig. 42–18). Show that $d = \lambda_F/2$, an approximation we made in our text discussion, is not as good as it is for a three-dimensional gas.

42–2 Lasers and the Behavior of Bosons

26. (I) A laser emits radiation of wavelength 590 nm and delivers power of 65 mW. How many photons are emitted per second?



27. (I) The characteristic red light of a He–Ne gas laser is due to stimulated emission between neon levels at 20.66 eV and 18.70 eV. Calculate the wavelength and frequency of the photon emission.

28. (I) A He–Ne laser emits radiation with a power of 42 mW at a wavelength of 632.8 nm. How many photons are emitted per second?

29. (I) A laser emits radiation at a wavelength of 555 nm. Photons are emitted at a rate of 8.5×10^{18} s^{-1}. What is the power of the laser?

30. (II) Free electrons in a magnetic field could form the basis of a tunable laser, in which the two levels involved in the transition are the "up" and "down" spin states of the electron in a magnetic field. How large a magnetic field is needed to operate the laser at 500 nm?

31. (II) Consider N identical bosons of mass m in an infinitely deep one-dimensional potential energy well of width L (Fig. 42–19). (a) What is the total energy of this system of particles in its lowest energy state? (b) What is the smallest amount of energy that can be absorbed by the system; that is, what is the minimum excitation energy of the system from its ground state?

▲ **FIGURE 42–19** Problem 31.

32. (II) The collimation of a laser beam is limited by diffraction; that is, the angular beam spread $\Delta\theta$ is at least as large as $\Delta\theta \cong \lambda/D$, where D is the diameter of the laser's aperture. What is the diameter of the beam spot projected on the Moon, 3.8×10^8 m from a laser of aperture diameter 18 mm emitting light of wavelength 550 nm?

33. (II) A laser beam projects light of wavelength 663 nm at the rate of 3.0×10^{17} photons/s. (a) What is the power of the laser? (b) What is the radiation pressure exerted by the beam on a shiny surface if the laser beam projects a circle 3.5 mm in diameter?

34. (III) In 1917, Einstein wrote a paper that describes the stimulated-emission process. We can summarize his results as follows: Suppose that an atom has two states. State 1 is the ground state; state 2 is an excited state. The atom is in an enclosure filled with blackbody radiation, which we recall from Chapter 17 has the energy-density function $u(f, T)$. The transition rate for excitation from state 1 to state 2, $\Gamma_{2\to1}$, is proportional to the number of atoms in state 1, N_1, times the density of photons present that have the proper frequency (such that the photons have the transition

energy): $\Gamma_{2\to1} = N_1 u(f,T) B_{12}$, where B_{12} is a proportionality constant. The transition rate for deexcitation from state 2 to state 1, $\Gamma_{2\to1}$, has two terms: a stimulated-emission term proportional to the number of atoms in state 2 times the density of photons present with the proper frequency, $N_2 u(f,T) B_{21}$, and a spontaneous-emission term proportional to the number of atoms in state 2. Thus $\Gamma_{2\to1} = N_2[u(f,T)B_{21} + A]$, where A is a constant. (a) In thermodynamic equilibrium, the transition rate in the two directions must be equal. Use this fact, together with the Boltzmann relation for the populations, $(N_1/N_2) = e^{-E_1/kT}/e^{-E_2/kT}$, to show that

$$u(f,T) = \frac{A}{B_{12}e^{hf/kT} - B_{21}}.$$

(b) In the classical limit, $u(f,T) = 8\pi f^2 kT/c^3$. Show that the quantum mechanical expression for u can match this form for large T only if $B_{12} = B_{21}$, and find the value of the ratio A/B_{12} from the matching requirement.

35. (III) From Problem 34, the rate per atom at which atoms in equilibrium with radiation at temperature T emit photons of frequency f has the form

$$\frac{\Gamma_{2\to1}}{N_2} = C\left(1 + \frac{1}{e^{hf/kT} - 1}\right),$$

where C is a constant. (a) Use the hint at the end of this problem to show that the average number of photons of frequency f per unit volume, $\langle n\rangle$, is given by

$$\langle n\rangle = \frac{1}{e^{-hf/kT} - 1}.$$

(b) Use this result to show that the deexcitation transition rate per atom is given by

$$\frac{\Gamma_{2\to1}}{N_2} = A(1 + \langle n\rangle).$$

This establishes the result that the transition rate for deexcitation increases linearly with the number of photons of the proper frequency already present, as is required for laser operation. [*Hint*: The distribution function to find n photons of energy hf is given according to Planck's work on blackbody radiation as $P_n = e^{-nhf/kT}(1 - e^{-hf/kT})$. The sum representing the average number is $\sum P_n n$, and this sum can be performed by noticing that $\sum_n x^n$ is a geometric series, and that $\sum_n n x^n = x(d/dx)\sum_n x^n$].

42–3 Superconductivity

36. (I) The critical temperature of a superconductor, T_c, varies with the isotopic mass of the element making up the superconductor, M, according to the relation $T_c\sqrt{M}$ = a constant. In lead, $T_c = 7.184$K for the isotopic molar mass 207.7 g. What is the critical temperature for the isotopic molar mass 206.3 g?

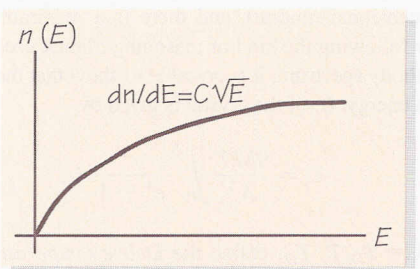
37. (I) An unknown constant potential difference V is placed across a Josephson junction, and an alternating current of frequency 23.3 GHz is produced. What is the value of V?

38. (I) What is the frequency of the AC component of the current when a DC voltage of 1.75 V is placed across a Josephson junction? A DC voltage of 0.80 μV?

39. (II) Verify that the units of magnetic flux are consistent with Eq. (42–15).

40. (II) The current-carrying ability of superconductors is limited by the fact that superconductivity breaks down in a large magnetic field. How large a current can be carried by a niobium-tin wire of diameter 0.60 mm if the critical magnetic field is 1.0 T?

41. (II) When a current passes through a Josephson junction, the resulting AC current can be regarded as corresponding to photons whose frequency is that of the AC current. For a particular Josephson junction, if these photons have an energy of 5.0×10^{-6} eV, what is the DC potential difference across the junction?



42. (II) The loop of a SQUID surrounds an area of 0.40 cm^2. If the phase of the interference current can be determined to an accuracy of $\pi/2$, to what accuracy can a magnetic field be determined? What current produces a field like this 12 cm away?

42–4 Superfluidity and Liquid Helium

43. (II) According to one approach that takes into account the quantum mechanical "clustering" behavior of the bosons that make up a superfluid, the temperature at which the superfluid forms is given by $T_c = [N/(2.612)(0.886)C]^{2/3}$, where $C = 2\pi V(2mk/h^2)^{3/2}$, V is the volume in which the N bosons are confined, and m is the mass of the boson. Apply this result to liquid ^{4}He. Take the density of the liquid to be 0.147 g/cm^3, and calculate T_c. (The experimental value of T_c for this system is 2.2K.)

General Problems

44. (II) (a) The energy-distribution function of electrons at $T = 0$ is given in Fig. 42–20. Use this to calculate the speed-distribution function. (b) Calculate $\langle v^4\rangle$ by using the result of part (a).

▲ **FIGURE 42–20** Problem 44.

45. (II) What is the radius of a star with a mass of 10^{-3} solar masses, assuming that the star has the density of the Sun? Compare your answer with the radius of Jupiter.

46. (II) Assume that the Fermi energy depends only on $\hbar$, the electron density n_e, and the mass of the electron. Use dimensional analysis to find that dependence.

47. (II) Assume that the Fermi energy depends only on $\hbar$, the electron density n_e, and the speed of light c. Use dimensional analysis to find that dependence.

48. (II) You want to verify the isotopic effect described in Problem 36 with a set of data you collected. Show that if an isotope equation of the type $T_c M^\gamma$ = a constant were correct, the data on a plot of $\ln(T_c)$ versus $\ln(M)$ would be a straight line whose slope determines γ. What is the curve if $\gamma = \frac{1}{2}$?

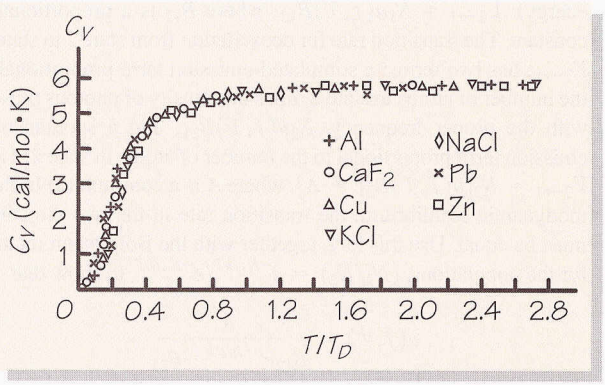
49. (II) Show that the isotopic-effect equation $T_c\sqrt{M}$ described in Problem 36 implies that T_c is proportional to v, where v is the speed of sound in a material with isotopic mass M.

50. (II) (a) Using the methods in the text, show that in a gas of free electrons in a box with sides of length L at $T = 0$K, the total number of electrons with energy less than E is

$$N = \left(E\frac{2m_e}{\hbar^2\pi^2}L^2\right)^{3/2}\frac{\pi}{3},$$

where $E < E_F$. (b) Use the results of part (a) to show that the number of electrons with energies between E and $E + dE$ is given by

$$n(E)\,dE = \frac{V}{2\pi^2}\left(\frac{2m}{\hbar^2}\right)^{3/2}\sqrt{E}\,dE,$$



where $n(E)$ is the energy-distribution function of the electrons. [*Hint*: The expression you want is given by $n(E)\,dE \equiv N(E + dE) - N(E)$.]

51. (II) Use the energy-distribution function of Problem 50 to show that the total energy of a gas of electrons in a box with sides of length L at $T = 0$K is given by $E_{\text{tot}} = \frac{3}{5}NE_F$.

52. (III) The behavior of the atoms of a crystal at temperature T under the influence of the springlike forces between the atoms is analogous to the behavior of light in a cavity at temperature T (blackbody radiation). The behavior of the lattice can be described by *phonons*, collective oscillations of the lattice that can be treated as particles analogous to the photons in a hot cavity. The phonons are identical bosons that obey the quantum rules for such particles. There is one important difference between the lattice vibrations and blackbody radiation: The number of possible modes of a lattice made up of N atoms is limited to $3N$ (corresponding to the three-dimensional motion), and there is a maximum frequency f_{max}. By following the kind of reasoning Planck used in deriving his blackbody spectrum, it is possible to show that the total lattice vibration energy, U, of the crystal is given by

$$U = \frac{9NkT}{\Lambda^3}\int_0^{\Lambda}\frac{x^3}{e^x - 1}\,dx,$$

where $\Lambda \equiv T_D/T$; T_D, called the *Debye temperature*, is given by $T_D = hf_{\text{max}}/k$. (a) Show that in the limit of $T \gg T_D$, the energy of the solid is the classical expression $3NkT$. (b) Show that in the limit $T \ll T_D$, $U \propto T^4$. (c) What is the temperature dependence of the specific heat at low temperatures? The curve formed by the expression for U matches well the experimental data over a large temperature range in many solids (Fig. 42–21; recall $C_V = dU/dT$). (After G. Burns, *Solid State Physics*, Academic Press, Inc., 1985, p. 369.)

53. (III) For stars whose mass is roughly one solar mass (2×10^{30} kg) and whose thermonuclear reactions have stopped because the fuel has been used up, the repulsive effects due to the Pauli exclusion principle *for electrons* are strong enough to keep the star from collapsing gravitationally. In that case, white dwarfs are formed. (a) Calculate the Fermi energy of the electrons in a white dwarf of mass M. (b) Calculate the radius of a white dwarf of mass M. If $M = M_\odot$ is one solar mass, what is the ratio of your result to the present radius of the Sun? [*Hint*: Follow our procedure for a neutron star. The gravitational pressure is the same as before, because only the protons and neutrons account for the mass. The number of electrons is the same as the number of protons, which is roughly half the total of protons plus neutrons. The radius of the Sun is 6.96×10^8 m.]

54. (III) When all the hydrogen in a star has burned, helium nuclei and electrons remain. Suppose that there are N electrons, and that the star is a sphere of radius R and mass $M \cong (N/2)m_{\text{He}}$. (a) Use Eq. (42–9) to estimate the degeneracy pressure. (b) The gravitational force of the helium nuclei exerts an inward pressure, which is approximately $p_{\text{grav}} = E_{\text{grav}}/V \cong (GM^2/R)/V$. Find p_{grav} in terms of R. (c) The star will collapse until the two pressures cancel, when it has a radius R_f. Calculate R_f in terms of m_e, m_{He}, and N. (d) Evaluate R_f for a star of one solar mass. (The result will be surprisingly small.)

55. (III) Use the methods of Problem 24 to calculate the Fermi energy of a gas of electrons, assuming that the mass of electrons can be neglected, so that $E = pc$. Under what conditions will the star of Problem 54 *not* collapse?

56. (III) What is the bulk modulus of a nucleus that consists of N neutrons and Z protons and has a radius $R = r_0A^{1/3}$, where $r_0 \cong 1.2 \times 10^{-15}$ m?

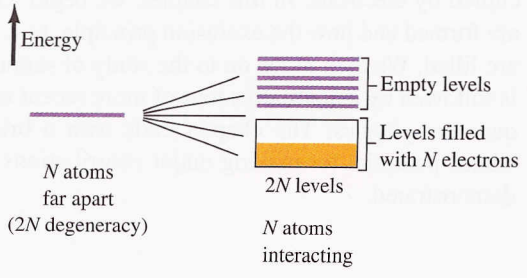
Chapter 43

◀ This scanning tunneling micrograph of a nanowire is just 10 atoms wide. The wire (red color) is a compound of a rare earth metal (lanthanide) and silicon and is laid down on a silicon substrate. Such wires are projected to be used in miniaturization of circuits.

Quantum Engineering

The close interplay of science and technology enriches both. At times, technology has led science, as in the case of thermal physics, which was stimulated by the need to understand the engines that propelled the Industrial Revolution of the early nineteenth century. At other times, science has led technology, as with the development of the electric power industry out of the discoveries of Faraday and Maxwell. Such processes occurred frequently throughout the twentieth century. The discovery of quantum mechanics has led to an ever better understanding of the detailed properties of materials; this understanding has been accompanied by important developments in the fabrication of materials required to satisfy the needs of technology. Semiconductors provide an important example. In Section 26–6, we described how the conduction properties of matter are determined by the presence of energy bands—ranges of energies within which possible levels are very closely spaced, spaced by gaps within which there are no allowed levels—and whether or not those bands are fully occupied by electrons. In this chapter, we begin with an explanation of why these bands are formed and how the exclusion principle, as it applies to electrons, explains how they are filled. We then move on to the study of semiconductors and their applications. This is followed by a qualitative tour of more recent technological developments that rely on quantum physics. The chapter ends with a brief discussion of some of the devices whose potential for making major contributions to future technology has already been demonstrated.

43–1 Energy Bands



Band structure in crystalline solids plays an important role in determining many of the properties of those solids, including, as we saw in Section 26–6, electrical properties such as conductivity. Crystalline solids have regions of energy with no allowed energy levels. No electrons within a given solid can have energies in the forbidden regions for the solid; the electron energies are restricted to certain finite ranges of energy—the bands of allowed energies. The presence of energy bands and the numbers of electrons that occupy the allowed energy levels determine why some materials are conductors, whereas others are insulators or semiconductors (Section 26–6). We are now in a better position to elaborate on why bands form. The band structure has such a powerful influence on the behavior of conductors and semiconductors that it is appropriate to discuss it here.

Let's start by recalling our discussion of the energy levels for two hydrogen atoms, Section 41–4. We found that we can think about a helium atom as something that results from moving two hydrogen atoms together. However, our naïve expectation for the binding energy of helium—that the value of the ground-state energy of helium is a simple multiple of the binding energy of hydrogen—is incorrect. This is because the electrons of the two hydrogen atoms interact with each other. In other words, a new interaction added to an existing system will generally shift the energy levels of the existing system. Just how are the energy levels shifted in this case? When the two hydrogen atoms are far apart, there are two electrons in a pair of identical levels of energy -13.6 eV (the ground state of an isolated hydrogen atom). We say that the two electrons are in *degenerate* energy levels. (Actually, there are four degenerate levels, because each electron can be in a spin "up" or spin "down" state, and these states have the same energy values.) As we saw earlier, when the atoms are brought so close together that helium forms, there is at least one level with energy less than -13.6 eV, namely, the true ground state of helium. The remaining three levels are pushed *upward* and correspond to excited states of helium. This is a general characteristic of energy levels:

When there are degenerate energy levels and an additional interaction comes into play, the levels are split—some moving upward and some moving downward relative to their original positions.

This observation plays an important role in band theory. Let's study N atoms of sodium, which have filled shells plus a single electron (the valence electron) in an $n = 3$, $\ell = 0$ state. There are $2N$ degenerate (equal-energy) states available to the valence electron when the atoms are far apart and there is no interaction between the atoms. (As before, the factor of 2 is present because the electron can be in a spin-up or spin-down state, which each have the same energy.) Now suppose that the N atoms form a crystal lattice with closely spaced lattice sites. Then the originally degenerate valence-electron states are split due to interactions between the atoms; N energy levels are pushed down, and N are pushed up, each by a slightly different amount, and there is a finite energy gap between the two sets of levels. The original $2N$ degenerate energy levels form two separate bands, each composed of a set of N very narrowly spaced levels.

Since electrons are fermions, there can be at most two—spin-up and spin-down—electrons in each of the levels, which fill in this way, starting at the level with the lowest energy and working upward. The N valence electrons of the sodium atoms fill only half of the band with the lower energy, which is made up of the N lowest-lying energy levels (Fig. 43–1). As we discussed in Section 26–6, an electric field can easily lift some

▶ **FIGURE 43–1** When many atoms are brought together to form a crystalline solid, the degenerate levels of N atoms split to form band structures, in which there are ranges of allowed electron energies and ranges (gaps) of forbidden energies. In sodium, the valence electrons fill one-half of a band.

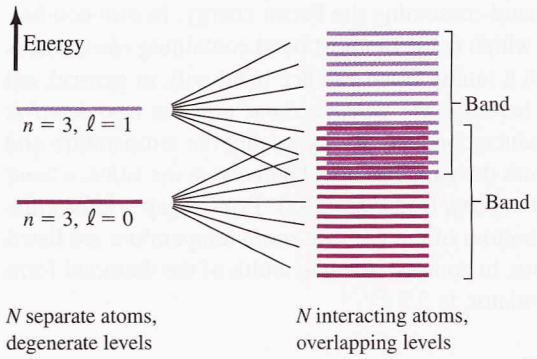


FIGURE 43–2 The origin of the band structure of N atoms of magnesium in a crystalline solid. The splitting of the degenerate levels with quantum number $n = 3$, $\ell = 0$ leads to a band that is completely filled with electrons. The degenerate levels $n = 3$, $\ell = 1$ also split, and the allowed band they form overlaps with the band formed from the $n = 3$, $\ell = 0$ levels.

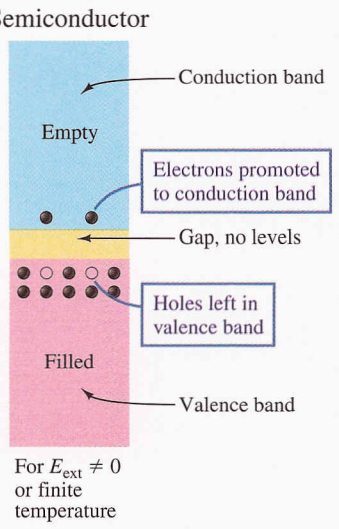


electrons at the top of the filled levels to the empty levels, where they can move without hindrance. Metallic sodium is thus a good conductor.

For contrast, we can consider N atoms of magnesium. The Z value of magnesium is one higher than that of sodium. Magnesium has the same atomic structure as sodium, except that there are *two* electrons in the $n = 3$, $\ell = 0$ states. The band formed from the originally degenerate states when the magnesium atoms combine into a lattice is therefore completely filled. Magnesium could be an insulator. However, empty levels that originally came from the $n = 3$, $\ell = 1$ states, which were above the $n = 3$, $\ell = 0$ levels when the two sets of levels were each degenerate, fan out into a second band. In magnesium the two bands overlap (Fig. 43–2). Thus there is room for electrons, under the influence of an electric field, to move into empty levels, and magnesium is a good conductor. There are other cases in which bands of this type do not overlap. Indeed, all the possibilities discussed in Chapter 26 can be realized.

Let us now turn back to the question of the "new" interactions that occur when the atoms are assembled into a regular lattice, which lead to the splitting of degenerate electron energy levels into a band structure. These are the interactions of electrons with ions other than the ones to which they were originally attached. In particular, if the ions were not present, the electrons would move freely in the "box" formed by the dimensions of the material. The electrons' wavelike aspect makes them behave analogously to waves on a string, namely as standing waves whose wavelengths must be integral multiples of the appropriate dimensions of the box. These waves are the waves formed by the wave function, and the electron is likely to be found where those waves have crests (or troughs). The crests and troughs are regularly spaced. At this point, we can imagine adding the ions at regularly spaced sites. Two modifications to our original depiction result: First, only those electrons whose wavelengths correspond to the ionic spacing can be supported in the material for reasons closely related to the Bragg scattering arguments we gave in Chapter 40. Second, half of the allowed waves of the electrons have peaks (or troughs) where the ions are found, and half have peaks (or troughs) exactly in between the ions. The energies of the half whose peaks are where the ions are found are lowered because these electrons are more likely to be near the ions to which they are attracted. The energies of the half whose peaks are in between the ion locations are raised because these electrons do not feel the force of attraction as strongly as they did when they were in an isolated atom.

43–2 Semiconductors

Two major features govern the electrical conduction properties of solids: the Pauli exclusion principle, which is obeyed by all electrons (see Chapter 42), and the presence of a band structure, with gaps. The Pauli exclusion principle implies that there are at most two electrons in each energy level, and as we have already reminded you, at low temperatures these levels are filled in order, starting from the lowest. The energy of the highest filled level is the *Fermi energy*, E_F. The band structure expresses the presence of energy gaps between allowed bands; there are no levels within such gaps, so no electrons can have energies there. In conductors, levels are filled to the Fermi energy, but

▲ **FIGURE 43–3** Semiconductors are characterized by a filled band (the valence band) with a relatively small energy gap to the next band (the conduction band), which is empty at zero temperature. Finite temperatures suffice to boost some electrons to the conduction band.

TABLE 43–1 • Gap Widths of Some Semiconductors†

Material	Gap Width (in eV)
Tin (gray form)	0.08
Tellurium	0.35
Lead sulfide	0.37
Germanium	0.67
Silicon	1.12
Gallium arsenide	1.43
Boron	1.5
Selenium	1.8

†At room temperature.

there are empty energy levels in the band containing the Fermi energy. In semiconductors and insulators, the *valence band*, which is the topmost band containing electrons, is filled right up to a gap. Materials with a totally filled valence band will, in general, act as insulators *unless the energy gap between the valence band and the next band is small*. In that case, it is possible to induce conductivity by raising the temperature and thermally exciting some electrons across the gap. The next band above the valence band is therefore referred to as the *conduction band* (see Fig. 43–3). Typical gap widths—the energy difference from the top to the bottom of the gap—at room temperature are listed in Table 43–1 for some semiconductors. In contrast, the gap width of the diamond form of carbon, which is regarded as an insulator, is 5.5 eV.

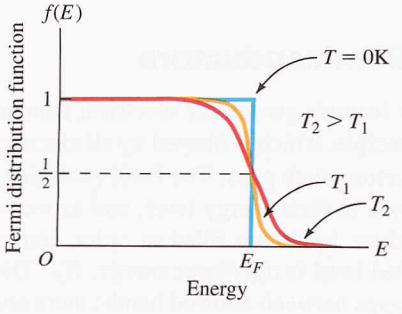
The Effects of Temperature

The behavior of semiconductors depends crucially on temperature. To study the effects of finite temperatures, it is simplest to look first at finite temperature effects in conductors. At $T = 0\text{K}$ (what we'll refer to as $T = 0$), we are certain to find an electron in every state up to an energy of E_F. If we suppose that the possible levels are so closely spaced as to represent a continuum, then at $T = 0$, the probability $f(E)$ that the state with energy E is occupied by an electron (actually two electrons, due to spin) is

$$\text{for } E < E_F\text{: } f(E) = 1,$$
$$\text{for } E > E_F\text{: } f(E) = 0. \tag{43–1}$$

When $T > 0$, some of the electrons will be thermally excited into previously unoccupied levels, leaving vacant energy levels behind them. For temperatures that are not too large (see the more detailed discussion below), this can happen only for electrons with energies near E_F because electrons with energies far below E_F are unlikely to get a sufficiently large thermal "kick." If electrons behaved according to classical rules, they would obey the Maxwell–Boltzmann distribution (see Chapter 19). But because electrons obey the Pauli exclusion principle, their energy distribution is instead described by the **Fermi–Dirac distribution**:

$$f(E) = \frac{1}{1 + e^{(E-E_F)/kT}}. \tag{43–2}$$



THE FERMI–DIRAC DISTRIBUTION

You can easily check that we recover Eq. (43–1) from this distribution in the limit $T \to 0$. Figure 43–4 shows the distribution for the increasing temperatures $T = 0$, T_1, and T_2. Notice that for $(E - E_F) \gg kT$, the exponential factor dominates in the denominator, and we get the approximation

$$f(E) \cong e^{-(E-E_F)/kT}. \tag{43–3}$$

Equation (43–3) has the form of the Maxwell–Boltzmann distribution, so the distribution is classical when the energy difference $E - E_F$ is large compared to kT. What is a typical value of kT? A useful number to remember is that room temperature, $T = 300\text{K}$, corresponds† to 1/40 eV.

▶ **FIGURE 43–4** The Fermi–Dirac distribution, $f(E)$, which describes the probability of finding one of a set of identical fermions with an energy E. The distribution is sketched for three successively higher temperatures, $T = 0$, T_1, and T_2.

†For $T = 300\text{K}$, $kT = (1.38 \times 10^{-23}\,\text{J/K})(300\text{K})/(1.6 \times 10^{-19}\,\text{J/eV}) = 2.6 \times 10^{-2}\,\text{eV} = 1/40\,\text{eV}$.

EXAMPLE 43–1 Assume that electrons in copper are distributed according to the Fermi–Dirac distribution. The Fermi energy in copper is $E_F = 7.04$ eV. (a) The *Fermi velocity* has magnitude v_F, the speed of an electron that moves with a kinetic energy equal to E_F. What is v_F for copper? (b) From the Fermi–Dirac distribution, $f(E_F) = 1/2$. What is the value of $f(E)$ at a temperature of 300K for an electron with a speed 1 percent higher than v_F? (c) Estimate the temperature at which the probability $f(E)$ is 10^{-10} if E is 1.2 eV above E_F.

Strategy (a) Assuming that the electrons are nonrelativistic, we can use $E_F = \frac{1}{2}m_e v_F^2$, and solve for v_F. The assumption about being nonrelativistic would be justified if v_F turns out to be a small fraction of c.

(b) This is a straightforward evaluation of the distribution function. It is helpful to note here that when the speed of an electron increases by 1 percent, the energy—proportional to the speed squared—increases by approximately 2 percent, and we can then make our estimate by taking E to be 2 percent larger than E_F.

(c) We set $f(E)$ equal to 10^{-10} and solve for kT, given the value of $E - E_F$. When $f(E) = 10^{-10}$, the exponential term in the denominator of $f(E)$ in Eq. (43–2) is much larger than 1, and we can use the approximation $f(E) \cong e^{-(E-E_F)/kT} = 10^{-10}$.

Working It Out (a) We have

$$v_F = \sqrt{\frac{2E_F}{m_e}} = \sqrt{\frac{2(7.04\text{ eV})(1.60 \times 10^{-19}\text{ J/eV})}{0.911 \times 10^{-30}\text{ kg}}}$$

$$= 1.57 \times 10^6\text{ m/s}.$$

This is only about half a percent of the speed of light.

(b) We take E to be 2 percent larger than E_F, $E = (1.02)(7.04\text{ eV}) = 7.18$ eV. With $kT = 2.6 \times 10^{-2}$ eV at $T = 300$K, $(E - E_F)/kT = 5.4$, and hence

$$f(E) = \frac{1}{1 + e^{5.4}} \cong 4.5 \times 10^{-3}.$$

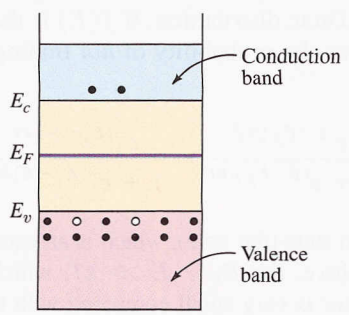
(c) According to the strategy, we have

$$f(E) \cong e^{-(E-E_F)/kT} = 10^{-10},$$

with $E - E_F = 1.2$ eV. Taking the natural log of both sides, $-(1.2\text{ eV})/kT = \ln(10^{-10}) = -10\ln(10) = -23$. Thus, $kT = (1.2\text{ eV})/23 = 0.052$ eV. This is twice the value of kT at $T = 300$K [see part (b)], so the desired estimate is 600K.

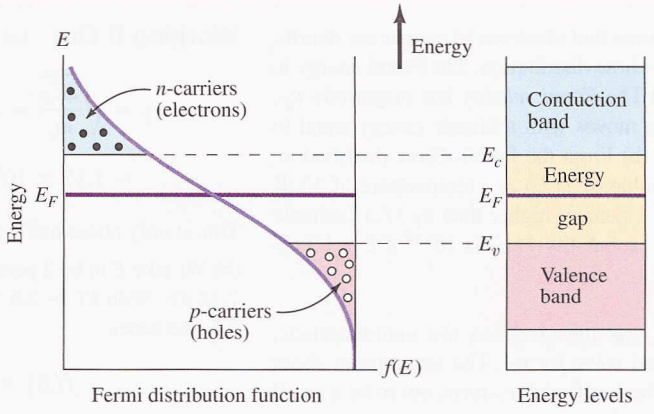
What Do You Think? We made a post-calculation check as to whether the electrons were nonrelativistic. Is there any way we could have argued that had to be so without a numerical evaluation of v_F?

*Answers to **What Do You Think?** questions are given in the back of the book.*



Semiconductors, Electrons, and Holes

To apply our ideas about finite temperatures to semiconductors, we must reconsider the role of the energy gap. Suppose that the band structure is that of a semiconductor; that is, at $T = 0$, the valence band is filled, the conduction band is empty, and the gap energy $E_g \equiv E_c - E_v$ is relatively small. Here, E_v is the maximum energy of the valence band (the *edge of the valence band*), and E_c is the lowest energy of the conduction band (the *edge of the conduction band*) (Fig. 43–5).



But just what is the Fermi energy for this situation? If we think of the Fermi energy as the energy above which there are no electrons (at zero temperature), then *any* energy value within the energy gap would serve, and that is not an answer to our question. Our procedure is as follows: We use Eq. (43–2) but replace the Fermi energy with an unknown quantity μ:

$$f(E) = \frac{1}{1 + e^{(E-\mu)/kT}}. \tag{43–4}$$

The quantity μ is a thermodynamic variable—the *chemical potential*—but the detailed properties of this variable need not concern us further. For the moment, μ is unknown, but we shall determine its value from a condition of the conservation of charge. In the following discussion, we shall conform to established practice for semiconductor engineering by writing E_F rather than μ throughout. When you see formulas for semiconductors with the parameter E_F, keep in mind that this is not the Fermi energy in the sense in which we first defined it.

◀ **FIGURE 43–5** The band structure of an intrinsic semiconductor is that of a filled valence band, a relatively narrow band gap, and, at $T = 0$, an empty conduction band. The solid circles represent electrons, and the open circles represent holes. At $T = 0$, there are no electrons in the conduction band and no holes in the valence band.

▶ **FIGURE 43–6** Electrons near the top of the valence band can jump the gap in a semiconductor at finite temperature. The Fermi–Dirac distribution describes the probability that an electron will have enough energy to be promoted to the conduction band. For every electron that can be promoted, a hole is left behind in the valence band.

To determine E_F, we must look more closely into the question of what happens when electrons move into the conduction band. When $T \neq 0$, some electrons will acquire enough energy to go into the conduction band, and the valence band will be correspondingly depleted of electrons (Fig. 43–6). At room temperature ($kT \cong 1/40$ eV), $E_g \gg kT$. We can then estimate that at room temperature the relative number of electrons able to jump the gap to the conduction band in, say, silicon, for which $E_g \cong 1$ eV, is $e^{-E_g/kT} \cong e^{-40} \cong 10^{-18}$, only a very small fraction of the electrons. This same reasoning would hold if, instead of E_g, we used the smaller quantity $E_c - E_F$, as long as $E_c - E_F$ were of the same order of magnitude as E_g (as it typically is). We would thus have a situation in which an energy distribution of the same form as Eq. (43–3) holds (although we have yet to determine E_F). Because the function in Eq. (43–3) decreases so rapidly as energy increases, the number of electrons per unit volume (the number density n) in the conduction band is well approximated by replacing E in Eq. (43–3) with the lowest energy in the conduction band, E_c:

$$n = N_c e^{-(E_c - E_F)/kT}. \tag{43–5}$$

The proportionality constant N_c will be treated in detail later, but we can say here that it represents a normalization that describes the total number of electrons that have been promoted to the conduction band. The electrons in the conduction band are free to move when an electric field is applied and form a current. These electrons are called *n-carriers* (*n* for negative).

Electrons that are thermally "promoted" into the conduction band leave vacancies in the valence band. Only the electrons with energies near E_v are promoted, so the vacancies are located at those energies. Such a vacancy is called a **hole**. Holes can move: When an electron moves to fill a hole, that leaves a hole in the electron's original position, which in turn is filled by a second electron, and so on. The hole movement traces the positions of the electrons that have filled the hole's previous position. If there is an electric field pointing in the $+x$-direction, then the succession of hole-filling electrons will have moved in the $-x$-direction, and thus the hole will flow in the $+x$-direction. (A helpful analogy might be an air bubble floating upward in a tank of water. The "vacancy" in the water, the air bubble, is constantly replaced by water falling down under the force of gravity; this water leaves its own vacancy, which thus continually moves upward.) The hole thus acts as a positively charged particle; we call such a hole a *p-carrier* (*p* for positive). The probability of finding a hole with energy E can be determined by the Fermi–Dirac distribution. If $f(E)$ is the probability of finding an electron with energy E, then the probability of *not* finding an electron with that energy is

$$1 - f(E) = 1 - \frac{1}{1 + e^{(E-E_F)/kT}} = \frac{e^{(E-E_F)/kT}}{1 + e^{(E-E_F)/kT}} = \frac{e^{-(E_F-E)/kT}}{1 + e^{-(E_F-E)/kT}}. \tag{43–6}$$

Here, E is the energy of the empty electron state (the hole), which is an energy in the valence band, so the factor $E_F - E$ is positive. For $E_F - E \gg kT$, which is typically the case, the exponential in the denominator is very small compared with unity, and the

right-hand side of Eq. (43–6) reduces to $e^{-(E_F-E)/kT}$. This exponential factor decreases so rapidly as the factor $E_F - E$ increases that, to a good approximation, we can replace $E_F - E$ by $E_F - E_v$. Thus the number density of holes is accurately given by

$$p = N_v e^{-(E_F-E_v)/kT}. \tag{43–7}$$

We shall give the proportionality constant N_v later. Note that the product of the n-carrier concentration and the p-carrier concentration is given by

$$np = N_c e^{-(E_c-E_F)/kT} N_v e^{-(E_F-E_v)/kT} = N_c N_v e^{-(E_c-E_v)/kT} = N_c N_v e^{-E_g/kT}. \tag{43–8}$$

CONCEPTUAL EXAMPLE 43–2 Suppose $E_F - E \gg kT$. Will the probability of finding a hole with energy E be large or small? Does your answer make sense physically?

Answer The probability of finding a hole with energy E is proportional to $1 - f(E)$, Eq. (43–6). This expression takes the approximate form $e^{-(E_F-E)/kT}$ and is not only small in our limit but has the classical Maxwell–Boltzmann form. The reason that this probability is small is that for large values of $E_F - E$, the hole is created by the promotion of an electron to the conduction band from deep within the valence band, rather than near the top of the valence band, which is a relatively small jump. This is a large jump in energy and is unlikely, exactly as thermodynamics tells us.

When each hole in the valence band is created by the promotion of an electron into the conduction band, the number of p-carriers equals the number of n-carriers. Semiconductors for which this is the case are called *intrinsic semiconductors*. We can now use this condition to determine E_F. With a subscript i to indicate that we are dealing with an intrinsic semiconductor, Eq. (43–8) implies that

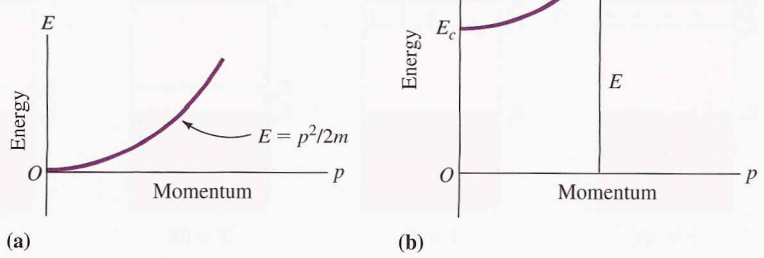
$$n_i = p_i = \sqrt{n_i p_i} = \sqrt{N_c N_v} e^{-E_g/2kT}. \tag{43–9}$$

Comparison of the exponential factor in this result with the exponential factors of Eqs. (43–5) and (43–7) is valid as long as N_c and N_v do not vary too rapidly with temperature, and shows that

$$E_c - E_F = E_F - E_v = E_g/2. \tag{43–10}$$

In other words, E_F (*or more properly, the chemical potential*) *is at the halfway point of the gap*. This result justifies our expectation that $E_c - E_F$ and $E_F - E_v$ are much larger than kT if E_g is.

An additional effect is important in semiconductors. The energy of a free electron with momentum p is $E = p^2/2m_e$, as in Fig. 43–7a. Figure 43–7b shows the energy–momentum relation that holds for the electrons in the conduction band if those electrons are free. Electron interaction with the lattice, however, changes this relationship. For small momentum, the principal effect is to change the steepness of the parabola, and this is equivalent to changing the electron mass to an *effective electron mass*, denoted by m^*. For semiconductors, m^* is typically an order of magnitude *smaller* than the true electron mass; for gallium arsenide (GaAs), $m^*/m_e \cong 0.067$, and for indium antimonide (InSb), this ratio is only 0.015. Furthermore, the effective mass of n-carriers need not be the same as that of p-carriers; generally m^* is much



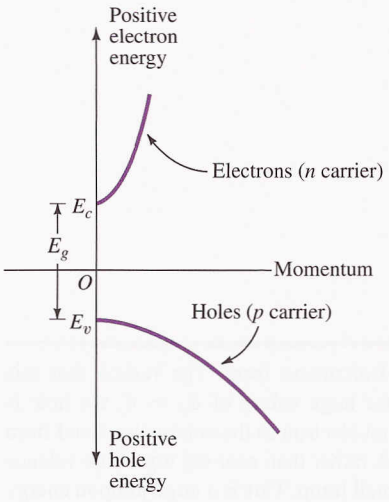


FIGURE 43–7 (a) Energy versus momentum for a free electron. (b) Energy versus momentum for an electron in the conduction band. The lowest possible energy for the electron is E_c.

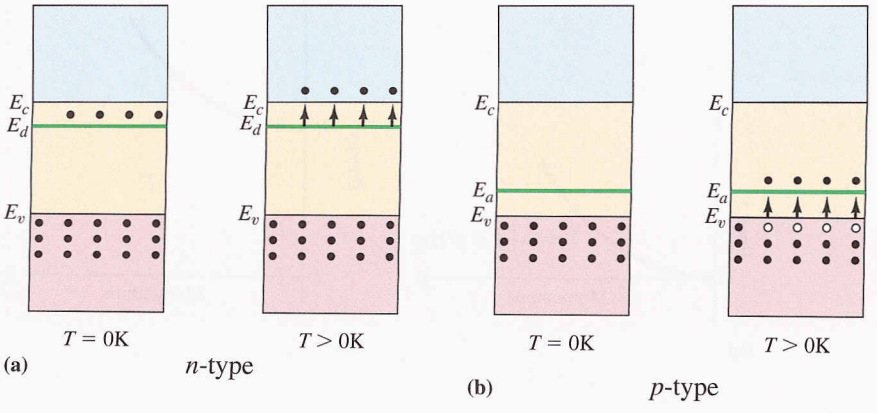
▲ **FIGURE 43–8** The energy–momentum relation for an electron in the conduction band (Fig. 43–7b) is modified because the electron behaves as though it has a modified mass m^*. Also shown is the energy–momentum relation for a hole, which in general has a different effective mass than does an electron.

smaller for n-carriers (Fig. 43–8). An understanding of why effective masses take on their particular values is beyond the scope of our discussion. Roughly speaking, the ratio m^*/m_e is small if E_g is small compared to the width of the conduction band.

Doping

In contrast to intrinsic semiconductors, in *extrinsic*, or *impurity*, *semiconductors*, additional n-carriers or p-carriers are supplied by the addition of atoms of another element—impurities—to the crystal lattice. The addition of impurities (whether artificially or naturally) is known as *doping*. It works as follows: Suppose that we add some arsenic atoms to germanium. The crystal structure will remain unchanged (each arsenic ion replaces one germanium ion in the lattice), but the electronic structure will change. Germanium has four valence electrons, whereas arsenic has five; the arsenic atom makes one more electron available for conduction and is said to be a *donor impurity*. When n-carriers are added in this way, the doped material is said to be an *n-type semiconductor*.

If the additional electron were not bound at all to the arsenic ion, it could fill an energy level only in the conduction band and therefore could easily carry current. Such an electron would have energy on the order of E_c. The additional electron is in fact bound to the arsenic ion, but only very weakly. If the arsenic were not part of the semiconductor lattice, we might expect the electron to be bound to the arsenic ion with an energy like the Bohr energy [Eq. (41–10) with $n = 1$]:



$$E = -\frac{e^4 m_e}{2(4\pi\varepsilon_0\hbar)^2} \cong -13.6\text{ eV}.$$

Within the lattice of the semiconductor, this binding energy is reduced in magnitude for several reasons. First, the mass of the electron is effectively reduced—typically by more than a factor of 10—from m_e to m^*. Second, the semiconductor medium has a dielectric constant κ(defined by $\varepsilon = \kappa\varepsilon_0$) that is typically more than 10 times larger than the value of 1 for a vacuum. These two factors change the binding energy to

$$E = -\frac{e^4 m^*}{2(4\pi\varepsilon\hbar)^2}. \tag{43–11}$$

Our numerical values for m^* and ε show that the magnitude of this energy is less than $\frac{1}{1000}$ that of the typical Bohr energy. Moreover, with the change to an effective mass the radius of the electron's Bohr orbit [see Eq. (41–8)] becomes so large that the electron is circulating within the larger environment of the semiconductor lattice and screening by other electrons occurs, reducing the magnitude of the binding energy still further. The small binding energy, on the order of 0.01 eV or less, manifests itself in the presence of additional energy levels very close to the bottom of the conduction band (Fig. 43–9a). The amount by which these energies differ from E_c is on the order of kT or less at room temperature. Thus the additional electron, which is bound at $T = 0$, is very easily excited to the conduction band at room temperature. In this circumstance, the donor electrons are far more important for conduction than the intrinsic electrons.

▶ **FIGURE 43–9** Energy-band structure for doped semiconductors. (a) In n-type semiconductors, E_F (labeled E_d, label d for donor) lies close to E_c. The levels of electrons (solid circles) from donor impurities lie above E_F and are easily excited at $T > 0$ into the conduction band. (b) In p-type semiconductors, E_F (labeled E_a, label a for acceptor) lies close to E_v. There are levels associated with the acceptor impurities that are quite close to E_v, so at finite temperatures, electrons from the valence band are easily promoted to these levels, leaving holes (open circles) in the valence band.

EXAMPLE 43–3 Calculate the ionization energy for a donor electron in doped indium antimonide, a semiconductor in which $\varepsilon/\varepsilon_0 = 17.9$ and $m^*/m_e = 0.015$.

Strategy The ionization energy E is the negative of the binding energy of the ground state of the donor atom [Eq. (43–11)]. We need only insert the new values of dielectric constant and mass.

Working It Out

$$E = \frac{e^4 m^*}{2(4\pi\varepsilon\hbar)^2} = (13.6\text{ eV})\left(\frac{m^*}{m_e}\right)\left(\frac{\varepsilon_0}{\varepsilon}\right)^2$$
$$= (13.6\text{ eV})(0.015)\left(\frac{1}{17.9}\right)^2 = 6.4 \times 10^{-4}\text{ eV}.$$

This much energy corresponds to a temperature of $T = E/k = 0.025\text{K}$.

If an impurity has a deficit of valence electrons, a surplus of p-carriers is created because holes form when electrons from the intrinsic semiconductor atoms become strongly attached to the impurity atoms. Such impurities are known as *acceptor impurities*. Boron, for example, has three valence electrons and is an acceptor impurity for germanium. Semiconductors doped with acceptor impurities are known as *p-type semiconductors*. By the same sort of reasoning that we used for n-type semiconductors, p-type semiconductors have the level structure shown in Fig. 43–9b, with some additional levels close to E_v. The n-carriers from the valence band are easily promoted to the acceptor levels, leaving holes in the valence band that are very effective at carrying charge.

As in intrinsic semiconductors, the effective Fermi energy of doped semiconductors determines the probability of promoting electrons and holes to levels where they can conduct. The Fermi energy E_F is found by correctly relating the densities of n-carriers and p-carriers. Since the carrier densities depend on the difference between the energy and E_F, as in Eq. (43–3), we might expect that the Fermi energy is close to E_c (i.e., it increases) in n-type semiconductors and is close to E_v (i.e., it decreases) in p-type semiconductors, and this is indeed the case. These results can be formally developed by starting with Eq. (43–8), which holds whether or not the semiconductor is doped. The constants N_c and N_v in Eq. (43–8) can be obtained by summing the number of electrons in the conduction band and the number of holes in the valence band, respectively:

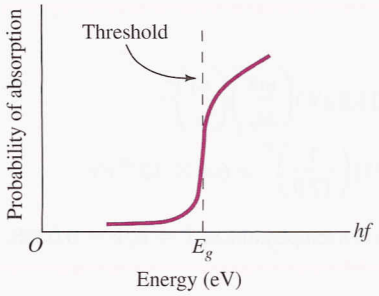
$$N_c = 2\left(\frac{m_n^* kT}{2\pi\hbar^2}\right)^{3/2} \quad \text{and} \quad N_v = 2\left(\frac{m_p^* kT}{2\pi\hbar^2}\right)^{3/2}, \tag{43–12}$$

where m_n^* and m_p^* are the effective masses of the n-carriers and p-carriers, respectively. Then Eq. (43–8) reads

$$np = n_i^2 = N_c N_v e^{-(E_c - E_v)/kT} = N_c N_v e^{-E_g/kT}. \tag{43–13}$$

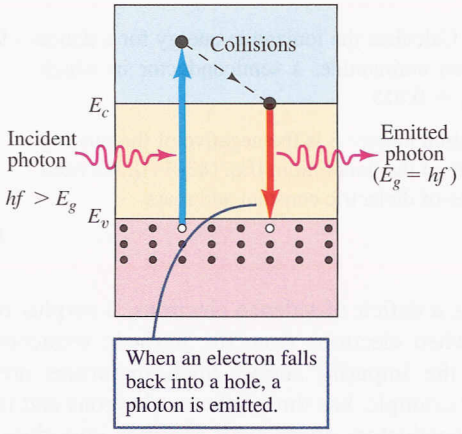
We have rewritten Eq. (43–8) as Eq. (43–13) because we have given it a greatly extended reach. Equation (43–13) relates the n-carrier and p-carrier densities in a *doped* semiconductor to the intrinsic carrier densities, whereas in its original form [Eq. (43–8)] it related the carrier densities in the undoped semiconductor.

Equation (43–13) has important consequences. For example, if we dope an intrinsic semiconductor with acceptor impurities to increase the density of holes, the density of electrons must decrease so that Eq. (43–13) continues to be satisfied. It is typical that the n-carriers dominate in an n-type extrinsic semiconductor, whereas p-carriers dominate in a p-type extrinsic semiconductor.



EXAMPLE 43–4 The effective masses in the semiconductor gallium arsenide are $m_n^*/m_e = 0.067$ and $m_p^*/m_e = 0.48$; the band gap is $E_g = 1.43\text{ eV}$. Find the intrinsic concentration of n-carriers and p-carriers in gallium arsenide at room temperature, where $kT = 0.026\text{ eV}$.

Strategy The concentration of intrinsic carriers in a semiconductor (doped or not) is given by Eq. (43–9). To evaluate this expression, we must include the normalization factors N_c and N_v.

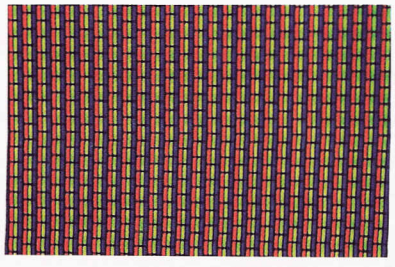


Working It Out With the help of Eq. (43–12), we obtain

$$n_i = \sqrt{N_c N_v}\, e^{-E_g/2kT} = 2\left(\frac{m_e kT}{2\pi\hbar^2}\right)^{3/2}\left(\frac{m_n^* m_p^*}{m_e^2}\right)^{3/4} e^{-E_g/2kT}$$
$$= 2\left[\frac{(0.91 \times 10^{-30}\text{ kg})(1.38 \times 10^{-23}\text{ J/K})(300\text{K})}{2\pi(1.05 \times 10^{-34}\text{ J}\cdot\text{s})^2}\right]^{3/2}$$
$$[(0.067)(0.48)]^{3/4} e^{-(1.43\text{ eV})/2(0.026\text{ eV})}$$
$$= 2.2 \times 10^{12}\text{ carriers/m}^3.$$

What Do You Think? We asked for the number of p-carriers as well as the number of n-carriers. Why didn't we carry out a separate calculation?

▲ **FIGURE 43–10** The probability of photon absorption in a semiconductor has a threshold when the photon energy equals the gap energy, because no energy levels are available for the absorbing electron at lower energies. Because a photon's energy is proportional to its frequency, the energy threshold can be expressed as a threshold in frequency.



▲ **FIGURE 43–11** An electron excited to the conduction band by photon absorption loses energy by collision until its energy reaches E_c; at that point it recombines with a hole in the valence band, with photon emission.

Optical Effects in Semiconductors

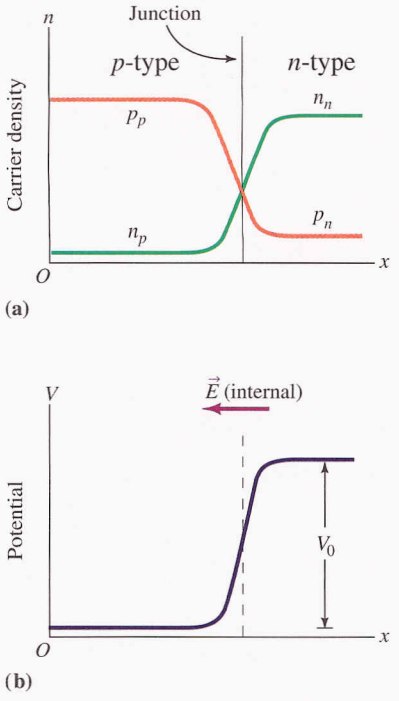
When a photon—a quantum of light—strikes a semiconductor, there is a probability that it will be absorbed by the electron system. This process has a threshold, given by a function of the photon's frequency f (Fig. 43–10). An electron in the material can absorb the photon only if the energy of the photon, hf, is greater than the gap energy; only at such energies are there empty levels available for electron occupation in the conduction band. Thus, some materials are transparent (a photon passes through without being absorbed) in certain frequency ranges but cease to be so for higher frequencies. An absorbing electron that is kicked up into the conduction band will lose energy by colliding with lattice atoms until its energy falls to near E_c; here, further energy loss is inhibited by the exclusion principle and/or the absence of energy levels below E_c. At that stage, the only way in which the electron can lose energy is to fall back into a hole in the valence band, a process called *recombination*. The electron–hole recombination can produce radiation called *photoluminescence* whose frequency is such that $hf_g = E_g$ (Fig. 43–11). The electrons can alternatively be initially excited into the conduction band by the bombardment of the material by high-energy electrons (*cathodoluminescence*) or by the action of an electric current in the material (*electroluminescence*).

When an electron–hole pair recombines rapidly, on the order of 10^{-8} s, the process is called *fluorescence*. A slower transition may arise when there are impurity levels in the gap, and the excited electron first undergoes a transition to those levels. If the impurity level has quantum numbers such that selection rules forbid the direct transition of an electron from it to the hole, the electron is said to be *trapped*. It will ultimately undergo a transition to a vacancy in the valence band (electron–hole recombination), but this may take as much as seconds or even minutes to occur. This process is termed *phosphorescence*, and the materials in which this occurs are called *phosphors*. The energy of the emitted photon is determined by the energy difference between the intermediate impurity level and the top of the valence band. We can thus choose the impurities such that radiation will be emitted in a variety of colors. In a color television tube, the screen is coated with phosphor dots that emit radiation in the primary colors (Fig. 43–12). The phosphors are excited by three incoming electron beams (cathodoluminescence), which are deflected to the proper spot on the screen by electric and magnetic fields determined by the incoming signal to the television. Each of the beams excites a different color.

▲ **FIGURE 43–12** Excited red, green, and blue phosphors are visible in this close-up view of a color television screen.

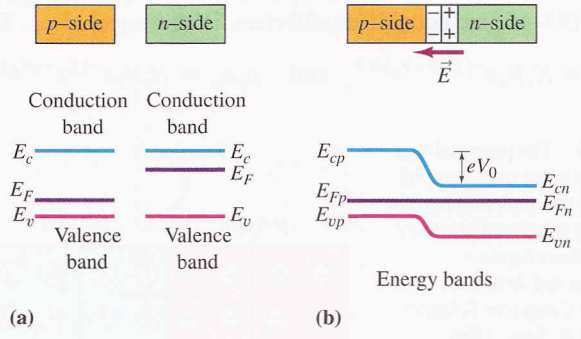
A semiconductor exposed to radiation for which $hf > E_g$ has an increased number of *n*-carriers and *p*-carriers and thus an increased conductivity. Devices whose conductivity changes when they are exposed to light—*photoconductive* devices—are used for lights that automatically turn on at dusk and off at dawn, or for measuring light intensity, as in exposure meters for cameras.

43–3 Semiconductor Structures



In applying our knowledge of energy distributions in single semiconductors to semiconductor structures (combinations of semiconductors in contact so that charge carriers can pass between them), one principle determines essentially all the important features: Like temperature, *the chemical potential*—which for semiconductors we call the Fermi energy —*has the same value throughout a system in equilibrium*. This follows from the fact that in the absence of external potentials and in thermodynamic equilibrium, there is no net flow of charge or of energy across the boundary between two materials. The materials may be the same type of semiconductor doped differently, two different intrinsic semiconductors, or even a semiconductor and a metal. You can prove this important result in Problem 54.

The *p-n* Junction



When a semiconductor doped to *n*-type and the same semiconductor doped to *p*-type are brought into contact, a *p–n junction* is formed. (We can also work with junctions between different semiconductors, known as *heterojunctions*.) Such a junction is of interest because it acts as a diode (see Section 33–5). We consider *p–n* junctions in which both semiconductors are made by doping the same intrinsic semiconductor. In Fig. 43–13a, we have used p_p and p_n to denote the hole densities and n_p and n_n to denote the electron densities in *p*-type and *n*-type semiconductors, respectively. The sketches are highly distorted because the ratio of the dominant carriers to the carriers of opposite sign on each side of the junction is typically on the order of 10^{11}; drawn to scale, the n_p and p_n levels would be indistinguishable from the horizontal axis. We shall henceforth refer to the regions of *n*-type and *p*-type semiconductors as the *n*-side and *p*-side, respectively.

The *p*-side has an excess of mobile holes, and the *n*-side has an excess of mobile electrons, though not necessarily with the same density. Electrical neutrality is preserved on the *p*-side by the (immobile) negative acceptor ions in the crystal lattice and on the *n*-side by the (immobile) positive donor ions. When the two materials are put in contact, the mobile holes on the *p*-side tend to diffuse into the *n*-side, and the mobile electrons on the *n*-side tend to diffuse into the *p*-side. This mixing continues until the Fermi energies in the two materials reach the same level. This occurs by the following mechanism: Charges flow until the net positive charge remaining on the *n*-side (the right) and the net negative charge remaining on the *p*-side (the left) set up an electric field that stops the diffusion (Fig. 43–13b). The *n*-side will be at a higher potential, V_0, than the *p*-side. But electrons have a *negative* charge, so the energy of electrons on the right is *reduced* by eV_0.

Let's look at the *p–n* junction with the aid of energy diagrams. Figure 43–14a shows the energy levels of the semiconductors before they are brought together. The gap energies are the same because both semiconductors are made by doping the same intrinsic semiconductor. When the junction is formed, the conduction and valence bands will be distorted (Fig. 43–14b). The internal potential V_0 is what brings the Fermi

▲ **FIGURE 43–13** A *p–n* junction is formed by placing an *n*-type and a *p*-type semiconductor in contact. The variable *x* is the linear distance across the boundary. (a) The number densities of *p*-carriers (p_p and p_n, respectively), and the number densities of *n*-carriers (n_p and n_n, respectively) in *p*-type and *n*-type semiconductors. These densities are not drawn to scale. (b) As described in the text, the diffusion of carriers causes a potential difference to build up across the boundary. The direction of the resulting electric field is shown.

▲ **FIGURE 43–14** (a) The energy-level structure of *n*-type and *p*-type semiconductors before they are joined in a junction. (b) After the junction is formed and equilibrium is established, the energy levels adjust in such a way that the Fermi levels of the two materials equalize. This lowers the electron energy levels on the *n*-side and raises the electron energy levels on the *p*-side. (After B. G. Streetman, *Solid State Electronic Devices*, Prentice Hall, 1980, p. 141.)

energies to the same level. From Figs. 43–13 and 43–14, we see this statement is equivalent to the relation

$$E_{Fn}^0 - E_{Fp}^0 = eV_0,$$

where E_{Fn}^0 and E_{Fp}^0 are the Fermi energies in the n-type and p-type semiconductors, respectively, *before* the materials are brought into contact. *After* the materials are brought into contact,

$$E_{cp} - E_{cn} = eV_0, \tag{43–14}$$

where E_{cp} and E_{cn} are the edges of the conduction band in the p-type and n-type semiconductors, respectively. This relation follows directly from Fig. 43–14b. A similar expression holds for the edges of the valence bands.

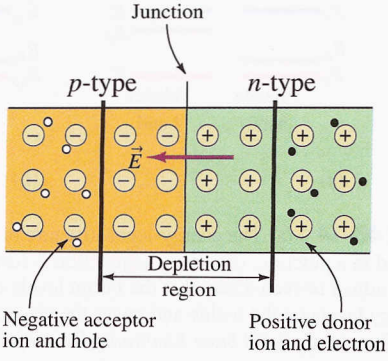
Note that V_0, which is known as the *contact potential*, is *not* an externally imposed potential. It is a property of the junction itself.

Let's suppose that the potential jump across the boundary is abrupt and study the consequences. (In real materials, the potential change occurs across a finite width called the *transition region*, or *depletion region*, as in Fig. 43–15. However, we shall ignore effects due to the transition region.) The densities of n-carriers on the two sides are, according to Eq. (43–5),

$$n_n = N_c e^{-(E_{cn}-E_F)/kT} \quad \text{and} \quad n_p = N_c e^{-(E_{cp}-E_F)/kT}.$$

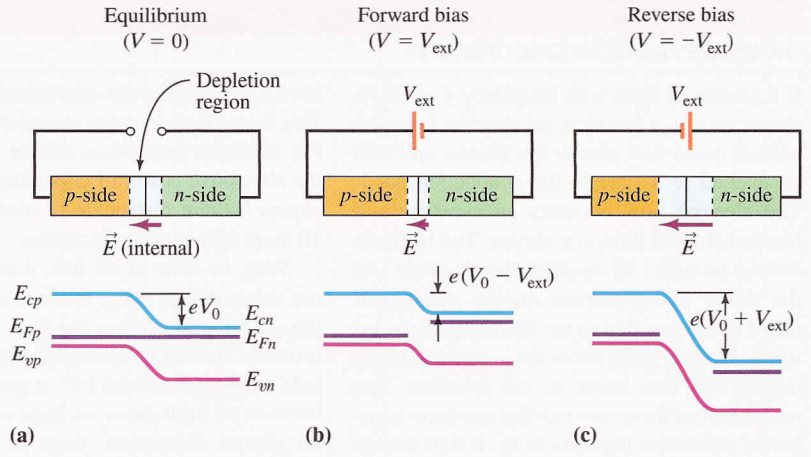
Thus

$$\frac{n_p}{n_n} = \frac{N_c e^{-(E_{cp}-E_F)/kT}}{N_c e^{-(E_{cn}-E_F)/kT}} = e^{-(E_{cp}-E_{cn})/kT} = e^{-eV_0/kT}, \tag{43–15}$$



where we have used Eq. (43–14) in the last step. Similarly, the ratio of the equilibrium hole densities on the two sides is

$$\frac{p_n}{p_p} = e^{-eV_0/kT}. \tag{43–16}$$



The ratios in Eqs. (43–15) and (43–16) help us to understand just how the currents in the two directions balance. Let's consider only the electrons—the flow of holes works in the same way. From Eq. (43–15), the concentration of electrons on the p-side is less than the concentration on the n-side by the factor $e^{-eV_0/kT}$, and these electrons have no potential barrier to climb to get to the n-side. There is a large density of electrons on the n-side, but to get to the p-side they need enough energy to climb a potential barrier of height eV_0, and as we know from our study of statistical mechanics, only a number reduced by the Maxwell–Boltzmann factor $e^{-eV_0/kT}$ will have that much energy. In this way, the flow of electrons in the two directions matches in equilibrium.

It follows from Eq. (43–14) that each of the products $p_n n_n$ and $n_p p_p$, which, from Eqs. (43–15) and (43–16) are equal in equilibrium, is also equal to n_i^2. Thus

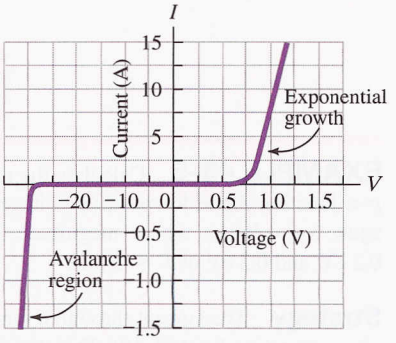
$$p_n n_p = N_c N_v e^{-(E_g+eV_0)/kT} \quad \text{and} \quad p_p n_n = N_c N_v e^{-(E_g-eV_0)/kT}. \tag{43–17}$$

▶ **FIGURE 43–15** The potential in a p–n junction changes value over a region of finite width called the depletion region. There is an internally generated electric field across the depletion region. (After Narciso Garcia and Arthur C. Damask, *Physics for Computer Science Students*, John Wiley & Sons, 1986, p. 457.)

◀ **FIGURE 43–16** (a) In the unbiased *p–n* junction, the intrinsic contact potential leads to equilibrium. (b) In forward biasing of a *p–n* junction, the energy levels on the *n*-side are raised relative to those on the *p*-side. (c) In reverse biasing of the same junction, the energy levels on the *n*-side are lowered relative to those on the *p*-side. (After B. G. Streetman, *Solid State Electronic Devices*, Prentice Hall, 1980, p. 151.)

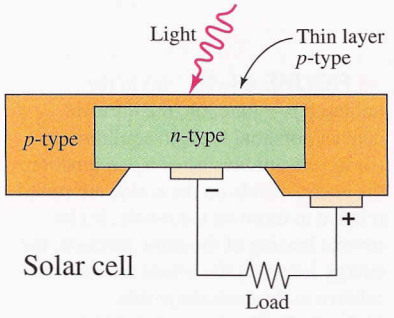
Biasing

Let's now apply an external potential, V_{ext}, across a *p–n* junction, which is then said to be *biased*. In this case, there can be a net flow of charge and a net flow of energy, in contrast to the unbiased case of Fig. 43–16a. Let's first assume that the external potential is such that the energies on the *p*-side are brought closer to the energies on the *n*-side (Fig. 43–16b). This external potential, by which the magnitude of the potential difference between the *n*-side and the *p*-side is *reduced* from $|V_0|$ to $|V_0| - |V_{ext}|$, is described as a *forward bias* voltage. The electrons that diffuse from the *n*-side to the *p*-side have less of a potential barrier to overcome. The same is true for the holes that diffuse from the *p*-side to the *n*-side (the potential difference is the same, but the charges of the carriers have opposite signs, so both have the same "hill" to climb). There is a net current from the *p*-side to the *n*-side, which rapidly increases as $|V_0| - |V_{ext}|$ decreases in magnitude. Note that there is also a small fixed current from the *n*-side to the *p*-side, associated with movement of electrons and holes without a potential barrier to overcome.



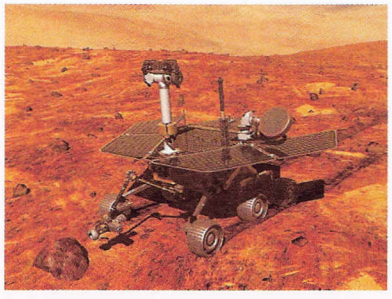
If the external potential is applied in such a way that the potential difference between the *n*-side and the *p*-side is *increased* from $|V_0|$ to $|V_0| + |V_{ext}|$, we have a *reverse bias* voltage (Fig. 43–16c). Both electrons from the *n*-side and holes from the *p*-side have an even harder time overcoming the additional barrier, and there is little current due to those charge carriers. However, the small fixed current from the *n*-side to the *p*-side is unaffected.

To make our argument more quantitative, let's suppose that a positive V_{ext} is a forward bias and a negative V_{ext} is a reverse bias. Consider first the current due to the motion of the holes, with positive current corresponding to positive charges moving to the right. The potential barrier $e(V_0 - V_{ext})$ inhibits positive carriers from the left (of density p_p) from flowing, and only the fraction $p_p e^{-e(V_0 - V_{ext})/kT}$ gets through. Positive carriers from the right do not encounter such a barrier, but their density is smaller by a factor $e^{-eV_0/kT}$, independent of V_{ext}. (The same is true separately for the *n*-carriers.) Take I_0, which is proportional to $e^{-eV_0/kT}$, to be the current of *p*-carriers from the right and *n*-carriers from the left. Without the external potential, I_0 would be canceled by the current of *p*-carriers from the left and *n*-carriers from the right, but those currents have now been modified by the factor $e^{-eV_{ext}/kT}$. Thus the *net* current flowing to the right is given by



$$I_{net} = I_0(e^{-eV_{ext}/kT} - 1). \qquad (43\text{–}18)$$

This current–voltage relation, called the *I–V characteristic* of the junction, is shown in Fig. 43–17.



The *I–V* characteristic shows that the *p–n* junction behaves like a *diode*, a device that allows current to pass in one direction but not in another. Such diodes can be used to construct rectifiers (see Chapter 33). The *p–n* junction can also act as a *solar cell* or a *light-emitting diode*.

▲ **FIGURE 43–17** *I–V* characteristic of a *p–n* junction. The junction behaves as a diode under an external potential V_{ext}. Note the change in scale for negative voltage.

▲ **FIGURE 43–18** Schematic diagram of a solar cell, which generates current across the load (resistor) when light shines on the p-side of a p–n junction.

▲ **FIGURE 43–19** This artist's concept of the Mars Rover that successfully explored the surface of Mars has solar cells on almost its entire top surface to supply the electrical power for the various tools, cameras, and communication equipment.

THINK ABOUT THIS. . .

HOW DOES A SOLAR CELL OPERATE?

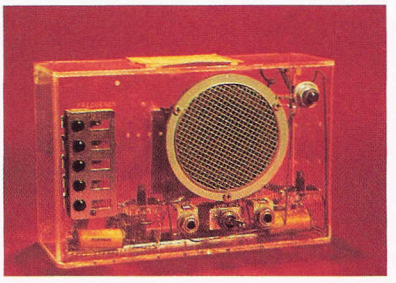
If a photon of light with frequency $f > E_g/h$ shines on a p–n junction, an electron from the valence band will absorb the photon and will be excited to a state in the conduction band. The electron now becomes an n-carrier and leaves behind a hole, a p-carrier. The intrinsic contact potential V_0 separates the electrons and the holes: The p-carriers on the p-side will move to the junction in the direction of the intrinsic electric field, while the n-carriers on the n-side will also move to the junction. The movement of these new carriers produces a potential difference opposite to V_0. It thus acts as a forward bias voltage across the junction, even in the absence of V_{ext}. A current is produced by this *photovoltaic effect*, and power can be delivered to an external circuit. In silicon, for example, photons of wavelength shorter than 1200 nm will give rise to a photovoltaic effect, meaning visible light will produce current in the junction.

A solar cell, a device that produces electricity from sunlight, is a p–n junction constructed in such a way that the solar photons can be absorbed in the area closest to the built-in contact potential—near the junction (Fig. 43–18). Sunlight is allowed to fall onto the top semiconductor, which is covered with an antireflective coating. The light penetrates the semiconductor and is absorbed in the junction region below. The materials are chosen with a band gap small enough to absorb even the long-wavelength component of solar light. It is also important to have a large absorption coefficient for the light. This factor favors certain materials over others. For example, amorphous silicon has 50 times the absorptive power of crystalline silicon, and copper indium diselenide is another factor of 10 more efficient for absorption.

Why, in view of all this, don't we simply use solar cells on every roof and dispense with the power grid? When the Sun is shining, it provides about 1 kW/m^2, and a typical household might use several kW at peak times. But because of limitations on light collection and on photon absorption, there is a theoretical maximum of 28 percent for conversion of solar energy into electric energy in silicon, and real silicon solar cells are even less efficient, on the order of 10 percent. Thus a large area of solar cells would be needed. Of course the Sun does not shine all the time, so one must collect enough energy for later use and store it as well. This all adds up to a prohibitive cost. The capital cost of an installation that could power a small house in ideal conditions can be counted in tens of thousands of dollars. Power generation by solar cells is cost-effective only in regions so remote from the grid that the cost of transmission from the grid exceeds the cost of the power cells, as for example on distant farms, or power for remote traffic control, buoys, or planetary exploration (Fig. 43–19). At a more manageable scale, you may be using solar cells or their equivalent on a daily basis in a watch or a calculator. ■

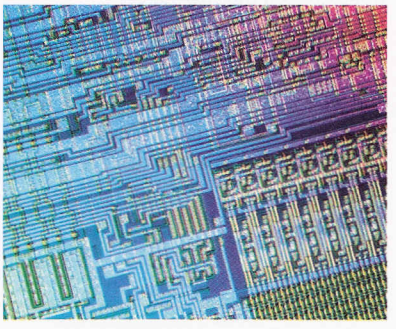
LEDs

A light-emitting diode (or LED), which is a p–n junction acting as a signal light, is essentially a solar cell that operates in reverse. When a forward bias is applied across the junction, electrons flow from the n-side to the p-side and holes from the p-side to the n-side. When the electrons arrive at the p-side, they recombine with available holes and emit light in the process. The holes that arrive at the n-side recombine with available electrons and also emit light. LEDs are widely used as electronic signaling lights because they are long-lasting, use little energy, can be switched on and off rapidly, and are compact.



EXAMPLE 43–5 Calculate the ratio of the currents through a p–n junction diode for positive voltages to those for negative voltages, for voltages whose magnitude is given by $eV_{\text{ext}} = 0.1$ eV, 0.2 eV, and 0.3 eV at $T = 300$K.

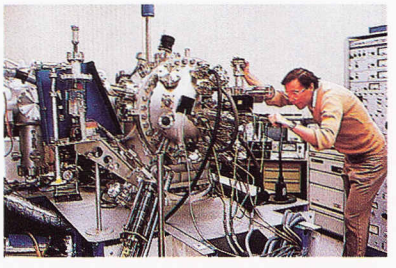
Strategy The current through a junction diode biased by a voltage is given by Eq. (43–18). Thus the ratio of the currents for positive to negative bias, R, is given in terms of $K \equiv eV_{\text{ext}}/kT$ by



$$R = \left| \frac{e^K - 1}{e^{-K} - 1} \right| = \frac{e^K - 1}{1 - e^{-K}}.$$

Working It Out At $T = 300$K, $kT = 2.6 \times 10^{-2}$ eV, so the parameter K has the values 3.9, 7.7, and 12 for $eV_{\text{ext}} = 0.1$ eV, 0.2 eV, and 0.3 eV, respectively. The respective values of R are then 48, 2.2×10^3, and 1.0×10^5. The rapid growth of these values as eV_{ext} increases illustrates the dramatic biasing power of relatively small potential differences.

Transistors: The *transistor* is a three-terminal device that can be used for sensitive control of currents flowing through circuits, particularly for amplifying or switching currents. One of the first transistors, the *bipolar junction transistor* (BJT), started a revolution in electronics that is still going on. That transistor and the theory of its operation were developed in 1948 and 1949 by John Bardeen, Walter Brattain, and William Shockley (Fig. 43–20). While we won't go into any of the details here, it is worth mentioning that a transistor is constructed by judiciously combining two oppositely doped semiconductors in a structure that places two junctions close by. It is possible in this arrangement to apply biasing voltages that allow a very small change in the current in one part of the transistor to lead to a very large change in the current of another part. In this way the transistor is a kind of amplifier. Depending on how the amplified current is used, the transistor can act as a very sensitive switch. Devices like these are today combined into building blocks for today's electronics. By the techniques to be described in Section 43–4, thousands or even millions of tiny semiconductor structures making up complicated circuits are fabricated as one unit; we call these circuits *integrated circuits* (Fig. 43–21). These circuits have enabled us to produce powerful desktop computers that take up very little space. The layers of material that make up the devices in integrated circuits are measured in fractions of nm, and the currents that flow in them may be on the order of mA.

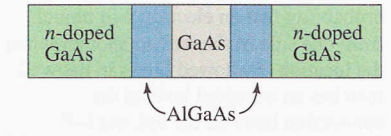


▲ **FIGURE 43–20** "Bardeen's box," constructed in 1949, contains a circuit with transistors as elements. The instant turn-on of the circuit impressed audiences who had been used to waiting a long time for circuits containing tubes to warm up.

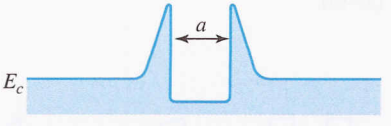
▲ **FIGURE 43–21** Photomicrograph of the surface of an integrated circuit.

43–4 Band-Gap Engineering

Technological advances in the fabrication of semiconductor structures have created a new tool chest for the electronics engineer and computer designer. One advance involves the ability to place thin layers of one or several materials on a single underlying layer (a *substrate*) of another material with very similar crystal structure. (Such techniques are the basis of integrated-circuit construction.) This procedure, known as *epitaxy*, has reached its highest refinement with *molecular-beam epitaxy* (Fig. 43–22). Examples are provided in structures in which single crystals of gallium arsenide form a substrate and compounds of aluminum and gallium arsenide ($Ga_{1-x}Al_xAs$, which are alloys of variable content, where x represents a fraction) form junctions with the substrate. Gallium, aluminum, and arsenic are evaporated in a vacuum chamber and projected as beams onto the gallium arsenide substrate. The beams form layers at a rate of about one per second on a substrate whose thickness can be controlled. The components of the deposited layers can be varied by exposing the substrate to different beams in different proportions. Impurities are easily added in desired proportions.



▲ **FIGURE 43–22** The molecular-beam epitaxy machine shown here is used to construct microscopic structures molecular layer by molecular layer.



Lithography is another indispensable technology for integrated circuits. With this process, we can create detailed patterns on a crystal surface. In scanning-electron-beam lithography, an opaque film on a transparent base is removed in a precise pattern by a moving electron beam. The resulting transparent features are as small as several nm. Light passes through this "negative" onto a semiconductor blank that has been coated with a polymer that disintegrates when light hits it. The coated semiconductor can then be etched by chemicals such as chlorine gas that act where the polymer has disintegrated. Alternatively, other materials can be deposited on the areas where the polymer has disintegrated, or doping ions can be introduced in those areas. A process such as this can be repeated to produce elaborate structures with many layers.

Quantum Wells, Quantum Wires, and Quantum Dots

When heterojunctions are combined in various ways, the condition that the Fermi energy is constant across junctions has an effect on the energies of the edges of bands, and these edges may form regions in which electrons have "walls" on two sides. Figure 43–23a shows a thin GaAs layer sandwiched between two AlGaAs layers, surrounded by GaAs that contains the donor ions; Fig. 43–23b is an energy diagram for this structure. The electrons in the GaAs layer move in a *quantum well*. Such potential wells are characterized by quantized energy levels. We can find the values of these energies by thinking of standing waves set up in the direction of the (small) distance a between the "walls" that confine the electron, just as atomic energies in the Bohr model follow from

(a)

(b)

▲ **FIGURE 43–23** (a) A heterostructure within which (b) a potential energy well of width a forms and confines electrons.

thinking about fitting standing waves into atomic orbits. The allowed energies of the quantum well are then given by

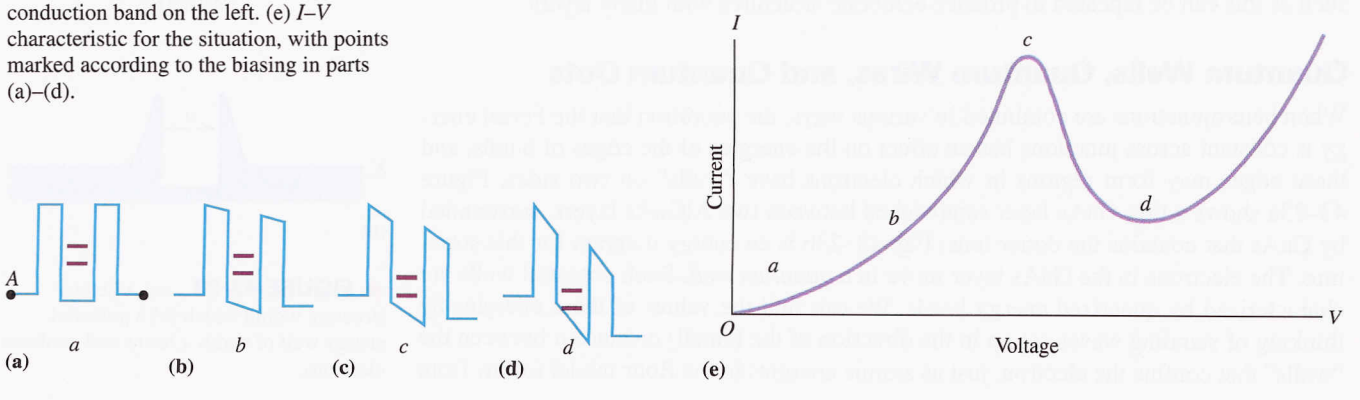
$$E_n = \frac{n^2\hbar^2\pi^2}{2m^*a^2}, \tag{43–19}$$

where n is any integer. The confining distance a is typically 10 to 100 nm. Although a is large compared with atomic dimensions, the fact that m^* is small partly compensates for this effect. Only the energy of lateral motion is quantized: The motion in the direction perpendicular to the plane of the page for Fig. 43–23a is not quantized.

EXAMPLE 43–6 Calculate the energy difference between the ground state and the first excited state in a quantum well of width 20 nm, given that the effective mass is $m^* = 0.070m_e$. What is the wavelength of a photon emitted when an electron undergoes a transition between the two states?

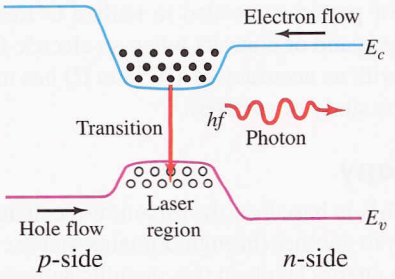
Strategy We use Eq. (43–19) to calculate the energy difference ΔE between levels characterized by $n = 2$ (the first excited state) and $n = 1$ (the ground state). Once we have this energy difference, the frequency of a photon emitted in a transition between these two levels is determined by $\Delta E = hf$, and the corresponding wavelength is $\lambda = c/f$.

Working It Out We have



$$\Delta E = E_2 - E_1 = \frac{(2^2 - 1^2)\hbar^2\pi^2}{2m^*a^2} = \frac{3\hbar^2\pi^2}{2m^*a^2}$$
$$= \frac{3(1.05 \times 10^{-34}\,\text{J}\cdot\text{s})^2\pi^2}{2(0.070)(0.91 \times 10^{-30}\,\text{kg})(2.0 \times 10^{-8}\,\text{m})^2}$$
$$= 6.4 \times 10^{-21}\,\text{J} = \frac{6.2 \times 10^{-21}\,\text{J}}{1.6 \times 10^{-19}\,\text{J/eV}} = 4.0 \times 10^{-2}\,\text{eV}.$$

Therefore the wavelength of a photon emitted when there is a transition between these levels is

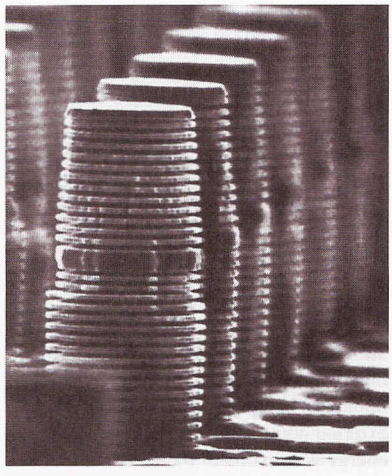


$$\lambda = \frac{c}{f} = \frac{hc}{\Delta E} = \frac{(6.6 \times 10^{-34}\,\text{J}\cdot\text{s})(3.0 \times 10^{8}\,\text{m/s})}{6.2 \times 10^{-21}\,\text{J}}$$
$$= 3.2 \times 10^{-5}\,\text{m}.$$

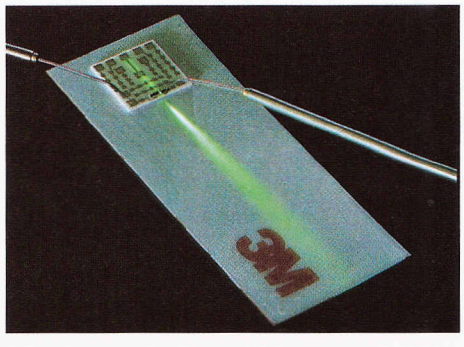
A quantum well can act as a very sensitive switch. Figure 43–24 shows how to arrive at the *I–V* characteristic for a device based on it. With zero voltage between points *A* and *B* (Fig. 43–24a), the quantum well presents a barrier to the *n*-carriers. There is no tunneling because the energy levels on both sides of the quantum well are occupied equally. When a voltage is applied, the *n*-carriers on the left are at a higher energy, and they can tunnel into empty levels (Fig. 43–24b). Thus, the current rises with *V*, as shown in Fig. 43–24e. When the bottom of the conduction band on the left is lifted high enough to match one of the low-lying quantized levels inside the well (Fig. 43–24c), there is a drastic increase in the flow of the current (Fig. 43–24e). A further voltage rise decreases the current because the bottom of the conduction band on the left no longer matches a well level (Fig. 43–24d). As the voltage increases further, the current decreases and then increases again as the second energy level is approached, as we see in Fig. 43–24e. The ability to pick the applied voltage that produces substantial tunneling makes for a sensitive switch.

Quantum wires and *quantum dots* represent further steps in the fabrication of systems in which quantum behavior is dominant. They correspond to electron-confining "pipes" and "boxes," respectively. Electrons in a quantum dot, the equivalent of a tiny three-dimensional box, have widely separated energy levels (see Problem 34). Such structures are promising as very precise switching devices.

▼ **FIGURE 43–24** The quantum well of Fig. 43–23 subjected to an external potential. (a) through (d) As the potential is increased, there is an enhanced probability that an electron will tunnel from one side of the well to another when the location of allowed levels in the well matches an occupied level in the conduction band on the left. (e) *I–V* characteristic for the situation, with points marked according to the biasing in parts (a)–(d).



◀ **FIGURE 43–25** Energy diagram for a semiconductor laser. The laser light is produced in the recombination of n-carriers and p-carriers at the central region.



Semiconductor Lasers

Semiconducting materials are well suited to the construction of microscopic lasers. Such lasers have already found uses in compact-disc players, amplifiers in satellite receivers, and communications with fiber optics. An energy diagram for a heterostructure illustrates how these lasers may be constructed. The semiconductor within which the laser light will be produced (for example, GaAs) is sandwiched between two layers of appropriately doped AlGaAs. The right side of the energy diagram in Fig. 43–25 is doped to n-type, and the left side is doped to p-type. A potential barrier keeps the electrons from flowing to the left near the bottom of the conduction band, and a counterpart barrier keeps the holes from flowing to the right near the top of the valence band. If a voltage is applied that causes more electrons to flow into the GaAs region and more holes to flow into that region, and the barrier prevents both n-carriers and p-carriers from flowing back, a population inversion is built up. Note that, unlike the lasers described in Chapter 42, the "pumping" is done automatically in these materials. The electrons and holes can recombine by the emission of photons, and these photons stimulate further, rapid recombination. This describes the process we treated in Chapter 42 for the production of laser light.

Figure 43–26 is an image of a set of *microlasers* that consist of a thin InGaAs quantum well, with stacks of AlAs, GaAs, and AlGaAs layers both above and below it. The laser action takes place in the quantum well and, because the well is narrow, the power required to make the laser work is very small. Many reflections of the light are required to get suitable amplification, and the large number of layers provide a certain amount of reflection at each interface. Even though the reflectivity at each interface is less than 1 percent, the large number of layers gives a total reflectivity back to the lasing material of 99 percent. Many lasers—millions of them—each with cylindrical geometry, can be formed on a single substrate by molecular-beam epitaxy and subsequent etching. Such laser arrays are useful for optical communications in fiber optics (Fig. 43–27).

▲ **FIGURE 43–27** Blue-green light is emitted by this semiconductor laser.

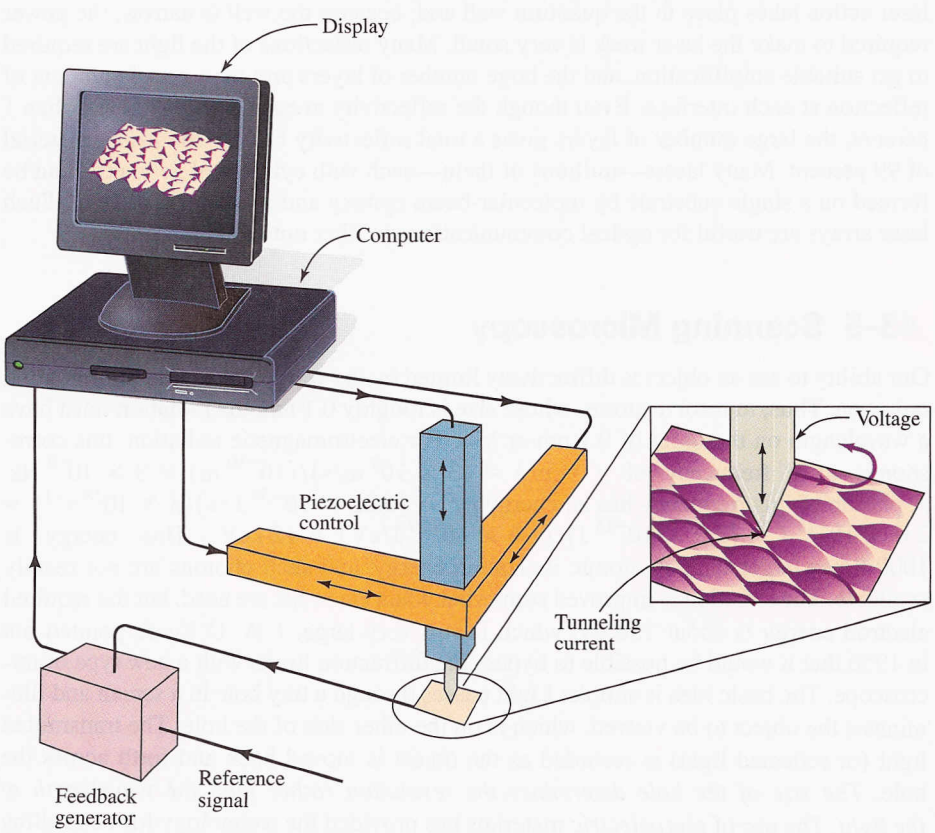
43–5 Scanning Microscopy

Our ability to see an object is diffractively limited by the wavelength of the illuminating radiation. Thus, to resolve atoms, whose size is roughly 0.1 nm, the radiation must have a wavelength on the order of 0.1 nm or less. For electromagnetic radiation, this corresponds to a frequency of $f = c/\lambda = (3 \times 10^8\ \text{m/s})/(10^{-10}\ \text{m}) = 3 \times 10^{18}\ \text{Hz}$. A photon of this frequency has an energy $hf = (6.62 \times 10^{-34}\ \text{J}\cdot\text{s})(3 \times 10^{18}\ \text{s}^{-1}) = 2.0 \times 10^{-15}\ \text{J} = (2.0 \times 10^{-15}\ \text{J})/(1.6 \times 10^{-19}\ \text{J/eV}) = 12\ \text{keV}$. This energy is 1000 times larger than an atomic ionization energy, and such photons are not readily available. The situation is improved somewhat when electrons are used, but the required electron energy is about 150 eV, which is still very large. J. A. O'Keefe pointed out in 1956 that it would be possible to bypass the diffraction limits with a new type of microscope. The basic idea is simple: Light passes through a tiny hole in a screen and illuminates the object to be viewed, which is on the other side of the hole. The transmitted light (or reflected light) is recorded as the object is moved back and forth across the hole. *The size of the hole determines the resolution rather than the wavelength of the light.* The use of *piezoelectric* materials has provided the technology for controlling

▲ **FIGURE 43–28** (a) When two metals are separated by a gap, there is no tunneling in equilibrium. (b) If an external potential is applied, the Fermi energy within one of the metals is lowered, leaving empty levels into which electrons from the side with the higher electron energies can tunnel. The height of the barrier to overcome is the metal's work function W.

the position of an object with the kind of precision needed to realize O'Keefe's idea. Piezoelectrics are ceramic materials that expand or contract when an electric field is applied to them. The ability to move them with an accuracy of 10^{-5} nm (!) has made scanning microscopy into a superb tool for the study of surfaces.

Scanning Tunneling Microscopy

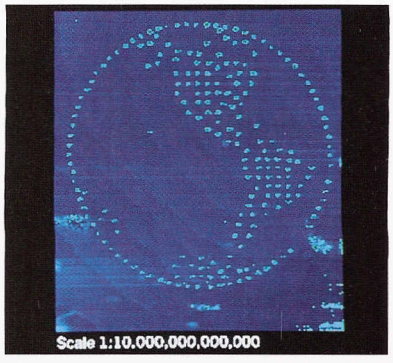


The scanning tunneling microscope (STM) is based on the quantum mechanical result that electrons can tunnel from one region to another through domains that are classically inaccessible. Figure 43–28a shows the energy levels in two metallic samples separated by a vacuum of width a. Electrons at the Fermi energy can cross over from one sample to the other in significant numbers only if (1) there are empty energy levels of the same energy, so that the exclusion principle does not prevent tunneling, and (2) the tunneling probability is sufficiently large. If an electric field is applied, thereby lowering the Fermi energy on one side as in Fig. 43–28b, then condition (1) is satisfied and tunneling can occur. An application of Eq. (40–11) shows that the rate at which electrons cross such a barrier is

$$f = e^{-(2/\hbar)a\sqrt{2mW}}, \tag{43–20}$$

where m is the electron mass and W is the work function of the metal (the height of the potential barrier between the metals). The important feature of Eq. (43–20) is the extreme sensitivity of the tunneling fraction (that is, the current) to the magnitude of the separation.

Figure 43–29 (see also Fig. 24–33) shows how an STM is built. A tungsten tip acts as a "hole in the screen." When such a tip is poised above a surface at a potential different from that of the tip, then, according to Eq. (43–20), the current passing through the tip is a sensitive indicator of its distance to the surface. The resolution depends on the tip size. Tips that end in a *single* atom are made by heating a crude tungsten tip and applying a strong electric field to it. The field pulls atoms away layer by layer, leaving a single-atom tip. With such tips it is possible to resolve features 0.1 nm across: *We can "see" single atoms on a surface.*

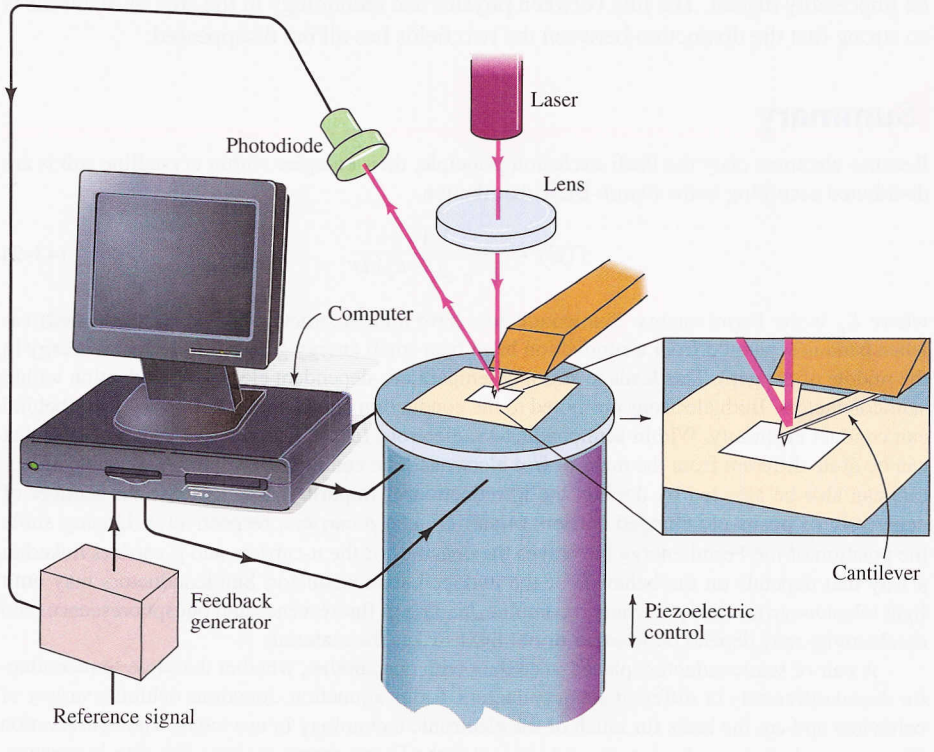


There are two ways of scanning a surface. In one method, piezoelectric supports that hold the tip are arranged to sense the tunneling current and move the tip up or down

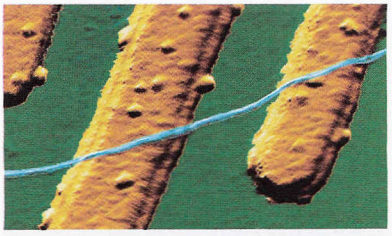
▶ **FIGURE 43–29** Schematic diagram of a scanning tunneling microscope.

so as to maintain a constant current or, equivalently, a constant distance from the surface. The voltages applied to the piezoelectric supports during this process provide a record of the surface topography. A second way of scanning the surface is to move the tip horizontally across the surface and see how the tunneling current varies for a fixed applied voltage. STMs are especially effective because miniaturization of the apparatus helps in the reduction of "noise": The smaller the apparatus, the higher the frequency of the random thermal vibrations, and this noise is relatively easy to filter out. In addition, STMs work better in air than in a vacuum because the random bombardment by air molecules also tends to average out noise.

STMs are used in a variety of surface studies. Electron charge distributions at surfaces can be measured, as can the way the distributions are affected by the deposition of very thin films on the surfaces. Another application involves the use of the STM tip to manipulate individual atoms or groups of atoms and move them around on the surface of the sample (Fig. 43–30; see also Fig. 24–35). There is potential for the creation of tailor-made molecular structures for specific tasks in microelectronic devices.



▲ **FIGURE 43–30** A map made of tiny dots that consist of just a few thousand atoms of gold. The map, about 1 micron across, was made by manipulating the gold dots with the tip of a scanning tunneling microscope.



Atomic Force Microscopy

Another imaging device, the *atomic force microscope* (AFM), images a surface by measuring the effect of the force it exerts on a small cantilever (like a diving board) rather than by probing it with a current (Fig. 43–31). This force is an atomic force, and the idea that it should be directly measurable sounds absurd. Nevertheless, if we calculate an interatomic spring constant $k = m\omega^2$, with $\omega = 10^{13}$ Hz (a typical atomic frequency) and $m = 10^{-25}$ kg, we find that $k = 10$ N/m. For comparison, the spring constant of a piece of aluminum foil 4 mm long and 1 mm wide acting as a cantilever is about 1 N/m. Because the atomic spring constant and the mechanical cantilever spring constant are comparable, atomic forces can be measured by sensing small displacements (0.1 nm) of such a cantilever.

In some AFMs, the cantilever is a piece of silicon or silicon oxide about 100 μm long and 1 μm thick. Such cantilevers have a spring constant in the range of 0.1 to 1 N/m. The sensor that detects the motion of the cantilever must detect displacements of less than 0.1 μm. One way of detecting this motion is to shine laser light on it and record the position of the reflected beam with a light detector. The light detector activates the piezoelectric base on which the sample is placed, and a current controls the base such that the distance

◀ **FIGURE 43–31** Schematic diagram of an atomic force microscope (AFM).

▲ **FIGURE 43–32** This atomic force micrograph (AFM) shows a blue carbon nanotube wire of only 10 atoms width (1.5 nm) lying across platinum electrodes (yellow).

between the sample and tip is held constant. The movement of the sample is translated into an image of the surface. Figure 43–32 illustrates the kind of image possible with an AFM.

The effect of the external environment on the AFM is quite negligible. Typical building vibration frequencies are about 10 to 20 Hz, whereas the resonant frequencies of the cantilever are about 10 to 100 kHz. Amplitude distortions due to external vibrations of frequency f are on the order of $(f/f_{\text{res}})^2$. Building vibrations thus contribute a correction of less than 10^{-3} nm to the displacement.

THINK ABOUT THIS. . .

DOES THE ATOMIC FORCE MICROSCOPE HAVE ADVANTAGES OVER THE SCANNING TUNNELING MICROSCOPE?

In the STM we make pictures of conducting materials; it works, after all, by measuring a current that passes between its tip and the material's surface. Some of the uses of the STM are described above. With an AFM, we can make images of the surface of *any* type of solid material, including insulators. Moreover, AFMs can be operated in a variety of environments: in air, in water, at low temperatures, or in a vacuum. The materials being probed also require little preparation, whereas the conducting properties of materials probed with STMs will change if, say, there is a layer of oxide on the surface. The AFM has also been used to study atomic-scale structure on the surfaces of graphite, mica, sodium chloride, and other nonorganic materials of this type. They have also been applied to the imaging of biological molecules such as amino acids, DNA, and proteins and have even imaged certain chemical processes *as they occur*. While the resolution of STMs takes us down to single atoms, the best AFMs cannot see quite as sharply, having resolutions on the range of 1 to 10 nm.

The Ultimate in Quantum Engineering

In this chapter, we have emphasized the interplay of physics and modern technology. We have touched on only a few topics—concentrating on those for which quantum physics is important. The ultimate aim of the kind of work we have described here is the production of devices in which single atoms or single electrons play the major role. For example, a computer memory that stores information by the presence or absence of an individual atom in a given surface site could conceivably store all the knowledge of the human race on a surface of area 1 cm^2! And transistors that operate by allowing single electrons to tunnel could compose the smallest possible circuit. The realization of these ideas may not be impossibly distant. The link between physics and technology in the area of materials is so strong that the distinction between the two fields has all but disappeared.

Summary

Because electrons obey the Pauli exclusion principle, their energies within crystalline solids are distributed according to the Fermi–Dirac distribution,

$$f(E) = \frac{1}{1 + e^{(E-E_F)/kT}}, \tag{43–2}$$

where E_F is the Fermi energy. Semiconductors have a band structure for which the (filled) valence band is separated from a conduction band by a small energy gap (with the Fermi energy in the middle of the gap). This leads to strongly temperature-dependent electrical conduction within semiconductors. Both electrons promoted to the conduction band and the holes they leave behind can conduct electricity. Within semiconductors, electrons (and holes) have effective masses that can be quite different from the mass of free electrons. The conduction properties of semiconductors can also be affected by doping, the introduction of impurities that increase the number of negatively or positively charged carriers (n-carriers and p-carriers, respectively). Doping shifts the position of the Fermi energy but leaves the densities of the n-carriers and p-carriers linked in a way that depends on the behavior of the undoped semiconductor. Semiconductors may emit light when n-carriers and p-carriers recombine, leading to fluorescence and phosphorescence, and conductivity may depend on whether or not light strikes the material.

A pair of semiconductors placed in contact with one another, whether the same semiconductor doped differently or different semiconductors, forms a junction. Junctions exhibit a variety of behaviors and are the basis for much of the electronic technology in use today. The conservation of energy and of charge leads to the principle that the Fermi energy across a junction is constant.

This principle dictates that an internally generated electric potential, the contact potential, is generated across the boundary of a *p–n* junction, a semiconductor structure consisting of a semiconductor doped with *p*-carriers in contact with the same semiconductor doped with *n*-carriers. The contact potential explains why *p–n* junctions act as diodes, devices for which current I_{net} in effect passes in one direction only when an external potential V_{ext} is applied:

$$I_{net} = I_0(e^{-eV_{ext}/kT} - 1), \tag{43–18}$$

where I_0 is a current associated with the contact potential. A *p–n* junction can also act as a light-emitting diode or as a solar cell.

The transistor is a three-terminal semiconductor device in which small changes in potential across one pair of terminals can lead to large amplification of the current that passes through another pair of terminals. Such devices are therefore useful for the sensitive control of currents and of voltages in circuits.

Modern techniques of material manipulation permit the elaboration of heterostructures, single-crystal structures built in a precisely controlled way from different materials. The electrical behavior of heterostructures depends intimately on quantum phenomena, even beyond the collective quantum effects that lead to any band structure. Microscopic semiconductor lasers and quantum wells are manifestations of this new technology whose limits are not yet known.

Scanning tunneling microscopes employ quantum tunneling to explore conductors, and atomic force microscopes allow us to explore nonconductors. Both instruments avoid resolution difficulties associated with diffraction and permit the study of matter at close to atomic scales.

Understanding the Concepts

1. You have just calculated the number density of *n*-carriers in undoped silicon, a semiconductor, at room temperature. Is it necessary to make a second calculation to find the number density of holes?
2. When a hole moves from the *p*-side of a junction to the *n*-side, why does its energy increase?
3. Does the Fermi energy still lie in the middle of the energy gap when the effective masses of the *n*-carriers and *p*-carriers are different?
4. Is the mechanism that makes metals opaque to visible light but transparent to X rays similar to the mechanism that makes semiconductors opaque to visible light but transparent to infrared light?
5. There are several methods by which electrons can be removed from a solid's surface. How can holes be removed?
6. What happens to the Fermi energy at low temperatures when a semiconductor is so heavily doped that the energy levels of the donor states overlap the conduction band?
7. How can the energy of a hole be raised as it travels from the *p*-side of a *p–n* junction to the *n*-side?
8. Why, physically, is it true that the smaller the effective mass of an *n*-carrier, the larger the drift velocity of the carrier?
9. We described why new states for electrons are available near the bottom of the conduction band in an *n*-type extrinsic semiconductor. Why are new states for holes available just above the top of the valence band in a *p*-type extrinsic semiconductor?
10. Is there a type of viscosity that acts on holes in a semiconductor and gives them a terminal velocity in an electric field, or do holes just accelerate under the influence of such a field? If there is a terminal velocity, is it the same as that of the electrons?
11. We referred to a current amplification in our discussion of transistors. Can this mean that the power is amplified? If so, where does the necessary energy come from?
12. The gap widths of the semiconductors in Table 43–1 are given at room temperature. How could a gap width depend on temperature?
13. Experiment shows that many insulators are transparent to visible light, many semiconductors are opaque to visible light and transparent to infrared light, and metals are opaque to all forms of visible light. Why might this be true?

Problems

43–2 Semiconductors

1. (I) In silicon, $E_g = 1.12\,\text{eV}$, and the effective mass of the *n*-carriers is $m^* = 0.31m_e$, where m_e is the electron mass. Find the number densities of *n*-carriers at 100K and at 300K. Compare your result with the number density of "free" electrons in copper, 8.5×10^{22} electrons/cm^3.
2. (I) What is the density of electrons in the conduction band of silicon, for which $m_n^* = 0.31m_e$, at temperatures of (a) 90K, (b) 293K, and (c) 450K? [*Hint*: See problem 1.]
3. (I) For sodium ($E_F = 3.23\,\text{eV}$) at room temperature (300K), calculate the occupation probability of an electron state of energy (a) 2 eV, (b) 3 eV, (c) 3.2 eV, (d) 3.26 eV, and (e) 4 eV.
4. (I) At what temperature is the probability that an energy state at 7 eV will be populated equal to 40 percent for copper ($E_F = 6.95\,\text{eV}$)?
5. (I) Find the energy gap of an intrinsic semiconductor in which 1.02×10^{-30} of the available energy levels near the bottom of the conduction band are occupied at $T = 126\text{K}$.
6. (I) The value of the Fermi–Dirac distribution function $f(E)$ for a particular energy value within a collection for electrons at a temperature $T = 65\text{K}$ is found to be equal to 0.4. What is the value of that function for the same energy value when $T = 85\text{K}$?
7. (I) What is the probability of finding an electron at the bottom of the conduction band in GaAs, for which $E_g = 1.43\,\text{eV}$, at $T = 300\text{K}$?
8. (I) The Fermi temperature T_F is defined by E_F/k, where k is Boltzmann's constant. What is T_F for (a) silver ($E_F = 5.1\,\text{eV}$), (b) copper ($E_F = 6.95\,\text{eV}$), and (c) a white dwarf star ($E_F \cong 2 \times 10^5\,\text{eV}$)?
9. (I) What is the maximum wavelength of light that will excite an electron from the valence band to the conduction band in (a) InSb ($E_g = 0.18\,\text{eV}$), (b) GaSb ($E_g = 0.68\,\text{eV}$), and (c) GaAs ($E_g = 1.43\,\text{eV}$)?

10. (I) The following table gives the energy above the edge of the valence band, ΔE, for the energy levels of various acceptor impurities in silicon:

Impurity:	Boron	Gallium	Indium	Nickel	Zinc
ΔE (in eV):	0.045	0.065	0.16	0.22	0.31

Find the maximum wavelength of the radiation required to excite electrons from the top of the valence band to these acceptor levels.

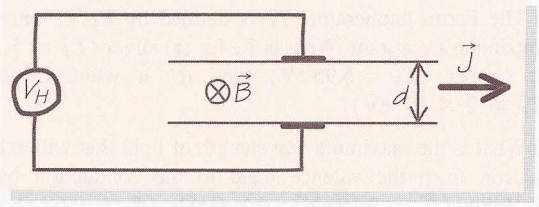
11. (I) Calculate the intrinsic carrier concentration in silicon at 400K, given that $m_n^* = 0.31m_e$ and $m_p^* = 0.56m_e$.

12. (I) At room temperature (300K), undoped GaSb has an energy gap of 0.68 eV. (a) What is the probability that an electron occupies an energy state at the bottom of the conduction band? (b) What is the probability that there is a hole state at the top of the valence band?

13. (II) The effective masses of n- and p-carriers in germanium are given by $m_n^* = 0.55m_e$ and $m_p^* = 0.37m_e$, respectively. The concentration n_i of n-carriers at 300K is $2.5 \times 10^{19}\ \text{m}^{-3}$. Use these data to calculate the gap width of germanium.

14. (II) The effective masses of n- and p-carriers in GaAs are given by $m_n^* = 0.067m_e$ and $m_p^* = 0.48m_e$, respectively. The gap width of GaAs is 1.43 eV. Use this information to find the intrinsic carrier density at 380K.

15. (II) A sample of silicon is doped so that the donor density is $n = 2.0 \times 10^{23}\ \text{m}^{-3}$. Find $E_c - E_F$ at $T = 300\text{K}$, given that the effective n-carrier mass in silicon is $m_n^* = 0.31m_e$. Compare your result with E_g for silicon.



16. (II) A sample of silicon is doped so that the hole density is $p = 2 \times 10^{22}\ \text{m}^{-3}$. Find $E_F - E_v$ at $T = 330\text{K}$, given that the effective p-carrier mass in silicon is $m_p^* = 0.56m_e$.

17. (II) The intrinsic semiconductor InSb has a gap energy of 0.18 eV, and the effective masses of the electrons and holes are $0.015m_e$ and $0.39m_e$, respectively. Find the carrier densities at $T = 100\text{K}$ and 300K.

18. (II) The *mobility*, μ, of a charge carrier in a material is defined as the drift speed of the carrier, v_d, divided by the magnitude of the electric field driving the current, $\mu \equiv v_d/E$. For germanium at 300K, the mobilities of electrons and holes are about $0.45\ \text{m}^2/\text{V}\cdot\text{s}$ and $0.35\ \text{m}^2/\text{V}\cdot\text{s}$, respectively. (a) Use the definition of μ and the relation between v_d and the current to calculate the free-electron density, n, if the conductivity is $8.3 \times 10^{-5}(\Omega\cdot\text{m})^{-1}$ and $n \gg p$. (b) Repeat part (a) for the hole density, p, assuming doping such that $p \gg n$.

19. (II) Calculate the electrical conductivity at room temperature of germanium doped to n-type if the density of n-carriers and p-carriers are $2.5 \times 10^{18}\ \text{m}^{-3}$ and $7.0 \times 10^{13}\ \text{m}^{-3}$, respectively. [*Hint*: Use the results of Problem 18.]

20. (II) The Hall Effect (see Chapter 28) is probed on an n-type semiconductor with carrier density n; the density of holes is negligible. Determine the magnitude and polarity of the Hall voltage if there is a current to the right with density j (Fig. 43–33). Repeat the derivation for a p-type semiconductor. Notice the difference in polarity.

▲ **FIGURE 43–33** Problem 20.

21. (II) Use the energy distribution for a collection of identical fermions at finite temperature T to (a) show that the distribution of speeds (the probability that a fermion has a speed between v and $v + dv$) is given by

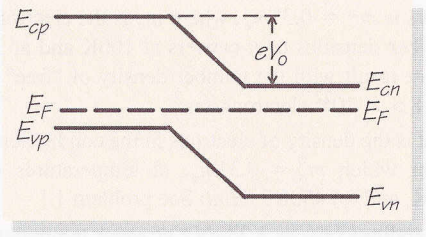
$$n(v)\,dv = \frac{8\pi m^3}{h^2}\frac{v^2\,dv}{1 + e^{[(mv^2/2)-E_F]/kT}}.$$

(b) What is the distribution for $kT \ll E_F$? [*Hint*: See Problem 50.]

22. (II) The Fermi energy can be defined as the energy at which the probability of finding an electron is $\frac{1}{2}$. (a) Show that this is the case at any temperature. (b) Refine this idea by using the fact that if the probability that an electron has an energy E *above* E_F is P, then the probability that an electron has an energy E *below* E_F is $1 - P$.

23. (III) Using a computer, plot the Fermi distribution as a function of energy for a material with a Fermi energy of 11 eV at temperatures 20K, 100K, 300K, and 1000K.

43–3 Semiconductor Structures



24. (I) A silicon solar cell produces electric current when the frequency of the light that falls on it is above 2.68×10^{14} Hz. What is the width of the band gap?

25. (I) Plot the factor $e^{eV_{\text{ext}}/kT} - 1$ [from Eq. (43–18)] as a function of temperature for a sample in which $eV_{\text{ext}} = 0.02$ eV over the range $100\text{K} < T < 350\text{K}$. Plot the same factor as a function of eV_{ext} (positive and negative) for $T = 300\text{K}$.

26. (I) The ratio of carrier densities p_n/p_p for a p–n junction at 350K is determined to be 0.86. What is the difference between Fermi energies for the n-type and p-type semiconductors?

27. (II) The Fermi energy of a heavily doped n-type semiconductor is close to E_c, whereas the Fermi energy of a heavily doped p-type semiconductor is close to E_v. (a) By using an energy diagram, show that when a p–n junction is formed from these semiconductors, a sufficient amount of reverse biasing will allow electrons to tunnel from the p-side to the n-side—a phenomenon known as the *Zener effect*. (b) The tunneling current is a sensitive function of the width of the barrier across which the electrons must tunnel. Show by means of energy diagrams that this width systematically decreases when the reverse bias increases, leading to a quickly building current. [*Hint*: Recall that the transition region has a finite width.] The Zener effect can be used in a *Zener diode*, in which a current flows when a reverse bias potential reaches a certain value.

28. (II) Consider a p–n junction formed from two samples of doped silicon. The two samples are as described in Problems 15 and 16 (Fig. 43–34). What is the value of eV_0 for this junction?

▲ **FIGURE 43–34** Problem 28.

29. (II) A germanium p–n junction has $n = 3.5 \times 10^{22}\ \text{m}^{-3}$ on the n-side and $p = 2.8 \times 10^{23}\ \text{m}^{-3}$ on the p-side. For germanium, $E_g = 0.67$ eV, $m_n^* = 0.55m_e$, and $m_p^* = 0.37m_e$. Find the locations of the Fermi energies before the junction is formed. Use your results to find eV_0 at (a) $T = 80\text{K}$ and (b) $T = 300\text{K}$.

30. (II) Many LEDs give off red light. Given this fact, estimate the width of the band gap for the materials from which such LEDs are constructed.

31. (II) A current of 2.5 mA flows through an LED with a band-gap energy of 1.4 eV. Assume that each current-carrying electron drops into a hole, and a single photon is thereby emitted. (a) What is the power emitted in the light? (b) How many photons/s are emitted?

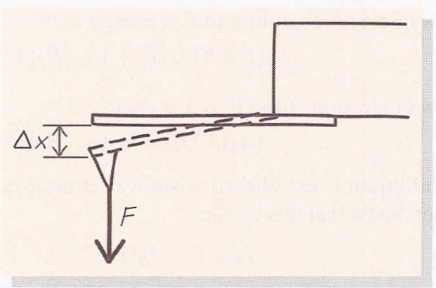
32. (II) Consider a heterostructure in which an intrinsic semiconductor with a narrow band gap is sandwiched between an intrinsic semiconductor with a larger energy gap. (a) Draw an energy diagram for this system. (b) What happens to any n-carriers in this system in the absence of external potentials?

43–4 Band-Gap Engineering

33. (II) A quantum well with a width of 9 nm is produced, and spectroscopic measurements show that the energy difference between the ground state and the first excited state within this well is 2.28×10^{-2} eV. What is the effective mass of electrons within the well?

34. (II) For a quantum dot, in which an electron is confined within three dimensions, the allowed energy values have the form

$$E = \frac{\hbar^2\pi^2 n_1^2}{2m^* a_1^2} + \frac{\hbar^2\pi^2 n_2^2}{2m^* a_2^2} + \frac{\hbar^2\pi^2 n_3^2}{2m^* a_3^2},$$



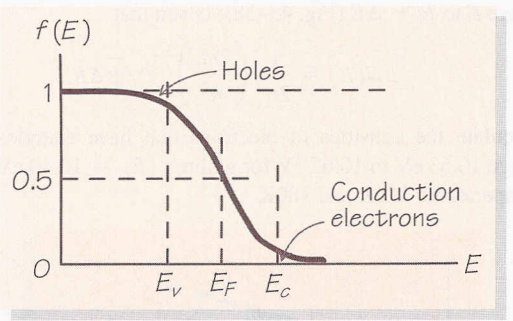
where m^* is the effective mass of an electron; a_1, a_2, and a_3 are the three confining dimensions of the box, and the n_i values are integers. Suppose that a particular quantum dot has dimensions 8 nm $\times$ 12 nm $\times$ 12 nm and that $m^* = 0.55m_e$. (a) Calculate the energy gap between the first and second excited states. (b) What is the wavelength of the radiation emitted in the transition between these two states?

43–5 Scanning Microscopy

35. (I) The current measured in a scanning tunneling microscope whose tip height is held fixed increases by a factor of 20 when the tip moves from point A to point B on the surface. How much closer to the tip is point B than point A? The work function of the sample is 2.3 eV.

36. (I) An atomic force microscope has a spring constant of 0.3 N/m. If a displacement as small as 0.8 nm must be detected, how much work must be done to displace the cantilever?

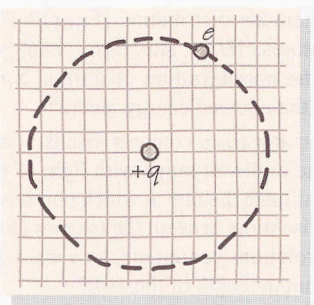
37. (II) The cantilever of an atomic force microscope has a spring constant of 0.6 N/m, and a laser sensor detects that it has been deflected by 0.2 nm (Fig. 43–35). What is the ratio of the force acting on the cantilever to that of the force of gravity on a fly of mass 0.1 g?



▲ **FIGURE 43–35** Problem 37.

General Problems

38. (I) An electric field of magnitude 10^6 V/m is applied in the $+x$-direction in a piece of intrinsic Si, for which the mobilities of electrons and holes at room temperature are 0.14 $m^2/V \cdot s$ and 0.050 $m^2/V \cdot s$, respectively (see Problem 18). What are the drift velocities (direction and magnitudes) of electrons and holes at room temperature?



39. (I) A germanium sample is doped with 1.1×10^{23} atoms/m^3 of arsenic. Given that the intrinsic n-carrier density is $n_i = 7.0 \times 10^{16}$ carriers/m^3, what is the hole concentration at equilibrium (Fig. 43–36)?

▲ **FIGURE 43–36** Problem 39.

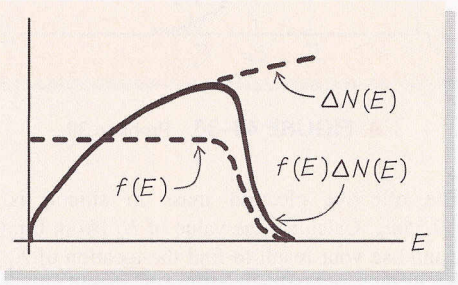
40. (II) The effective electron mass in silicon is given by $m_n^* = 0.55m_e$. Calculate the value of N_c [from Eq. (43–12)] at 300K, and use your result to find the location of E_F relative to the edge of the conduction band for the doped silicon sample of Problem 39.

41. (II) A donor electron moves in doped indium antimonide, for which $\varepsilon/\varepsilon_0 = 17.9$ and $m^* = 0.015m_e$. Find the radius of a circular atomic orbit of such an electron in terms of the Bohr radius a_0 (Fig. 43–37). The effective nuclear charge for such a loosely bound electron is $Z = 1$.

▲ **FIGURE 43–37** Problem 41.

42. (II) An electron in germanium moves about a positive center of charge $+e$ to form a hydrogen-like atom in its ground state. Calculate the wavelength of the photon needed to raise the electron to the first excited state. What is the change in the radius of the orbit? ($\kappa = 15.8$ and $m_n^* = 0.55m_e$ in germanium.)

43. (II) The impurity concentration in semiconductors must be low in order to keep the interaction between individual electrons or hole charge carriers negligible. Estimate the maximum concentration of As impurities in germanium that avoids an overlap between the ground state wave functions about adjacent impurities. Express your result in terms of a volume density (impurities/cm^3) as well as in terms of the ratio impurities/atoms. (For germanium, $\kappa = 15.8$ and $m_n^* = 0.55m_e$, $\rho = 5.32$ g/cm^3 and $A = 72.6$.)



44. (II) Repeat the calculation of Problem 43 for InSb with Sb impurities. (For InSb, $\kappa = 17.9$ and $m_n^* = 0.015m_e$, $\rho = 5.9$ g/cm^3 and $A_{In} = 114.8$, and $A_{Sb} = 121.8$.)

45. (II) A magnetic field of 1.80 T is applied to doped indium antimonide. What is the angular frequency of the donor electrons? [*Hint*: See Problem 41 for the parameters of this semiconductor, and Chapter 28 for a discussion of the cyclotron frequency.]

46. (II) The number of electrons with energy in the range E to $E + \Delta E$ contained in a volume V is given by $f(E)\Delta N(E)$, where $f(E)$ is the Fermi–Dirac distribution function and $\Delta N(E)$ is the number of states available to the electrons in the range E to $E + \Delta E$ (Fig. 43–38). Given that

$$\Delta N(E) = \frac{V}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\sqrt{E}\Delta E,$$

calculate the densities of electrons that have energies in the range 10.63 eV to 10.65 eV for gallium ($E_F = 10.40$ eV) at the temperatures 110K and 380K.

▲ **FIGURE 43–38** Problem 46.

47. (II) Repeat the calculation of Problem 46 for the energy interval between 12.65 eV and 12.67 eV.

48. (II) For a set of identical fermions at high temperature, the average occupation number of any given energy level $f(E) \ll 1$. Show that the Fermi–Dirac distribution approaches the Maxwell–Boltzmann distribution [Eq. (19–28)] in the limit of high temperatures. [*Hint*: The factor $\exp(-E_F/kT)$ is determined from the normalization condition $\Sigma_i n_i = N$ where the index i labels the allowed energy levels.]

49. (II) The laser that reads a compact disc is a semiconductor laser of power in the milliwatt range with light of wavelength around 800 nm. (a) Estimate the rate at which photons are emitted. (b) If the compact disc turns beneath the (narrow) laser beam at several hundred revolutions per minute, how many photons will strike a region 0.1 mm in length of the disk?

50. (II) Consider a group of N atoms that obey Maxwell–Boltzmann statistics. The atoms have only two energy states, a ground state at energy E_0 and an excited state at energy E_1. The energy difference $\Delta E = E_1 - E_0 \gg kT$. Show that the average energy of the atoms at temperature T is $E_0 + \Delta E e^{-\Delta E/kT}$.

51. (II) Monochromatic light shines on a thin film of silicon ($E_g = 1.12$ eV), and the electrical resistance is measured across the film. (a) What happens to the resistance as the wavelength of the light increases, starting with a wavelength in the ultraviolet range? (b) At what critical wavelength does a change in resistance occur? (c) Does the resistance increase or decrease at the critical wavelength?

52. (III) Use the expression for $\Delta N(E)$ given in Problem 46 to express (a) the total number of electrons in a volume V and (b) the average energy of an electron in a volume V at temperature T. (c) Find the limits of your results for parts (a) and (b) for $T \to 0$.

53. (III) A degenerate semiconductor is a semiconductor that is so heavily doped that the doping ions participate in the formation of their own band structure. The Fermi energy may lie within the original conduction band in a degenerate n-type semiconductor, and within the original valence band in a degenerate p-type semiconductor. When a p–n junction is formed from a semiconductor that is degenerate on both the n- and p-sides, a *tunnel diode* is formed. Under these circumstances tunneling is possible when there is an external voltage. Draw an energy diagram (a) for the equilibrium state (no external voltage across the junction); (b) for a reverse bias. How will the tunneling current vary as the reverse bias increases from zero? (c) Draw an energy diagram for a *small* forward bias. How will the tunneling current vary as the small forward bias increases from zero? (d) Show that when the forward bias increases beyond a critical value, the tunneling current begins to *decrease*. This phenomenon is called *negative resistance*.

54. (III) In this problem, we show that the Fermi energy is constant across a boundary. Consider two materials, A and B, in contact so that charge carriers can pass between them; the materials are in thermal equilibrium. At thermal equilibrium, there is no net energy flow and no net charge flow across the boundary. Let the number of states in a unit volume per unit energy interval around the energy E that electrons can occupy in each material be $n_A(E)$ and $n_B(E)$, respectively. The conditions of no energy flow and no charge flow mean that the flow of electrons from A to B at any E value equals the flow of electrons from B to A at that same E value. The flow of electrons from A to B at energy E is proportional to the number of electrons present in A times the number of empty states present in B; that is, to the density of occupied states in A times the density of empty states in B. Now the density of occupied states is

density of occupied states =
(density of available states) × (probability of occupation)
$= n(E)f(E)$,

where $f(E)$ is the probability of occupation given by the Fermi–Dirac distribution, Eq. (43–2).

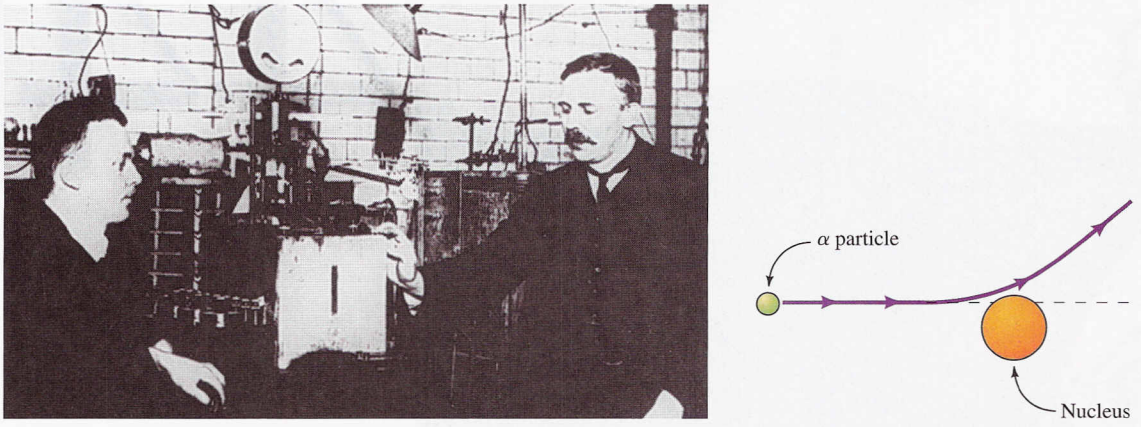
(a) Show that
density of unoccupied states =
(density of available states) × (probability of vacancy)
$= n(E)[1 - f(E)]$.

(b) For our situation,
flow of electrons from A to B at energy $E \propto$
$\{n_A(E)f_A(E)\}\{n_B(E)[1 - f_B(E)]\}$;
flow of electrons from B to A at energy $E \propto$
$\{n_B(E)f_B(E)\}\{n_A(E)[1 - f_A(E)]\}$.
Equilibrium is established when we set these equal to each other. Show that this implies
$$f_A(E) = f_B(E).$$

(c) By comparing the result of part (b) with Eq. (43–2), show that the parameters E_F in the two materials are equal.

Chapter 44

This marvelous image was made in neolithic times on the wall of a cave, where it has remined protected from the elements for 30,000 years. The age was established by analyzing the quantities of carbon atoms containing different nuclear types within the pigments. Radiometric dating of this kind depends on knowledge of the lifetimes of the various nuclear species.



Nuclear Physics

The nucleus, which lies at the center of the atom, contains all the positive charge and almost all the atomic mass. Understanding the properties of the nucleus has had enormous consequences for technology and for society in general. We shall describe the nuclear constituents, the static properties of nuclei, and the radioactive decays of certain nuclei. We shall also see how nuclei react with one another. The practical applications of nuclear physics are widespread and include power generation, radiometric dating, investigation of materials through imaging, food conservation, and cancer treatment.

44–1 Static Properties of Nuclei

Nuclear Constituents

The *nucleus* contains more than 99.9 percent of the atom's total mass but has a radius some 10^5 times smaller than the radius of the atom as a whole. The effects of the nucleus were seen in scattering experiments guided by Ernest Rutherford in 1911. Even before Rutherford made his discovery, Joseph J. Thomson noted the presence of electrons in atoms. The number of electrons in a neutral atom is equal to the *atomic number* Z, a quantity directly tied to chemical properties. Another number used for atoms is atomic weight, which is proportional to the atom's mass. If you take the atomic weight as a multiple A of the atomic weight of hydrogen, for which $Z = 1$, you could ask whether A matches Z as Z increases. In fact, one finds that as Z increases, A eventually becomes more than twice as large as Z.

(a) (b)

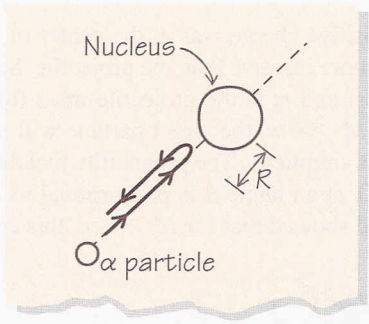
▲ **FIGURE 44–1** (a) Ernest Rutherford (here, on the right with Hans Geiger) directed the scattering experiments that revealed the atom's nuclear structure. (b) Alpha particle scattering from a nucleus.

In addition, Thomson had measured the charge-to-mass ratio of the electron, and coupled with H. A. Wilson's and Robert Millikan's measurements of the electron charge, the electron's mass was deduced to be much less than the atomic mass. Because the atom is neutral, it must contain a positive charge $+Ze$ in addition to the electron charge $-Ze$. What was *not* known was how the positive and negative charges were distributed within the atom or what carried the positive charge.

The atomic model favored at the turn of the twentieth century—that proposed by Thomson and known as the Thomson model (or the *plum pudding* model)—had point-like electrons embedded within a uniform distribution of positive charge. We described in Section 8–8 how we could learn of the existence of a steel pellet in a volume of cotton candy by firing BBs at the candy. Similar reasoning applies to the exploration of atoms by scattering. Rutherford undertook his study of atoms by scattering *alpha* (α) *particles* from atoms in a thin gold foil (Fig. 44–1). Alpha particles are produced when certain heavy elements decay, as we shall see in Section 44–3. Rutherford had earlier analyzed the charge and mass of α particles and knew that they consisted of doubly ionized helium atoms (charge $+2e$).

CONCEPTUAL EXAMPLE 44–1 What happens when an energetic alpha particle approaches an atom that is constructed according to the Thomson model?

Answer An α particle is some 8000 times more massive than an electron and would scarcely be deflected by a collision with an electron. According to the Thompson model, the positive charge is spread over the full volume of the atom, and when an α particle enters the positive charge distribution, it is only deflected by the imbalance of charge between what is "above" and "below" the α trajectory. In fact, the largest effect occurs when the α particle passes the edge of the charge distribution, and that is an effect that is demonstrably small. (See material leading to Eq. (44–1).)



Rutherford's experiment showed that far too many α particles scattered through large angles—a factor of 10^{10} for angles greater than 90°—than could be explained by the Thomson model (see Conceptual Example 44–1). However, if both the positive charge and the mass of the atom were concentrated in a central structure, the scattering angle could be large. We can estimate the typical scattering angle θ of an incident α particle deflected by its electrical interaction with a positively charged sphere of radius R as follows: $\theta \cong \Delta p/p$, where $p = m_\alpha v$ is the momentum magnitude of the α particle, v is its speed, and Δp is the sideways momentum transfer that the α particle receives as it passes the spherical charge distribution. The typical deflection occurs when the α particle passes close to the edge of the positive charge distribution (Fig. 44–1b). In this case, we can approximate Δp by $F\Delta t$, where $F = (Ze)(2e)/(4\pi\varepsilon_0 R^2)$ is the magnitude of the Coulomb force between the charge distribution and the α particle that reaches the edge of the distribution, and Δt is a characteristic time interval over which the force acts to deflect the α particle. We approximate this time interval by a characteristic size R of the target divided by the speed v of the projectile, $\Delta t \cong R/v$. Thus

$$\theta \cong \frac{F\Delta t}{p} = \frac{(Ze)(2e)}{4\pi\varepsilon_0 R^2}\frac{R/v}{m_\alpha v} = \frac{2Ze^2}{4\pi\varepsilon_0 m_\alpha v^2 R}. \qquad (44\text{–}1)$$

The factor $1/R$ in this result indicates that the smaller the radius of the nucleus, the larger the typical scattering angle will be. For R equal to the atomic radius (about 0.1 nm), the deflection is negligible. Rutherford's results could be explained with R on the order of 10^{-5} of the atomic radius.

EXAMPLE 44–2 An α particle with kinetic energy of 5.0 MeV moves directly toward a gold nucleus ($Z = 79$) at rest. The gold nucleus is much heavier than the α particle. How close does the α particle come to the gold nucleus before it turns around?

Setting It Up We illustrate this situation in Fig. 44–2.

▲ **FIGURE 44–2** A head-on collision in which an α particle is deflected straight back from a nucleus.

Strategy It is the Coulomb repulsion between the gold nucleus and the α particle that causes the α particle to slow down, stop, and then turn around. To analyze this situation more quantitatively, assume that the gold nucleus is so heavy that it remains fixed. This makes it simple to use the conservation of energy to solve the problem. The initial total energy of the system is $E = K + U$. We take the Coulomb potential energy U to be zero when the colliding particles are far apart. We have for the Coulomb potential energy of two objects with charges Z_1e and Z_2e separated by a distance r

$$U(r) = \frac{Z_1 Z_2 e^2}{4\pi\varepsilon_0}\frac{1}{r}.$$

By evaluating the total energy E when the target and projectile are far apart, we see that E is equal to K, or 5 MeV, and it remains that value throughout. When the α particle reaches the turnaround point, its kinetic energy is zero, and the energy is entirely potential energy. At this point, the separation is R (Fig. 44–2).

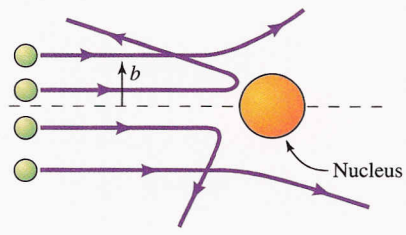
Working It Out We apply the conservation of energy by equating the energies of the α particle-gold nucleus system at $r = \infty$ and $r = R$, setting $Z_1 = 2$ (Z_1e is the α particle charge) and $Z_2 = 79$ (Z_2e is the gold nucleus charge):

$$K\Big|_{r=\infty} + U\Big|_{r=\infty} = K\Big|_{r=R} + U\Big|_{r=R};$$

$$K + 0 = 0 + \frac{(2)(79)e^2}{4\pi\varepsilon_0}\frac{1}{R}.$$

We solve for R:

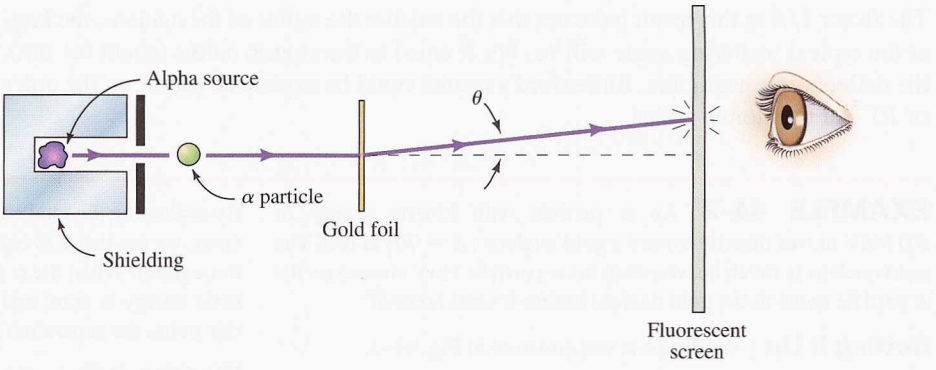
$$R = \frac{(2)(79)e^2}{4\pi\varepsilon_0}\frac{1}{K} = (2)(79)(1.6\times10^{-19}\,\text{C})^2 \times (9\times10^{9}\,\text{N}\cdot\text{m}^2\cdot\text{C}^{-2}) \times \frac{1}{5.0\times10^{6}\,\text{eV}}\frac{1\,\text{eV}}{1.6\times10^{-19}\,\text{J}}$$



$$= 4.6\times10^{-14}\,\text{m}.$$

This distance is well inside even the innermost Bohr radius, but outside the nucleus itself (see below for more on the nuclear size). You might recall from discussion on fundamental forces in Section 5–5 that nuclear forces are short range and the nuclear force will be negligible at this distance (see Section 44–2). The technique we used here to estimate R is the one Rutherford himself used as a first estimate.

What Do You Think? The de Broglie wavelength of a 5-MeV α particle is about 6×10^{-15} m. Discuss whether quantum mechanical effects might be evident. *Answers to* ***What Do You Think?*** *questions are given in the back of the book.*



Scattering Distributions

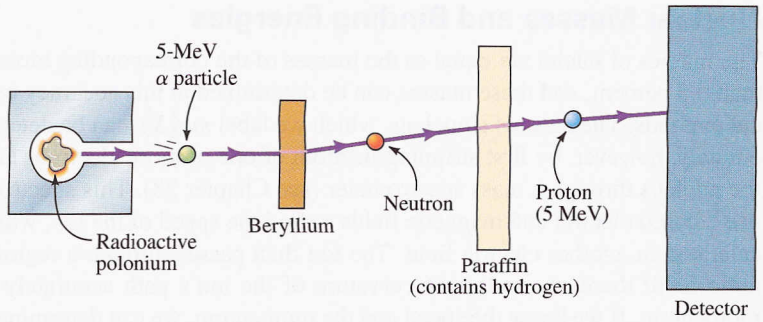
Rutherford was able to make a more sophisticated calculation of what happens when a collimated beam of α particles is fired at a set of atoms constructed on the basis of the nuclear model. Some of the α particles follow a line directly toward a nucleus, and some follow a line off to the side (Fig. 44–3). For a given line, the force anywhere along that line is the Coulomb force, and the trajectory of the α particle can be calculated. If the beam of α particles is spread uniformly across a region with a collection of target nuclei, then an α particle that arrives at a particular transverse distance b (Fig. 44–3) from a head-on collision with the nucleus will scatter at a particular angle. Rutherford was able to predict a precise *distribution* of the number of α particles deflected at any given angle, assuming always that the α particle never actually penetrates the nucleus.†

▲ **FIGURE 44–3** A beam of α particles sent into a sample of material will scatter from a nucleus at many different angles.

†Rutherford could make only a classical calculation, even though we now know that quantum physics dominates at these scales. By an extraordinary stroke of luck, the inverse-square law obeyed by the Coulomb force is the *only* force law for which a quantum mechanical calculation gives a distribution identical to that given by a classical calculation.

▶ **FIGURE 44–4** Schematic diagram of the experiment in which Geiger and Marsden observed the scattering of α particles from gold atoms in gold foil.

Rutherford assumed that *all* the positive charge was at the center of the atom and was contained in a concentration much more massive than the projectile. Suppose that M is the target mass (of charge Z_2e) at rest and m is the projectile mass (of charge Z_1e) moving with kinetic energy K. Then if $M \gg m$, the target particle will not recoil. We will consider only this case because of its simplicity. The probability that the particle will be scattered into a small solid angle $d\Omega$ at an angle θ is proportional to $d\Omega$ times the *collision cross section*, $\sigma(\theta)$. Rutherford showed that for $M \gg m$, this cross section is given by



$$\sigma(\theta) = \frac{(Z_1 Z_2 e^2)^2}{16(4\pi\varepsilon_0)^2} \frac{1}{K^2} \frac{1}{\sin^4(\theta/2)}. \tag{44–2}$$

The critical features are the inverse-square dependence on K and the strong dependence on θ.

Rutherford's assistants Hans Geiger and Ernest Marsden painstakingly counted the scattering of α particles from a thin gold foil by observing the particles that arrived on a fluorescent screen (Fig. 44–4). These experiments verified Eq. (44–2) and hence also the existence of the nucleus and Rutherford's concept of the atom. Rutherford also noticed a deviation from the prediction of Eq. (44–2). When an α particle is on a path directly toward a nucleus, it backscatters at 180° (see Example 44–2). If the Z value of the target is small enough and the energy of the incident α particle is high enough (greater than 5 MeV in Rutherford's experiment), the α particle has enough energy to overcome the Coulomb force and penetrate into the nucleus. The force that the α particle experiences is thereby modified, and Eq. (44–2) is no longer correct. The penetrating α particle experiences a nuclear force, and Rutherford's observation was the first time the nuclear force was seen in scattering.

Neutrons: The nucleus cannot be composed of protons alone: Almost all the mass of an atom is in its nucleus, and the atomic weight is roughly twice the atomic number. Rutherford speculated in 1920 that a nucleus could consist of Z protons and $N = A - Z$ particles of about the same mass as the proton but with no electric charge—particles later called **neutrons**. Here, A is the *mass number*, or the number of protons plus neutrons in the nucleus. But massive neutral particles are hard to detect. When charged particles pass through matter, Coulomb forces leave a path of ionized atoms that is easy to observe by various detection techniques. When neutral particles such as neutrons pass through matter, they do not ionize the matter very easily.

How, then, were neutrons observed? When atoms of boron or beryllium are bombarded with α particles, observation of the recoiling nuclei shows that neutral particles are produced. These neutral particles are not necessarily neutrons; they could, for example, be photons. In 1932, James Chadwick showed these particles to be neutrons by allowing them to pass into material that contains a good deal of hydrogen, such as paraffin. He observed that a rather energetic proton was occasionally produced (Fig. 44–5). He interpreted this as the result of a collision between the neutral component and a hydrogen nucleus, which consists of just a single proton. By measuring the momentum of the observed proton and by using momentum conservation, Chadwick verified

◀ **FIGURE 44–5** Schematic diagram of Chadwick's experiment to discover neutrons. Paraffin contains a high percentage of hydrogen and hence of nuclei consisting of single protons that act as targets for any incoming projectiles. A kinematic analysis shows that only neutrons scattering from hydrogen nuclei could have knocked forward the observed protons.

that the neutral component could not be a photon. Instead, he concluded that the particle, which is now called the *neutron*, must have about the same mass as the proton. Thus, some 20 years after Rutherford's discovery of the nucleus, the nature of the nuclear components was firmly established.

The proton and the neutron collectively are known as **nucleons** because they are both found in the nucleus and they share many of the same properties. An important common property is that they have an intrinsic angular momentum $\hbar/2$—we say that they have "spin $\frac{1}{2}$," like the spin of the electron, and like the electron the nucleons are fermions. We'll have more to say about the spin of the nucleons and of the nucleus later; see also Conceptual Example 44–3. An important difference between protons and neutrons is that unlike protons, free neutrons are not stable but decay with a lifetime $\tau \cong 890$ s. Neutrons do *not*, however, decay within stable nuclei.

The properties of the nucleus depend on the force that holds it together, called the *nuclear*, or *strong*, force. We know that such a force must exist because, without it, the repulsive Coulomb force between protons would cause the nucleus to fly apart.

CONCEPTUAL EXAMPLE 44–3 Before the neutron was discovered, the only possible constitution of a nucleus with a given (A, Z) was A protons and $(A - Z)$ electrons, leaving a net charge of $+Ze$. Early indications were that the nitrogen nucleus $(A = 14, Z = 7)$ had a total angular momentum that was an integral multiple of $\hbar$. Is this consistent with a nucleus made of A protons and $A - Z$ electrons? How does the inclusion of neutrons change things?

Answer In Chapter 41 we discussed angular momenta and how they add, so we know that orbital angular momentum is always an integral multiple of $\hbar$ ("integer angular momentum"), and the only way the total angular momentum can also be an integer is for the addition of all the spins to add to an integer. Now 14 protons (each with spin $\frac{1}{2}$) have a total spin that is integer-valued, while the total spin angular momentum of the $14 - 7 = 7$ electrons has a half-integer value. Thus the total angular momentum in this case would be a half-integer multiple of $\hbar$, and this contradicts the data for nitrogen. Introducing neutrons, the nucleus is made of Z protons and $A - Z$ neutrons; for $Z = 7$ and $A - Z = 7$, we have altogether an even number of spin $\frac{1}{2}$ particles, with a total spin angular momentum that has to be integer-valued in accordance with observation. This is yet another argument against the nucleus being composed of electrons and protons.

Some Terminology

Recall that the number of nucleons in a single nucleus is the mass number A. This quantity very nearly determines the mass of the nucleus; the number of protons is the atomic number Z; and the number of neutrons is $N = A - Z$. A **nuclide** is a nucleus of an element with a given Z and A and is written as ${}^{A}_{Z}\mathrm{X}$, where X is the chemical symbol of the element. For example, the nuclide ${}^{4}_{2}\mathrm{He}$ is a helium nucleus $(Z = 2)$, with 2 protons and 2 neutrons. The nuclide ${}^{3}_{2}\mathrm{He}$ also occurs naturally; it has only a single neutron. This notation is redundant because the chemical symbol alone specifies Z, so we frequently write the simpler form ${}^{4}\mathrm{He}$. The proton is a hydrogen nucleus, ${}^{1}_{1}\mathrm{H}$, but we shall more frequently use the standard symbol p for the hydrogen nucleus. As we have just seen for helium, the nucleus of a given chemical element has a particular Z value, but a range of N values are possible. For example, neon has three stable nuclides (${}^{20}\mathrm{Ne}$, ${}^{21}\mathrm{Ne}$, and ${}^{22}\mathrm{Ne}$) and several unstable ones. Nuclides with the same Z value are known as **isotopes** of the given element (see Chapter 19). The gram-atomic weight of a chemical element—the mass of 1 mol of that element—is actually an average over the different naturally occurring isotopes of that element weighted by the relative abundance of those isotopes.

TABLE 44–1 • Some Atomic Masses

Element	Atomic Mass (u)
$^{1}_{1}$H	1.007825
$^{2}_{1}$H	2.014102

Nuclear Masses and Binding Energies

The masses of nuclei are equal to the masses of the corresponding atoms to within less than 0.5 percent, and these masses can be determined at this accuracy by purely chemical methods. The mass of a nucleus, which we label $m(^{A}_{Z}X)$, can be determined more accurately, however, by first stripping its atom of one or more electrons and then sending the nucleus through a mass spectrometer (see Chapter 28). This spectrometer may first use crossed electric and magnetic fields to find the speed of the ion, which has been accelerated in another electric field. The ion then passes through a region of fixed magnetic field; there, the radius of curvature of the ion's path accurately determines the momentum. If we know the speed and the momentum, we can determine the mass. With such devices, the masses of ions can be determined to an accuracy of better than 1 part in 10^8. The fact that atomic masses and not nuclear masses are obtained is not a handicap, because the electron masses normally cancel in calculations with nuclei.

Note that nuclear abundances, the relative amounts of isotopes that occur in nature, can also be established from mass spectrometry. Ionized atoms from a naturally occurring sample of the element pass through the spectrometer. Because their masses are different, each isotope follows a different path, and the relative number that follow each path is a measure of their abundance.

A useful mass unit for nuclear and atomic physics is the *atomic mass unit* (u), which is defined as one-twelfth the mass of a ^{12}C atom. Such a mass standard is useful because the *relative* masses of atoms (and nuclei) can be measured with high precision, even when we can express the atomic mass unit in terms of the kilogram with much less precision:

$$1\ \text{u} = 1.66057 \times 10^{-27}\ \text{kg}. \tag{44–3}$$

We can also express masses in eV/c^2 or MeV/c^2 by using the relativistic relation between mass and energy. We find

$$1\ \text{u} = 931.494\ \text{MeV}/c^2. \tag{44–4}$$

In atomic mass units, the nucleon masses are

$$m_p = 1.00728\ \text{u} = 938.272\ \text{MeV}/c^2 = 1.67262 \times 10^{-27}\ \text{kg} \tag{44–5a}$$

and

$$m_n = 1.00860\ \text{u} = 939.566\ \text{MeV}/c^2 = 1.67493 \times 10^{-27}\ \text{kg}, \tag{44–5b}$$

whereas the mass of the electron is

$$m_e = 5.48 \times 10^{-4}\ \text{u} = 0.510995\ \text{MeV}/c^2 = 0.910939 \times 10^{-30}\ \text{kg} \tag{44–5c}$$

and the mass of the hydrogen atom is

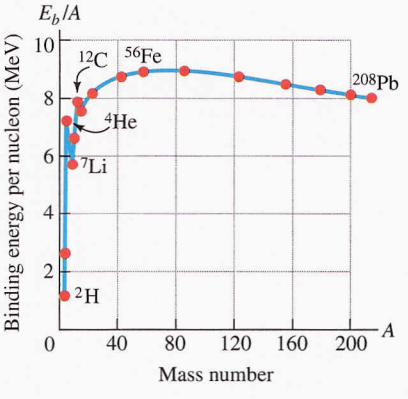
$$M(^{1}\text{H}) = 1.00783\ \text{u} = 938.283\ \text{MeV}/c^2 = 1.67356 \times 10^{-27}\ \text{kg}. \tag{44–5d}$$

Note in Eqs. (44–5) the standard notation of M for atomic mass and m for nuclear and particle masses. Table 44–1 gives the values of some atomic masses in u. The corresponding nuclear mass can be found by subtracting Zm_e from the atomic mass.

Binding Energy: From Eqs. (44–5), the sum of the masses of 6 protons, 6 neutrons, and 12 electrons is 12.0989 u—about 1 percent greater than the mass of a ^{12}C atom, exactly 12 u. This discrepancy is due entirely to the nuclear mass: The mass of a carbon nucleus is less than the sum of the masses of 6 protons and 6 nucleons by this same amount. *In general, the mass of a stable nucleus is less than* $Zm_p + Nm_n$ due to the energies of binding the nucleons into the nucleus and to special relativity. Separating a nucleon (or collection of nucleons) from a stable nucleus takes energy.

The *binding energy* E_b of a nucleus is the energy released when the nucleus is formed from A independent constituent nucleons. To understand the relation between binding energy and nuclear mass, we must use mass–energy equivalence (see Chapter 39). Because energy must be added to a nucleus to transform it to free nucleons, the energy of the nucleus is less than the sum of the energies of free nucleons; moreover, by the equivalence of mass and energy, the mass of the nucleus is less than the sum of the masses of the

TABLE 44–2 • Some Nuclear Binding Energies



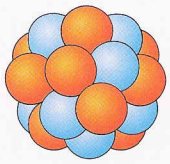
Nucleus	Total Binding Energy (MeV)	Binding Energy per Nucleon (MeV/nucleon)
$^{2}_{1}$H	2.23	1.1
$^{4}_{2}$He	28.3	7.1
$^{12}_{6}$C	92.1	7.7
$^{16}_{8}$O	127.5	8.0
$^{56}_{23}$Fe	492.3	8.8
$^{63}_{29}$Cu	552.1	8.8
$^{238}_{92}$U	1803	7.6

constituents. These considerations hold for *any* bound system, but this effect is a small one for atoms and the other bound systems we have considered previously. For the nucleus, the attractive forces between nucleons are so strong that the binding energy is a significant fraction of the total mass. Thus, by the relativistic relation between mass and energy, *the mass of a nucleus is on the order of 1 percent less than the sum of its nucleon masses*. More precisely, the binding energy is c^2 times the difference between the atomic mass and the sum of the masses of Z hydrogen atoms and N neutrons:

$$E_b \equiv [ZM(^1\text{H}) + Nm_n - M(^A X)]c^2. \tag{44–6}$$

This quantity is positive for stable nuclei. Table 44–2 gives the total binding energies of some nuclei. In the case of ^{12}C, we obtain $E_b = (12.0989\text{ u} - 12.0\text{ u})\,c^2(931.494\text{ MeV/uc}^2) = 92.12\text{ MeV}$, from Eq. (44–6).

Table 44–2 also gives the *binding energy per nucleon*, E_b/A, as well as the total binding energy. Once A is 12 or larger, the binding energy per nucleon is fairly constant, between 7 and 9 MeV/nucleon. We plot this quantity as a function of the mass number, A, in Fig. 44–6. Note the position on this curve of ^{4}He, which has an exceptionally large E_b/A value and is therefore strongly bound, and the region around ^{56}Fe, for which the curve exhibits a broad maximum. The fact that the binding energy per nucleon increases from zero for small nuclei and decreases as A increases for $A > 60$ tells us a lot about nuclear stability. We see that the total mass–energy per nucleon *decreases* (the total binding energy increases) when two small nuclei combine into an intermediate one (for instance, E_b/A for ^{2}H is 1.1 MeV, whereas E_b/A for ^{4}He is 7.1 MeV). Similarly, the total mass–energy per nucleon decreases when one large nucleus, such as ^{235}U, for which $E_b/A \cong 7.5$ MeV, forms two intermediate nuclei, for which E_b/A may be around 8.5 MeV, or when a large nucleus forms a remnant nucleus plus a ^{4}He nucleus (an α particle). Thus, decays of large nuclei into smaller nuclei are to be expected. Whether these decays actually occur or not, and the rate at which they occur, depend on details of the structure of the decaying nucleus. For example, a decay may occur only when there is tunneling through a potential barrier (see Chapter 40).



▲ **FIGURE 44–6** The binding energy per nucleon, E_b/A, as a function of the mass number A.

Other Properties

Size and Internal Distribution of Mass and Charge: When the energy of a particle bombarding an atom is increased to the point at which the particle can penetrate the nucleus, we can study the *internal* structure of the nucleus by analyzing the distribution of the scattering. This is a refinement of Rutherford's experiments. If the nucleus is bombarded with electrons, which interact *only* through the Coulomb force with the nucleus, we learn about the distribution of charge within the nucleus. If the nucleus is bombarded with α particles, protons, or neutrons, we learn instead about the distribution of nucleons within the nucleus. Both types of experiments give roughly the same picture of both the radius and the internal makeup of the nucleus; in other words, protons and neutrons are distributed in much the same way within the nucleus. In particular, both the mass and the charge of a nucleus of mass number A are distributed *uniformly* out to a radius R_A given by

$$R_A = r_0 A^{1/3}, \tag{44–7}$$

▲ **FIGURE 44–7** Nucleons are closely packed within nuclei. We have used red to indicate neutrons and blue to indicate protons.

where $r_0 \cong 1.2 \times 10^{-15}$ m. The mass (and charge) density within this volume is very nearly the same for all nuclei. Beyond R_A, the mass and charge densities drop rapidly to zero. The fact that R_A is proportional to $A^{1/3}$ means that the volume, approximately equal to $\frac{4}{3}\pi R_A^3$, is proportional to A: volume $= \frac{4}{3}\pi R_A^3 = \frac{4}{3}\pi(r_0 A^{1/3})^3 = \frac{4}{3}\pi r_0^3 A$. In the classical model, the nucleus resembles a set of closely packed marbles (Fig. 44–7).

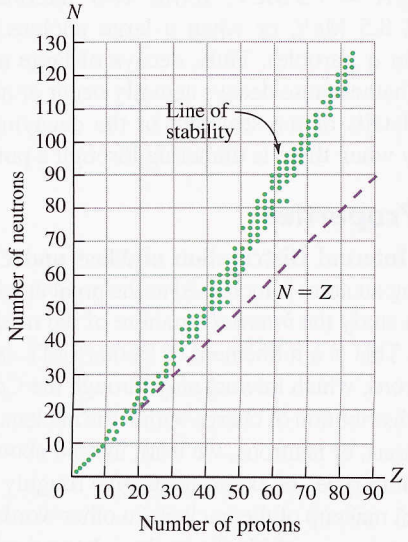
We can also mention here that nucleons themselves have an internal structure. One way to learn about that is with further use of the Rutherford type of experiment. The substructure of nucleons is one of the subjects of Chapter 45.

EXAMPLE 44–4 We discussed neutron stars in Section 42–1. Compare the density of a nucleus to that of a neutron star.

Strategy In Example 42–3 we determined the radius of a neutron star of mass three times that of our star to be 1.0×10^4 m. From this we can determine the density of a neutron star by a straightforward calculation of M/V. To determine the density of a nucleus we use the mass of a nucleon ($m_N = 1.67 \times 10^{-27}$ kg) and the nuclear radius ($r = r_0 A^{1/3}$) already discussed in this section.

Working It Out We find the two densities to be

$$\rho(\text{neutron star}) = \frac{3M_{\text{Sun}}}{(4\pi/3)r^3_{\text{Neutron star}}} = \frac{3(2.0 \times 10^{30}\ \text{kg})}{(4\pi/3)(1.0 \times 10^4\ \text{m})^3} = 14 \times 10^{17}\ \text{kg/m}^3;$$



$$\rho(\text{nucleus}) = \frac{M}{V} = \frac{m_N A}{4\pi r_0^3 A/3} = \frac{3 \times 1.67 \times 10^{-27}\ \text{kg}}{4\pi(1.2 \times 10^{-15}\ \text{m})^3} = 2.3 \times 10^{17}\ \text{kg/m}^3.$$

Thus a neutron star is some $14/2.3 = 6$ times more dense than a nucleus.

What Do You Think? Can you give some reasons why the two densities are so close?

Stability: Although nuclides with Z values up to $Z = 92$ (uranium) occur naturally, not all of these nuclides are stable. The nuclide $^{209}_{83}$Bi is the heaviest stable nucleus.† Even though uranium is not stable, however, its longest-lived isotope, ^{238}U, has a half-life (see Chapter 40) of some 4 billion years. At low Z values, nuclei tend to have the same number of neutrons and protons ($N \cong Z$), but as Z increases, N tends to exceed Z. Figure 44–8 shows that the stable nuclides lie in a region called the *line of stability*. This curve has the rough form $N \cong Z$ for small Z and $N \cong 1.6\,Z$ for large Z.

▶ **FIGURE 44–8** The stable nuclides plotted on a graph of neutron number, N, versus proton number, Z. Note that for heavier nuclides, N is larger relative to Z. The stable nuclides group along a curve called the line of stability.

†Actually, it is not perfectly stable, but its lifetime is so large—on the order of 10^{19} years—that its possible decay has no practical consequence.

CONCEPTUAL EXAMPLE 44–5 Why do heavier nuclei have more neutrons than protons? [*Hint*: Think about the different kinds of interactions that exist between these constituents.]

Answer While the nuclear force is short range, no more than a few $\times 10^{-15}$ m, the Coulomb force is long range, with r-dependence $1/r^2$. Nucleons, both neutrons and protons, interact via the nuclear force mainly with their nearest neighbors in a way that holds the nucleus together, while protons repel each other via the Coulomb force. If we consider nuclei with more nucleons, the attractive force on each nucleon stays the same, because the force is short range and the number of nearest neighbors no longer changes. But because it is a long-range force, the Coulomb repulsion on any additional protons increases, with all the protons present acting on that additional proton. The repulsive Coulomb interaction becomes more and more important, and it is less energetically favorable to have as many protons as neutrons. The nuclide ^{40}Ca is the heaviest stable nuclide for which $N = Z$. (See the discussion on p. 1218)

There are approximately 250 stable isotopes on the line of stability. When the number of stable isotopes is expressed in terms of whether Z and N are even or odd, a striking pattern emerges. About 60 percent of the stable isotopes have both Z and N even; about 20 percent have Z even, N odd; and 20 percent have Z odd, N even. Only 5 stable isotopes have both Z and N odd. The strong preference for nuclei to have both Z and N even can be understood by a pairing force of the kind that leads to Cooper pairs in superconductivity (see Chapter 42). In addition to the stable nuclides shown in Fig. 44–8, there are several thousand unstable nuclides with varying N and Z that surround the line of stability. We'll describe the unstable nuclides further in Section 44–4.

EXAMPLE 44–6 (a) From data on atomic masses, determine the total binding energy and binding energy per nucleon of ^{56}Fe. (b) How much energy does it take to remove a proton from ^{56}Fe?

Strategy (a) Equation (44–6) allows us to find the total binding energy and subsequently the binding energy per nucleon for any nucleus. Table 44–1 and Eqs. (44–5) contain the masses necessary for us to apply Eq. (44–6) to the case of iron.

(b) The same principle that led us to the binding energy leads to the answer to this question. We find the difference between the mass of a parent nucleus (here ^{56}Fe) and the sum of the masses of the atom with a single proton as its nucleus (here ^{1}H) and the atom that is left behind when the single proton is removed from the parent (here ^{55}Mn). The energy that corresponds to this mass difference is called the *separation energy*, and here we are finding the proton separation energy. Generally, the separation energy for a parent nucleus ${}^A_Z X$ is

$$S_p({}^A_Z X) = [M({}^1\text{H}) + M({}^{A-1}_{Z-1}X') - M({}^A_Z X)]c^2. \qquad (44\text{–}8)$$

Working It Out

(a) When Eq. (44–6) is applied to ^{56}Fe, we find

$$\begin{aligned} E_b({}^{56}\text{Fe}) &= [Z_{{}^{56}\text{Fe}} M({}^1\text{H}) + N_{{}^{56}\text{Fe}} m_n - M({}^{56}\text{Fe})]c^2 \\ &= [26M({}^1\text{H}) + 30m_n - M({}^{56}\text{Fe})]c^2 \\ &= [26(1.007825\text{ u}) + 30(1.008665\text{ u}) - 55.934939\text{ u}]c^2 \\ &= (0.528461\text{ uc}^2)(931.494\text{ MeV/uc}^2) = 492.258\text{ MeV}. \end{aligned}$$

The binding energy per nucleon is (492.3 MeV)/(56 nucleons), about (8.8 MeV)/nucleon.

(b) From the discussion above, Eq. (44–8), the proton separation energy for ^{56}Fe is

$$\begin{aligned} S_p({}^{56}\text{Fe}) &= [M({}^1\text{H}) + M({}^{55}\text{Mn}) - M({}^{56}\text{Fe})]c^2 \\ &= [1.007825\text{ u} + 54.938046\text{ u} - 55.934939\text{ u}]c^2 \\ &= (0.0109\text{ uc}^2)(931.494\text{ MeV/uc}^2) = 10.18\text{ MeV}. \end{aligned}$$

The proton separation energy for ^{56}Fe is particularly large—10.2 MeV—because ^{56}Fe is a particularly strongly bound nucleus.

What Do You Think? Write down the equation for the neutron separation energy of ^{56}Fe. Do you think the neutron separation energy will be somewhat larger, somewhat smaller, or equal to the proton separation energy?

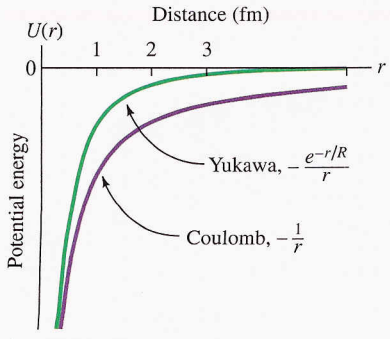
Spins and Magnetic Dipole Moments: Nuclei have angular momentum, just as atoms do. This angular momentum is usually called the *spin* of the nucleus because, without knowing the internal structure of the nucleus, we can regard it as intrinsic. Nucleons have a spin of $\hbar/2$. As is true of electrons in atoms, the nucleons that compose the nucleus can have an orbital angular momentum. The total angular momentum of a nucleus results from adding the orbital angular momentum and the spins according to the rules of quantum mechanics, supplemented by the exclusion principle. (The exclusion principle states, for example, that two protons cannot move "in the same orbit" and both have spin-up.)

Associated with the angular momentum of a nucleus is a magnetic dipole moment, and this magnetic moment provides the means of detecting the angular momentum of the nucleus. We described *nuclear magnetic resonance* in Section 31–6, in which the nuclear magnetic dipole moment is detected because of a resonance phenomenon.

Another means of detecting the nuclear magnetic dipole moment is to note that a magnetic dipole produces a magnetic field and, because atomic electrons have both spin and orbital angular momenta, the energy of these electrons depends on this nuclear magnetic field. The small resulting shift in electron energy levels is referred to as *hyperfine splitting* of the atomic spectra, a splitting some thousand times smaller than the fine-structure splitting discussed in Chapter 41.

The orders of magnitude of nuclear magnetic moments are those of the magnetic dipole moments of the proton and neutron themselves. We would estimate these magnetic dipole moments in turn to be on the order of $e\hbar/2m_pc$ (a quantity known as the *nuclear magneton*) for the proton and zero for the (neutral) neutron, similar to the magnetic dipole moment of $e\hbar/2m_ec$ for the electron. (The composite nature of protons and neutrons—see Chapter 45—modifies this expectation somewhat.) Note that the nuclear magnetic moment is some 2000 times smaller than the electron magnetic moment because of the masses involved. That is why the hyperfine splitting of atomic spectra is some 1000 times smaller than the fine-structure splitting.

44–2 Nuclear Forces and Nuclear Models



One of the major tasks of nuclear physics is to discover the nature of the nuclear force. It must be strong enough to overcome the electrical repulsion between protons. An energy of 5 to 10 MeV is required to free a nucleon from a nucleus. This value can be compared with the 13.6 eV of energy needed to ionize hydrogen or the 3 to 5 eV needed to free an electron from a metal (the work function). By this measure, the nuclear forces are about a million times stronger than the electric forces that bind atoms.

The fact that the nucleon separation energy is on the order of a few MeV even for nuclei as heavy as lead ($A \cong 208$) implies that the number of "bonds" that attach a nucleon to a nucleus does not grow as the nucleus grows; we say that the nuclear force becomes *saturated* when a nucleon is surrounded by other nucleons. *The nuclear force has a short range comparable to the spacing between nucleons in a nucleus.* By the range, we mean the distance beyond which the nuclear force rapidly decreases. From our formula for the nuclear radius, Eq. (44–7), we can deduce that the spacing between nucleons is on the order of 1 **fermi** (fm), or 10^{-15} m (also known as a *femtometer*). The conclusion that the nuclear force has a short range is supported by scattering experiments, which also allow us to measure the range quantitatively.

We can summarize the quantitative behavior of nuclear interactions as follows. Except at distances much less than 1 fm, a reasonable representation of the nucleon–nucleon potential energy is

$$U(r) = -g^2\frac{e^{-r/R}}{r}, \tag{44–9}$$

where r is the distance between the two nucleons, the parameter R is called the range, approximately 2×10^{-15} m, and g^2 is a measure of the strength of the potential energy. Figure 44–9 illustrates this potential energy as well as a potential energy of the same strength but with a Coulomb form, $U_c = -g^2/r$, for comparison; these two potential energies have the same behavior for small r. The potential energy of Eq. (44–9) is known as the *Yukawa potential*, named for its originator, Hideki Yukawa. It can be justified in the context of quantum mechanics (as we shall see in Chapter 45).

▲ **FIGURE 44–9** The Yukawa potential $U(r) \propto -e^{-r/R}/r$, and the Coulomb form $-1/r$ for comparison. We have chosen $R = 2.0$ fm.

In our discussion, we have referred to the nucleon–nucleon force, not the proton–proton force, the proton–neutron force, or the neutron–neutron force. Numerous scattering experiments, as well as the study of nuclear binding energies for nuclei with the same A value but different Z values and N values, show that, basically, the only differences in the interactions of neutrons and protons are due to electromagnetism.

A full description of nuclear potentials takes us far beyond the Yukawa potential. First, there is a repulsion (a *core repulsion*) between the nucleons at separation distances less than about 1 fm. Second, nuclear forces have a substantial dependence on the orientation of the spin of the nucleons. Third, and perhaps most important, nuclear forces normally involve more than just two interacting particles. In atomic physics this

does not present much of a problem, because the forces are relatively weak, and mathematical tools exist by which we can handle such forces when many particles are involved. In nuclear physics, the forces are *strong*, as measured by the parameter g^2 in Eq. (44–9). Analytic mathematical techniques for the systematic treatment of such forces do not exist. The problems posed by nuclear forces are too difficult to be solved from a fundamental theory. Despite this difficulty, scientists know much about nuclei. As in the case of bulk materials, models and approximations that explain different, limited features of nuclei have been developed for describing the nucleus. We shall discuss two of these models—the shell model and the liquid-drop model.

The Shell Model

In Chapter 41, we learned that the energy levels of electrons in an atom form a shell structure under the influence of the Coulomb attraction of the nucleus. Despite the fact that nuclear forces are quite different from Coulomb forces, individual nucleons in a nucleus also appear to have well-defined energy levels. The description of the nucleus based on this idea is known as the **shell model** (or as an *independent-particle model*).

The *experimental* values of Z and N for which the binding energy is particularly large are 2, 8, 20, 28, 50, 82, 126, and these values are called *magic numbers*. A calculation assuming a three-dimensional spring force gives values of 2, 8, 20, 40, 70, ... These predicted numbers do not represent a perfect match to the experimental magic numbers and indicate that the order of filling levels is different in reality than a simple harmonic oscillator potential would suggest. In 1949, Hans Jensen and Maria Goeppert-Mayer independently pointed out that the energy should contain terms not included earlier that involve both the spin of a single nucleon and its orbital angular momentum. This *spin–orbit coupling* is the same type of coupling that causes splitting of atomic levels (see Section 41–3). By including this type of coupling, splitting of levels occurs and the ordering of levels is changed. The observed magic numbers are thereby more correctly predicted, as is the complicated pattern of level splittings seen in nuclei.

The Liquid-Drop Model

The short range of nuclear forces and the small amount of space between the constituent nucleons suggested to Niels Bohr that a nucleus should behave in some ways like a continuous fluid, such as water. The model based on this idea, the **liquid-drop model**, contains no reference to the behavior of individual nucleons and in this sense is complementary to the shell model. We note two similarities between nuclear data and the behavior of incompressible fluids. First, the density of all nuclear matter is roughly constant, just as for an incompressible fluid. Second, the binding energy per nucleon, E_b/A, is roughly constant from nucleus to nucleus.

Following this analogy, we can write an *empirical* formula for the mass of a nucleus, $M(^AX)$, based on the energy of a liquid drop, as follows:

1. A zeroth-order term is the sum of the rest masses of the nucleons:

$$ZM_H + Nm_n = ZM_H + (A - Z)m_n. \tag{44–10}$$

2. A term proportional to the volume of the nucleus (or $\propto A$, as we have shown) takes into account the nearly constant binding energy per nucleon:

$$-a_V A, \tag{44–11}$$

where a_V is positive because a binding energy reduces the mass of the nucleus.

3. A term proportional to $A^{2/3}$ or, equivalently, to the surface area of the nucleus,

$$+a_S A^{2/3}, \tag{44–12}$$

accounts for the fact that a nucleon near the surface is not bound as strongly as one in the interior, so a_S takes into account a reduced binding energy and is positive. This term is the analogue of a surface-tension term in a liquid drop.

The remaining three terms take into account some simple observations specific to the nucleus:

4. A term that accounts for the Coulomb repulsion between all the protons in the nucleus. This term tends to increase the mass of the nucleus. If we suppose that the protons are distributed uniformly throughout a sphere of radius $R_A = r_0 A^{1/3}$ [Eq. (44–7)], then the energy required to assemble that charge is†

$$\frac{3}{5}\frac{Z^2e^2}{4\pi\varepsilon_0 r_0 A^{1/3}} = 0.72\frac{Z^2}{A^{1/3}}\text{MeV} \tag{44–13}$$

(see Problem 24–91). The contribution of the energy to the mass is this quantity divided by c^2.

5. A term that has a minimum for $N = Z$ accounts for the tendency for the number of neutrons to equal the number of protons. If terms 1 through 4 were the only terms present, then the energy could be lowered by taking Z to zero; that is, nuclei would consist exclusively of neutrons. In fact, there are no nuclei with many more neutrons than protons, and nuclei are particularly stable when $N \cong Z$. This term is written as

$$+a_A\frac{(A-2Z)^2}{A}, \tag{44–14}$$

where a_A is positive.

6. Several terms describe the tendency for nuclei with even numbers of protons and/or neutrons to be more deeply bound than nuclei with odd numbers of protons and/or neutrons. This tendency occurs because the spins of two nucleons in each "shell" are antiparallel. Such terms have the empirical form

$$\text{for } Z, N \text{ even:} \quad \Delta = -\frac{a_p}{\sqrt{A}}. \tag{44–15a}$$

$$\text{For } Z \text{ even, } N \text{ odd; or } Z \text{ odd, } N \text{ even:} \quad \Delta = 0. \tag{44–15b}$$

$$\text{For } Z, N \text{ odd:} \quad \Delta = +\frac{a_p}{\sqrt{A}}. \tag{44–15c}$$

TABLE 44–3 • Parameters of the Semiempirical Mass Formula

Parameter	Value (u)
a_V	1.7×10^{-2}
a_S	1.8×10^{-2}
a_C	7.5×10^{-4}
a_A	2.5×10^{-2}
a_p	1.3×10^{-2}

The sum of all these terms is the **semiempirical mass formula**:

$$M_A = ZM_H + (A-Z)m_n - a_V A + a_S A^{2/3} + \frac{a_C Z^2}{A^{1/3}} + a_A\frac{(A-2Z)^2}{A} + \Delta. \tag{44–16}$$

The parameters are determined empirically by fitting this relation with many different nuclear masses. One set of parameters is given in Table 44–3. For these values, the curve in Fig. 44–6 for $A = 20$ and above is in good agreement with Eq. (44–16). For very light nuclei, the notion of a nucleus that looks like a droplet with a volume and a surface loses meaning, and the mass formula does not work very well, but otherwise the fit is excellent.

EXAMPLE 44–7 (a) Use the semiempirical mass formula to calculate the atomic masses of ^{208}Pb and ^{209}Pb. (b) Calculate the neutron separation energy for ^{209}Pb.

Strategy (a) This is simply a matter of evaluating Eq. (44–16) with the parameters of Table 44–3. (b) We discussed the neutron separation energy in Example 44–6, and its value for ^{209}Pb is

$$S_n(^{209}\text{Pb}) = [m_n + M(^{208}\text{Pb}) - M(^{209}\text{Pb})]c^2.$$

The masses here were evaluated in part (a).

Working It Out

(a) Equation (44–16) gives

$$\begin{aligned} M(^{208}\text{Pb}) &= (82)(1.007825\text{ u}) \\ &\quad + (208-82)(1.008665\text{ u}) - (1.7\times10^{-2}\text{ u})(208) \\ &\quad + (1.8\times10^{-2}\text{ u})(208)^{2/3} + (7.5\times10^{-4}\text{ u})\left[\frac{(82)^2}{(208)^{1/3}}\right] \\ &\quad + (2.5\times10^{-2}\text{ u})\left\{\frac{[208-2(82)]^2}{208}\right\} - \left(\frac{1.3\times10^{-2}\text{ u}}{\sqrt{208}}\right) \\ &= 207.921\text{ u}; \end{aligned}$$

†In some instances, the calculated coefficient 0.72 of the factor $Z^2/A^{1/3}$ in Eq. (44–13) is replaced by the empirical parameter $a_c \cong 0.60$. This is a very small difference in the contribution of the energy to the masses of nuclei. In Table 44–3, we use the calculated form.

$$M(^{209}\text{Pb}) = (82)(1.007825\text{ u}) + (209 - 82)(1.008665\text{ u}) - (1.7 \times 10^{-2}\text{ u})(209) + (1.8 \times 10^{-2}\text{ u})(209)^{2/3} + (7.5 \times 10^{-4}\text{ u})\left[\frac{(82)^2}{(209)^{1/3}}\right] + (2.5 \times 10^{-2}\text{ u})\left\{\frac{[209 - 2(82)]^2}{209}\right\} + 0$$
$$= 208.915\text{ u}.$$

(b) The neutron separation energy of ^{209}Pb is

$$S_n(^{209}\text{Pb}) = [m_n + M(^{208}\text{Pb}) - M(^{209}\text{Pb})]c^2 = [1.008665\text{ u} + 207.912\text{ u} - 208.915\text{ u}]c^2 = (0.0057\text{ u}c^2)(931.494\text{ MeV/u}c^2) = 5.3\text{ MeV}.$$

The experimental values of the masses are $M(^{208}\text{Pb}) = 207.97663$ u and $M(^{209}\text{Pb}) = 208.98107$ u, and the experimental value of the neutron separation energy is 3.9 MeV. The 5.3 MeV separation energy that we calculated from the semiempirical mass equation does not take into account the shell-model magic numbers, for which nuclei are particularly strongly bound. On average, the nucleon binding energy is around 8 MeV.

What Do You Think? The nuclide ^{208}Pb is an example of a "doubly magic" nucleus ($Z = 82$, $N = 126$), so it should be *very* strongly bound. Why might this mean that the neutron separation energy for ^{209}Pb is relatively low?

A classical droplet, even one made of an incompressible fluid, can deform in shape, and the same is true for nuclei in the liquid-drop model. This changes the energy, because the surface area changes. Surface forces tend to return the droplet to a spherical shape, but the Coulomb energy term favors a larger deformation. When we compare these two effects for nuclei, we find that the liquid drop becomes unstable for more massive nuclei, and these nuclei may break up into two smaller droplets. The liquid-drop model thus provides an explanation of the fission process (see Section 44–5).

44–3 Energetics of Nuclear Reactions

By nuclear reactions, we generally mean the processes that occur when nuclei interact through collisions. All the possibilities for different types of collisions outlined in Chapter 8 occur. Two nuclei may have an elastic collision or various types of inelastic collisions. A nucleus may absorb energy and then decay by one of several modes, which we shall discuss in Section 44–4. Mass may be transferred from one nucleus to another by the exchange of nucleons. Colliding nuclei may coalesce—a process called **nuclear fusion**. The decay of a single unstable nucleus may be regarded as a nuclear reaction. Examples are α decay, in which a nucleus decays to a helium nucleus and another nucleus; and **nuclear fission**, in which the decay products include two nuclei of more or less equal size. In all these interactions, the conservation laws we have developed throughout this book apply, including the conservations of energy, momentum, angular momentum, and charge.

At the simplest level, collisions between nuclei allow us to measure kinematic quantities such as masses or angular momenta. A terminology special to nuclear reactions has been developed. Consider a nuclear collision in which both the initial and final states consist of two nuclei:

$$A + B \rightarrow C + D.$$

Energy conservation applies, but we must use relativistic relations. For any one nucleus (or particle) of mass M, this energy takes the form

$$E = K + Mc^2,$$

where K is the kinetic energy of the nucleus. The value of K depends on the frame of reference, but the conservation of energy, $E_A + E_B = E_C + E_D$, applies in any reference frame. If we suppose that nucleus B is the target nucleus, at rest in the laboratory frame of reference, then the conservation of energy takes the form

$$(K_A + M_Ac^2) + M_Bc^2 = (K_C + M_Cc^2) + (K_D + M_Dc^2) \qquad (44\text{–}17)$$

in that reference frame. Depending on the masses of the nuclei involved, the reaction can be *exothermic* (having more kinetic energy in the final state than in the initial state) or *endothermic* (having less kinetic energy in the final state). A kinematic parameter that describes such properties is the *Q value* of the reaction:

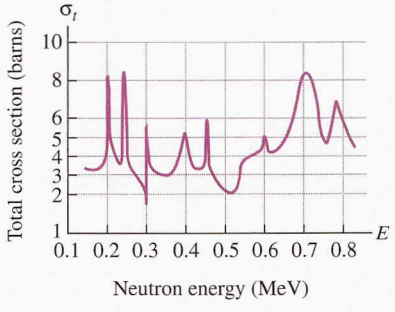
$$Q \equiv K_C + K_D - K_A - K_B. \qquad (44\text{–}18)$$

By including the possibility that nucleus B has kinetic energy, we have written a general relation. A positive Q value corresponds to an exothermic reaction, and a negative Q value corresponds to an endothermic reaction. By moving all the kinetic energy terms in Eq. (44–17) to one side of the equation and all the mass terms to the other, we can express the Q value in terms of atomic masses:

$$Q = (M_A + M_B - M_C - M_D)c^2. \tag{44–19}$$

By measuring kinetic energies in a reaction and comparing Eqs. (44–18) and (44–19), we can use the Q value for mass measurements that cannot otherwise be made. Note that although we have used laboratory frame quantities in Eq. (44–18), our original definition of Q, Eq. (44–19), shows that Q is actually an invariant.

The variety of measurements of different nuclear reactions—including their dependence on different variables of the collision process, such as the projectile energy and angle—gives us much of our knowledge of nuclear structure and nuclear forces. The most useful concept for collisions is the *collision cross section*, which, as we described in Chapter 19, measures the effective area taken up by the colliding nuclei. The cross section is a measure of the probability of interaction; the larger the cross section, the more probable the collision and hence the reaction. We can thus define a cross section *for each possible reaction* that measures the relative probability of each of these processes.



One of the important features of the cross section is the presence of *resonances*, which we define here as bumps in the curve of cross section versus collision energy of the same form as the resonance curve of Fig. 13–23. A bump in the cross section centered around E_0 of width ΔE implies that the nucleus is strongly affected by the incident projectile when the total energy is in the range $E_0 - \Delta E/2$ to $E_0 + \Delta E/2$. Here, the nucleus–projectile system behaves like a nucleus with an excited state around E_0, but spread over an energy range ΔE. In other words, *the presence of a resonance peak in a cross section signals the presence of an excited state at that energy*. Indeed, these excited states are often referred to as resonances.

The role of resonances in this process is most clearly understood by thinking of the reaction as $A + B \rightarrow$ resonance $\rightarrow C + D$, where A and B are nuclei that interact to form the resonance, and C and D are the nuclei, among several other possibilities, that result from the decay of the resonance. The resonance, which is also referred to as a *compound nucleus*, may live for a relatively long time—time enough to allow the compound nucleus to "forget" how it was formed. There are a number of predictive consequences based on the idea that how the decay of the resonance occurs is independent of how the resonance was formed.

The lifetime τ of this excited state is related to the width of the bump in the curve of the cross section by the Heisenberg uncertainty principle,

$$\tau \Delta E \cong \hbar. \tag{44–20}$$

Thus *the width in energy of the resonance is $\hbar$ divided by the lifetime of the resonance*: the shorter-lived the resonance, the broader the resonance peak. In nuclear physics, resonances may have widths ranging from about 0.1 eV, corresponding to a lifetime of 10^{-14} s, to as much as 1 MeV, corresponding to a lifetime of 10^{-21} s. In Fig. 44–10, we see resonance shapes in the probability (total cross section) for neutron absorption by ^{23}Na. Each peak corresponds to an excited state of the nuclide ^{24}Na, which then decays. In some interactions of nucleons and other particles that participate in the nuclear force, resonances occur with widths as large as 100 MeV. This corresponds to a lifetime of 10^{-23} s, about the time it takes for light to cross the nucleus!

▲ **FIGURE 44–10** The total cross section for the absorption of neutrons by ^{23}Na. Energy is measured in the laboratory frame of reference. The peaks, also known as resonances, correspond to excited states of ^{24}Na. (After S. F. Mughabghab et al., *Neutron Cross Sections*, Academic Press, 1984.)

44–4 Radioactivity

Henri Becquerel discovered radioactivity in 1896, even before the existence of the nucleus had been established. **Radioactivity**—the name was coined by Marie Curie (Fig. 44–11)—is the phenomenon of nuclear decay. Nuclei can decay in a variety of *modes* or *channels*—for example, by emitting photons or α particles. Different physical laws may govern different decay modes, so each mode may have a different probability of occurring. The lifetime τ of a collection of radioactive nuclei is a

constant with dimensions of time that determines the rate at which a set of such nuclei decay: If N_0 is the number of nuclei present at $t = 0$, then $N(t)$, the number of nuclei that remain after a time t, is given by Eq. (40–17), $N(t) = N_0 e^{-t/\tau}$. An alternate way to write this equation is to define the **decay constant** λ as $\lambda \equiv 1/\tau$, so that

$$N(t) = N_0 e^{-\lambda t}. \tag{44–21}$$

The rate at which nuclei decay, the *decay rate*, is $-dN/dt$. From Eq. (44–21),

$$\frac{dN}{dt} = -\lambda N_0 e^{-\lambda t} = -\lambda N. \tag{44–22}$$

The decay rate λN, also called the *activity*, is high when the number of unstable nuclei is large and when the decay constant is large (the lifetime is small). We also employ the *half-life*, $t_{1/2}$, the time for half of a given sample of unstable nuclei to decay. The half-life is related to the lifetime by $t_{1/2} = (\ln 2)\tau = 0.693\,\tau$ (see Problem 40–64). The SI unit of activity is the *becquerel* (Bq): 1 Bq = 1 decay/s.

If a nucleus can decay in two or more ways, then the total decay rate is a sum of decay rates for the various decay modes. Think of several holes in a leaky can: The total rate of flow from the can is the sum of the rates from each of the holes. The decay rate from the mode labeled by the subscript j (for example, j may label the α-decay mode) is proportional to the decay constant λ_j for that mode, so the total decay rate is proportional to the sum of all the decay constants. In other words, there is a total decay constant λ given by

$$\lambda = \sum_j \lambda_j. \tag{44–23}$$

If the decay in one mode, say, mode 1, is much more rapid than that in all the other modes, then λ_1 is much larger than the other decay constants, and the λ_1 term dominates the sum in Eq. (44–23). In that case, $\lambda \cong \lambda_1$. It is as though one hole in our leaky can is much larger than the others. We say that the nucleus *decays predominantly through the channel* labeled by λ_1.

With the exception of fission reactions (to be discussed in Section 44–5), a typical radioactive decay involves a nucleus (the *parent nucleus*) that emits a particle and is thereby converted into a *daughter* nucleus. Three different types of decays can occur, labeled α, β, or γ according to the particles emitted.

▲ **FIGURE 44–11** Marie Curie in her laboratory at the Sorbonne, Paris, circa 1908. Curie and her husband, Pierre Curie, performed important early work on radioactivity for which she earned two Nobel prizes.

EXAMPLE 44–8 A sample of uranium ore emits α radiation characteristic of ^{235}U at a rate of 9.3×10^5 decays/s. What mass of chemical uranium is present in the ore? The half-life of ^{235}U is 7.04×10^8 yr, and the abundance of naturally occurring ^{235}U in a sample of uranium is 0.72 percent.

Strategy We are given the decay activity and half-life for ^{235}U. From the half-life, we can find the decay constant λ; with λ and the activity, we can find the number of ^{235}U nuclei. Then we can use the abundance of ^{235}U to find the total quantity of uranium.

Working It Out We have $\lambda = 1/\tau = 0.693/t_{1/2}$. From the relation for the activity, Eq. (44–22), we find the number of ^{235}U atoms to be

$$N = -\frac{1}{\lambda}\frac{dN}{dt} = -\frac{t_{1/2}}{0.693}\frac{dN}{dt}$$
$$= -\frac{(7.04 \times 10^8\ \text{yr})(3.16 \times 10^7\ \text{s/yr})}{0.693}(-9.3 \times 10^5\ \text{decays/s})$$
$$= 3.0 \times 10^{22}.$$

Given this number of ^{235}U atoms, we can use Avogadro's number to find the mass m of ^{235}U:

$$m = (3.0 \times 10^{22}\ \text{atoms})\left(\frac{1\ \text{mol}}{6.02 \times 10^{23}\ \text{atoms}}\right)(235\ \text{g/mol}) \cong 12\ \text{g}.$$

Because ^{235}U makes up 0.72 percent of naturally occurring uranium, the total amount of uranium is

$$(1/0.0072)(12\ \text{g}) = 140(12\ \text{g}) = 1.7\ \text{kg}.$$

What Do You Think? The density of uranium is about 19 times that of water. Estimate the size of the piece of uranium referred to in this example. Could anyone lift a basketball made of solid uranium unaided?

Alpha Decay

Decay in the **α-decay mode** is written as

$$^{A}_{Z}X \rightarrow ^{A-4}_{Z-2}X' + ^{4}_{2}\text{He}, \tag{44–24}$$

where X and X' are the chemical symbols of the parent and daughter nuclei, respectively. Here, we have recognized that the emitted α particle is actually a ^{4}He nucleus. An example of this type of decay is $^{238}_{92}\text{U} \rightarrow ^{234}_{90}\text{Th} + ^{4}_{2}\text{He}$.

Alpha decay involves the quantum mechanical tunneling of an α particle through a potential barrier. For α decay to occur, the mass of the parent nucleus must be greater than the sum of the masses of an α particle and the daughter nucleus. The systematics of nuclear masses implies that α decay is increasingly more likely to occur as the size of a nucleus increases. Many nuclei above $Z = 83$ are unstable in this mode.

Nuclear forces are understood well enough to allow us to predict the probabilities of α decay. Because the rate at which tunneling occurs is extremely sensitive to the width and height of the potential barrier, the range of lifetimes of nuclei in the α-decay mode is huge, from 3×10^{-7} s to 1.4×10^{17} s!

EXAMPLE 44–9 ^{241}Am (an isotope of americium) decays in the α-decay mode: $^{241}\text{Am} \rightarrow \alpha + ^{237}\text{Np}$. Calculate the kinetic energy of the α particle if the ^{241}Am nucleus decays at rest and the atomic masses are $M(^{241}\text{Am}) = 241.05682$ u, $M(^{4}\text{He}) = 4.002603$ u, and $M(^{237}\text{Np}) = 237.04817$ u.

Strategy Both conservation of energy and conservation of momentum must be applied here. From the conservation of energy, we have $M(^{241}\text{Am}) = M(^{4}\text{He}) + M(^{237}\text{Np}) + K_f/c^2$, and this can be solved for K_f, the kinetic energy of the two-body final state. As long as this is much less than the rest mass of either final nucleus, we can treat the motion nonrelativistically, and use $K_f = K(^{4}\text{He}) + K(^{237}\text{Np})$, where $K = p^2/2M$ for the respective nuclei. Finally, the conservation of momentum applied to the final state gives $0 = p(^{4}\text{He}) + p(^{237}\text{Np})$, or $p(^{237}\text{Np}) = -p(^{4}\text{He})$, leaving only the single quantity $p(^{4}\text{He})$ in our expressions and allowing us to solve for it and hence for $K(^{4}\text{He})$.

Working It Out We solve the equation above for K_f:

$$\begin{aligned} K_f &= [M(^{241}\text{Am}) - M(^{4}\text{He}) - M(^{237}\text{Np})]c^2 \\ &= (241.05682\text{ u} - 4.002603\text{ u} - 237.04817\text{ u})c^2 \\ &= 0.006047\text{ uc}^2 = (0.006047\text{ uc}^2)(931.474\text{ MeV/uc}^2) \\ &= 5.633\text{ MeV}. \end{aligned}$$

This kinetic energy is indeed small enough to allow us to use nonrelativistic relations. We use the equation for K_f to solve for $K(^{4}\text{He})$, writing $p \equiv p(^{4}\text{He}) = -p(^{237}\text{Np})$:

$$\begin{aligned} K(^{4}\text{He}) &= K_f - K(^{237}\text{Np}) = K_f - \frac{p^2}{2M(^{237}\text{Np})} \\ &= K_f - \frac{p^2}{2M(^{4}\text{He})}\frac{M(^{4}\text{He})}{M(^{237}\text{Np})} = K_f - K(^{4}\text{He})\frac{M(^{4}\text{He})}{M(^{237}\text{Np})}. \end{aligned}$$

We can solve this relation for $K(^{4}\text{He})$:

$$K(^{4}\text{He}) = \frac{K_f}{1 + \left[\dfrac{M(^{4}\text{He})}{M(^{237}\text{Np})}\right]} = \frac{5.633\text{ MeV}}{1 + (4.00\text{ u}/237\text{ u})} = 5.539\text{ MeV}.$$

What Do You Think? Is the kinetic energy of the ^{237}Np nucleus (a) much larger than, (b) much smaller than, or (c) about equal to the kinetic energy of the α particle?

Beta Decay

In the **β-decay mode** of a nucleus, an electron and an *antineutrino* ($\bar{\nu}$) (or a positron and a neutrino) are emitted, leaving a daughter nucleus. The antineutrino is the antiparticle of the neutrino (ν), just as the positron is the antiparticle of the electron. The properties of the antineutrino and the neutrino are, for our purposes, identical.

Wolfgang Pauli postulated the existence of the neutrino in 1930 on the basis of experimental data on β decay. An important feature of the neutrino, which has zero charge and spin $\hbar/2$, is that it interacts so weakly with matter that any one neutrino will traverse *light-years* of ordinary matter before the probability of interacting with the matter is significant. It is therefore not surprising that the neutrino was not *independently* observed to initiate a collision process until 1956, 60 years after β decay was first observed. In β decay we observe the electron and (sometimes) the daughter nucleus but, as a result of the neutrino's weak interaction, never the neutrino. Finally, the neutrino has one other important property: Its mass is very small—at most a few eV/c^2, less than 10^{-5} times the electron's mass—and this value is negligible in all the situations we deal with here.

When an electron is emitted in nuclear β decay, the daughter nucleus has a charge $+e$ more than that of the parent nucleus; that is, *Z increases by 1 in this β-decay process*. As we did in Eq. (44–24), we write this β-decay process symbolically as

$$^{A}_{Z}X \rightarrow ^{A}_{Z+1}X' + e^- + \bar{\nu}. \tag{44–25}$$

An example of this type of decay is $^3\text{H} \rightarrow {}^3\text{He} + e^- + \bar{\nu}$. In this form of β decay, a neutron has in effect been converted to a proton, an electron, and an antineutrino within the nucleus. Indeed, the most primitive β decay is that of the neutron itself:

$$n \rightarrow p + e^- + \bar{\nu}. \tag{44–26}$$

For *free* neutrons, the lifetime for this process is approximately 890 s. Thus neutrons by themselves are unstable. In contrast, neutrons within nuclei that do not undergo β decay are stable. The primary β-decay mode, Eq. (44–25), is possible only for the mass condition

$$M_P > M_D \tag{44–27}$$

(see Problem 32), where M_P and M_D are the atomic masses of the parent and daughter nuclei, respectively. For nuclei that undergo β decay, the kinetic energy of the electrons ranges up to 10 MeV, with 1 MeV being typical.

If the neutrinos in β decay cannot be observed directly, how was it possible for Pauli to predict their existence and properties as early as 1930? The existence of the neutrino was inferred on the basis of several types of conservation laws. First, conservation of momentum and of energy have rather different consequences for three-body decay (one in which the parent nucleus decays to three particles; Fig. 44–12a) than for two-body decay (Fig. 44–12b). In two-body decay of a nucleus at rest, the energies of each of the two decay products are fixed: The conservation of momentum and of energy *uniquely* determine the magnitudes of the momentum and the energy of the decay products. This is not true in three-body decay, in which different configurations of the three bodies allow for a range of energies for all three bodies. Various configurations allow the electron's kinetic energy to range from zero up to a maximum value, as shown in Fig. 44–13. A similar plot for a two-body decay would show a single energy value at the energy maximum K_{max}.

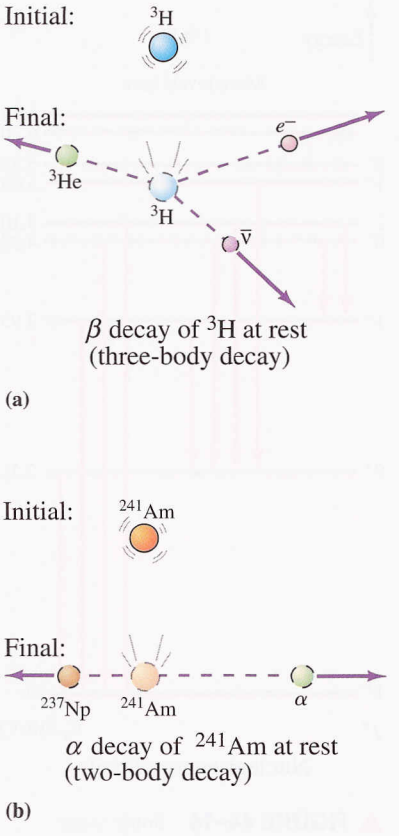
Pauli surmised from the broad curve observed in Fig. 44–13 that three particles—including the otherwise invisible neutrino—must be present. Angular momentum conservation leads to the same conclusion. If the decay of the neutron were the two-body decay $n \rightarrow p + e^-$ rather than a three-body decay, we would have a discrepancy. Neutrons, like protons and electrons, have a spin of $\hbar/2$, but the rules of angular momentum addition do not allow two $\hbar/2$ spins to add to a total spin of $\hbar/2$. The addition of a third particle with a spin of $\hbar/2$ can resolve the discrepancy; in this way, Pauli was able to predict that the invisible third particle, the neutrino, was a fermion. Although the form of the curve depends in principle on the mass of the neutrino, in fact to the accuracy available to us the curve is the one that would be obtained by assuming that neutrinos are massless, confirming our remark that any mass it has is negligible.

Lifetimes of β decays vary from about 1 s to more than 10^{20} s. The energy dependence and low rate of β decay of some nuclei suggest that the β-decay process is not a quantum mechanical tunneling process but rather a primary manifestation of the *weak force* (one aspect of the electroweak force; see Chapter 5).

We can mention two other forms of β decay here—both of them consequences of the weak force. The first is *positron emission*, which takes the form

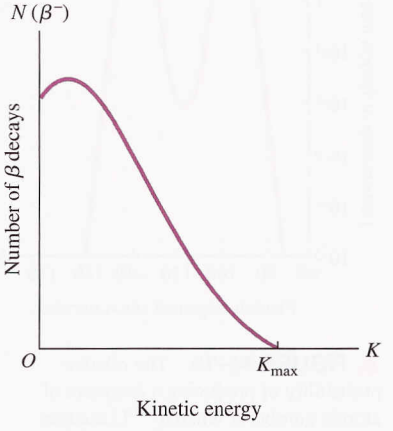
$$_{Z+1}^{A}X \rightarrow {}_{Z}^{A}X' + e^+ + \nu. \tag{44–28}$$

This process is allowed under the mass condition



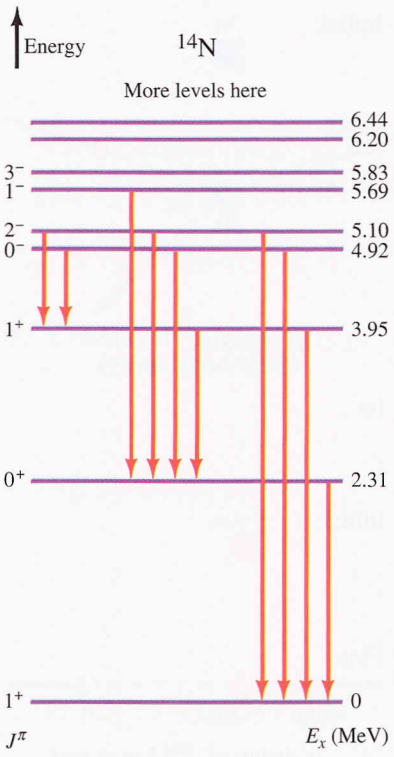
$$M_X > M_{X'} + 2m_e. \tag{44–29}$$

The second variant is *electron capture*, in which an electron from an atomic orbit is absorbed by the nucleus:

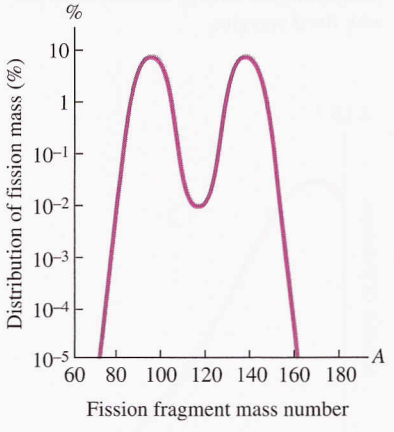


$$_{Z+1}^{A}X + e^- \rightarrow {}_{Z}^{A}X' + \nu. \tag{44–30}$$

Electron capture is possible under the mass condition



$$M_X > M_{X'}. \tag{44–31}$$



▲ **FIGURE 44–12** (a) Beta decay is a three-body decay, as opposed to (b) α decay, a two-body decay. In each case the parent nucleus is at rest. In the three-body decay, a variety of directions and energies are possible for the decay products, subject to overall energy and momentum conservations. In the two-body decay, the decay products emerge back-to-back and with fixed energies.

▲ **FIGURE 44–13** The energy of the electron for a large sample of β decays. The energy is not fixed, but rather spread, a consequence of the kinematics of three-body decay. The maximum possible electron energy, K_{max}, is the energy the electron would have if there were no neutrino in the decay.

▲ **FIGURE 44–14** Some γ-ray decay transitions in ^{14}N. The notation J^π describes the respective quantum states labeled by quantum numbers not discussed here. E_x labels the energy of the states relative to the ground state. Not all possible transitions are shown. Many more levels exist above 6.44 MeV in ^{14}N.

▲ **FIGURE 44–15** The relative probability of producing a fragment of atomic number A when a ^{236}U nucleus undergoes fission. When slow neutrons induce fission, a variety of daughter nuclides (fragments) are produced. Note that it is *less* likely that fragments with exactly half the size of the parent, in this case ^{236}U, are produced than that the fragments are of unequal size. (After W. E. Burcham, *Nuclear Physics*, McGraw-Hill, 1963.)

Note that the mass conditions for the primary decay mode and electron capture are identical. However, β decay tends to occur for neutron-rich nuclei, and electron capture for neutron-poor nuclei. Practically all the kinetic energy in electron capture goes to the neutrino because of the conservation of energy and linear momentum (see Example 44–9).

Gamma Decay

A nucleus in an excited state can decay in the **γ-decay mode**: It emits photons as it decays to its ground state or to lower-lying excited states (Fig. 44–14), just as an atom in an excited electronic state can. Because the typical energy differences between nuclear excited states and the ground state are some 10^6 times greater than the corresponding energy differences in atoms, lighting a match is not enough to excite the nucleus, even if it is enough to excite an atom or molecule. However, daughter nuclei are often produced in their excited states in α, β, or even γ decay, and these residual states can then decay by the γ-decay mode. Photons with energies as high as a few MeV were not at first recognized as electromagnetic radiation and were therefore given a special name, γ-rays; we speak of the γ-decay mode of the nucleus. The lifetimes of γ decay range from 10^{-17} s to as much as 10^8 s.

Radioactivity and Life

Radioactivity has significant effects on biological systems. Some effects are desirable—medical diagnosis and treatment, for example—and some are just the opposite. Undesirable effects occur when one of the forms of radiation deposits energy in a normal living cell. That energy is typically absorbed when ionization occurs. Chemical bonds are broken, destroying needed substances in the cell. New ions may induce abnormal chemical reactions. We can distinguish three levels of damage: The chemical functioning of cellular processes may be so badly interrupted that the cell dies or is unable to reproduce; internal controls on the cell's behavior may be lost, so that the cell becomes cancerous; or the gene structure of the cell may be changed, resulting in abnormal offspring. On the positive side, we know that cancerous cells as well as healthy ones can be destroyed with radiation. In many cases lives are saved or extended for many years because of radiation treatment that targets its effects on cancerous cells. The danger of a given radioactive substance is associated with the activity, the energy of the radioactive decay products, and the amount of that energy deposited in the body. One measure of possible damage is the energy of the radiation absorbed per mass of the organism. The corresponding SI unit is the *gray* (Gy): 1 Gy $\equiv$ 1 J/kg. A dose of several Gy over the entire human body may be lethal, and 10 Gy or more is lethal within a short period. Because damage depends on just how the energy is deposited, a more precise measure takes into account the type of radioactive decay products that produce a given dose.

We are constantly exposed to cosmic rays from outer space and from natural radioactivity of materials around us on Earth, receiving a dose of some 10^{-3} Gy/yr from such sources. Exposure to radioactivity from human-made sources must be compared to this natural background. For example, an inhabitant of the United States receives on average less than half the natural dose in diagnostic X rays, and the background radioactivity associated with properly controlled nuclear-power generation is only about 3×10^{-5} of this value.

44–5 Fission and Fusion

Fission

We have mentioned that α decay is a tunneling process. It is a type of **fission**, a process in which a nucleus breaks into two pieces of more or less equal size. Fission occurs in large nuclei because the energetics favor it. The liquid-drop model helps us to understand why fission occurs. When a large nucleus breaks into two fragments, the sum of the Coulomb repulsion terms from Eq. (44–13) for the two pieces is considerably less than that of the corresponding single term of the parent nucleus. The Coulomb term alone implies that the most energetically favorable fission process is one in which the parent nucleus breaks into two equal pieces. In real fission processes, the two fragments are typically of different sizes (Fig. 44–15).

THINK ABOUT THIS. . .

WHAT IS THE SIGNIFICANCE OF RADIOACTIVE SERIES?

It is often true that the daughter nucleus produced in a radioactive decay is itself unstable. The result is a *radioactive series*, in which a succession of unstable nuclei decay in a cascade to some stable nucleus or nuclei. The existence of these series helps us to understand a great deal about the kinds of nuclei that are found in nature.

Along the steps of the cascade that makes up a series, some nuclei may have two competitive decay modes, such as an α-decay mode and a β-decay mode, in which case we say that there is *branching*. Figure 44–16 shows the uranium series, which starts with ^{238}U. Beta decays pull the branching line closer to the line of stability. Of the three possible decay modes, only α decay changes A. Therefore, if a series starts with a parent whose A value has the form $A = 4n$, where n is an integer, then all the nuclides with $A = 4n - 4$, $4n - 8$, and so forth will be encountered until a stable nucleus is obtained. Similarly, if the starting nucleus has $A = 4n + 1$, then nuclei with $A = 4n - 3$, $4n - 7, \ldots$ are reached. A third series with $A = 4n + 2$ and a fourth with $A = 4n + 3$ are also possible, but the "fifth" series, with $A = 4n + 4$, is identical to the $A = 4n$ series. Thus *there are only four different radioactive series*. The series shown in Fig. 44–16 for $^{238}_{92}$U is the $A = 4n + 2$ series; a series starting with $^{232}_{90}$Th is the $A = 4n$ series.

The lifetimes of the original parent nuclei are 6.4×10^9 yr for $^{238}_{92}$U and 2.0×10^{10} yr for $^{232}_{90}$Th. The fact that these numbers are comparable to the age of the solar system explains why we can still find these nuclides in nature: If the lifetimes of the parent nuclei were shorter, all the parents would have decayed by now. Moreover, the fact that the daughter nuclei are continuously being replenished through decays of the parent nuclei explains why we find extremely short-lived nuclei in nature. For example, in the decay series starting with $^{238}_{92}$U, the sixth step produces $^{222}_{86}$Rn, and this nucleus undergoes α decay to $^{218}_{84}$Po with a half-life of 3.8 d, certainly much less than the age of the solar system. Yet $^{222}_{86}$Rn can be found by chemical means in uranium ore.

The end product of a radioactive series is a stable nucleus. The series starting with $^{238}_{92}$U includes 14 steps with 4 different branchings. In the series starting with $^{232}_{90}$Th, there are 10 steps with 1 branching. Despite the branchings, there is a unique end product in each case: the stable nuclides $^{206}_{82}$Pb and $^{208}_{82}$Pb, respectively.

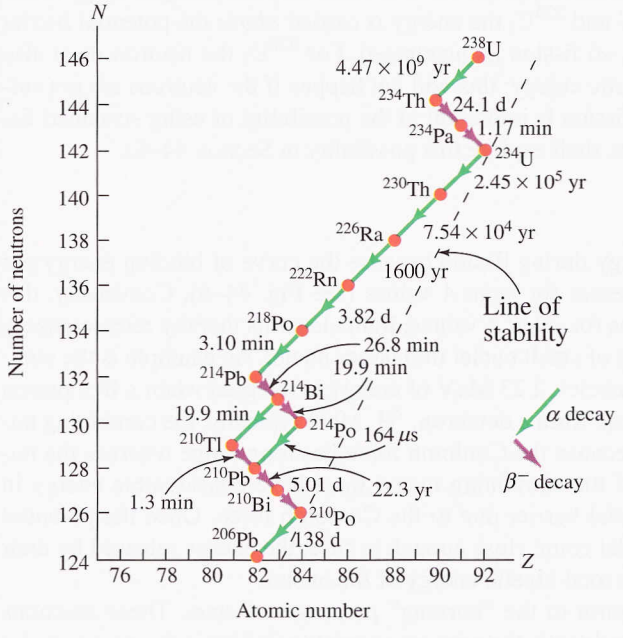


FIGURE 44–16 The decay series of ^{238}U plotted on a graph of N versus Z. Half-lives of each nuclide are also shown. Only one of the four different branchings of this series is shown.

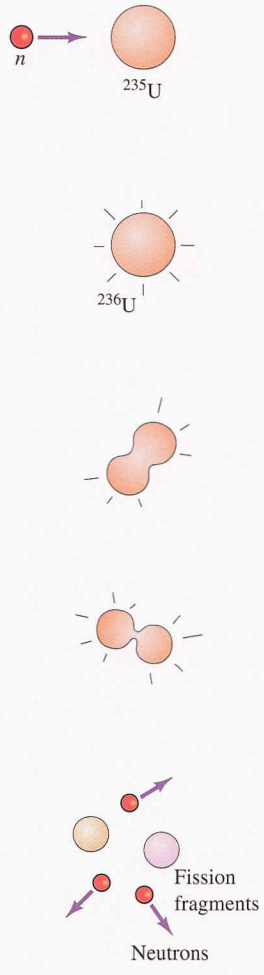
EXAMPLE 44–10 Find the difference in energies due to the Coulomb term alone between a $^{238}_{92}$U nucleus and two $^{119}_{46}$Pd (palladium) nuclei.

Strategy We find the energy due to the Coulomb energy term, Eq. (44–13), for a parent nucleus with Z protons and A nucleons, and then we do the same for each of the two daughter nuclei with $Z/2$ protons and $A/2$ nucleons. We want to find the difference ΔE between the term for the parent and the sum of the terms for each (identical) daughter.

(continues on next page)



Working It Out The steps above lead in a direct way to

$$\Delta E = \frac{3}{5}\frac{Z^2e^2}{4\pi\varepsilon_0 r_0 A^{1/3}} - 2\left[\frac{3}{5}\frac{(Z/2)^2e^2}{4\pi\varepsilon_0 r_0 (A/2)^{1/3}}\right]$$
$$= (1 - 2^{-2/3})\frac{3}{5}\frac{Z^2e^2}{4\pi\varepsilon_0 r_0 A^{1/3}}.$$

We are interested in the case $Z = 92$ and $A = 238$. Numerical evaluation gives

$$\Delta E \cong (1 - 2^{-2/3})(9.8 \times 10^8\,\text{eV}) = 3.6 \times 10^8\,\text{eV} = 360\,\text{MeV}.$$

This is a substantial amount of energy even for a nuclear reaction. But it is not the whole story, because other terms contribute to energy differences of this type. It does, however, give a reasonable order-of-magnitude estimate of the kinds of energies that are released when nuclear fission occurs.

▲ **FIGURE 44–17** The fission process. (a), (b) The ^{236}U nucleus produced by neutron bombardment of ^{235}U is in unstable equilibrium, and (c)–(e) breaks into two daughter nuclei. Several free neutrons are also produced.

If the Coulomb energy destabilizes large nuclei, why do such nuclei even exist? The answer is that the presence of an energy proportional to the surface of a liquid drop provides a barrier against breakup. The surface term in the energy is positive and is minimized when the nucleus is spherical [Eq. (44–13)]. In Fig. 44–17, we show a sequence in which a large liquid-drop nucleus formed by neutron absorption in ^{235}U breaks into two fragments. As the fragments start to separate, the surface—and hence the surface energy—*increases* without the Coulomb energy changing very much. As the fragments separate further, the surface-energy term makes it energetically favorable for the separating fragments to "neck off." It is only when the nuclei have separated into two spheres that the surface energy no longer changes. The fact that the sum of surface and Coulomb energies initially increases as the fragments start to separate means that there is a potential barrier. This barrier is on the order of 5 MeV for nuclei such as uranium.

Because of the potential barrier, fission of the type we described can only proceed through quantum mechanical tunneling. This process is called *spontaneous fission*; it occurs at a slow rate. Another process, called *induced fission*, occurs when free neutrons are captured by heavy nuclei such as uranium. The resulting nucleus is an excited state, with the added neutron having a binding energy of about 5 MeV. This is about the height of the potential barrier against fission, and the new nucleus thus has enough energy to undergo fission easily. For ^{233}U and ^{235}U, the energy is carried *above* the potential barrier even for very slow neutrons, so fission is guaranteed. For ^{238}U, the neutron must also supply at least 1 MeV of kinetic energy; this will not happen if the neutrons are not sufficiently energetic. Induced fission is important in the possibility of using sustained fission for power production (we shall explore this possibility in Section 44–6).

Fusion

Heavy elements release energy during fission because the curve of binding energy per nucleon decreases as A increases for large A values (see Fig. 44–6). Conversely, this curve increases as A increases for *small* A values; light elements thereby release energy during **fusion**, the combining of small nuclei into larger nuclei. An example is the combining of free nucleons into nuclei: 2.23 MeV of energy is released when a free proton and a free neutron combine and form a deuteron, ^{2}H. More typically, the combining nuclei are each charged, and because the Coulomb force has long range whereas the nuclear force does not, each of the combining nuclei must have considerable energy in order to surmount the potential barrier due to the Coulomb force. Once the potential barrier is passed and the nuclei come close enough to fuse, the energy released by their fusion is much more than the total kinetic energy of the nuclei.

Fusion reactions are central to the "burning" processes of stars. These reactions occur in cycles of reactions or decays, the primary example of which is the *proton cycle*:

$$p + p \rightarrow {}^2\text{H} + e^+ + \nu, \text{ with 0.4 MeV of energy released;} \quad (44\text{–}32a)$$

$${}^2\text{H} + p \rightarrow {}^3\text{He} + \gamma, \text{ with 5.5 MeV of energy released;} \quad (44\text{–}32b)$$

$${}^3\text{He} + {}^3\text{He} \rightarrow {}^4\text{He} + 2p + \gamma, \text{ with 13.0 MeV of energy released.} \quad (44\text{–}32c)$$

The internal temperature of stars is high enough to give some colliding nuclei sufficient energy to overcome the Coulomb repulsion involved in all three of these reactions. The *net* effect of this cycle is to convert four protons into an α particle along with the emission of

energy in the form of photons and two neutrinos. Although the energy given to a neutrino is lost (in the sense that the neutrino does not interact further in a way that deposits its energy), the photons continue to heat the interior. This is the source of the energy that eventually arrives on Earth from our own star, the Sun.

EXAMPLE 44–11 Calculate the total energy released each time a ^{4}He nucleus is produced in the proton cycle. To the energies described in Eqs. (44–32), add the energy released when each of the 2 positrons produced annihilates with 2 electrons (already present in the star), producing 4 photons and a kinetic energy equivalent to four times the electron mass—the positron and electron have the same mass, 0.51 MeV/c^2—namely, 2.0 MeV: $2e^+ + 2e^- \rightarrow 4\gamma +$ 2.0 MeV.

Strategy We must write out the full set of reactions in the proton cycle, measuring the energy that is released at each step. For the third reaction of the cycle, Eq. (44–32c), two ^{3}He nuclei are present, so the reaction of Eq. (44–32b) must occur twice. Similarly, the reaction of Eq. (44–32a) must also occur twice.

Working It Out The chain of reactions that produces one ^{4}He nucleus is

$$\begin{aligned}
&2(p + p) + p + p + 2e^- \\
&\quad \rightarrow 2(^2\text{H} + e^+ + \nu + 0.4\ \text{MeV}) + p + p + 2e^- \\
&\quad \rightarrow 2(^3\text{He} + \gamma + 5.5\ \text{MeV}) + (2e^+ + 2\nu + 0.8\ \text{MeV}) + 2e^- \\
&\quad \rightarrow (^4\text{He} + 2p + \gamma + 13.0\ \text{MeV}) + (2\gamma + 11.0\ \text{MeV}) \\
&\qquad\qquad + (2e^+ + 2\nu + 0.8\ \text{MeV}) + 2e^- \\
&\quad \rightarrow (^4\text{He} + 2p + \gamma + 13.0\ \text{MeV}) + (2\gamma + 11.0\ \text{MeV}) \\
&\qquad\qquad + (2\nu + 0.8\ \text{MeV}) + (4\gamma + 2.0\ \text{MeV}) \\
&\quad = {}^4\text{He} + 2p + 7\gamma + 2\nu + 26.8\ \text{MeV}.
\end{aligned}$$

What Do You Think? We have produced a ^{4}He nucleus at the end. What happens to the remaining particles of the proton cycle?

EXAMPLE 44–12 The total power output of the Sun, its *luminosity*, is about 3.9×10^{26} W. Assume that the Sun is made entirely of protons, that its luminosity remains constant, and that it "burns" protons via the proton cycle until all the protons have been converted into α particles. How long can the Sun burn in this way? You may use the results of Example 44–11.

Strategy From the results of Example 44–11, four protons are required to produce one α particle, so the energy released *per proton* is 26.8 MeV/4 = 6.7 MeV. We can use this to determine how many protons/second are used to produce the Sun's power output. We can calculate the total number of protons from the total mass of the Sun, and comparison between the total number of protons present and the number used per second for the helium cycle allows us to determine how long the Sun will burn this way.

Working It Out The number of protons in the Sun is $N_p = (\text{mass of Sun})/m_p = (2.0 \times 10^{30}\ \text{kg})/(1.67 \times 10^{-27}\ \text{kg/proton}) = 1.2 \times 10^{57}$ protons. The number of protons converted per second N from the Sun's total power is

$$N = \frac{\text{Sun's power}}{\text{energy/proton}} = \frac{3.9 \times 10^{26}\ \text{J/s}}{(6.7\ \text{MeV/proton})(1.602 \times 10^{-13}\ \text{J/MeV})} = 3.6 \times 10^{38}\ \text{protons/s}.$$

The time T it would take for all of the Sun's protons to be burned is then

$$T = \frac{\text{Number of protons}}{\text{Rate protons react}} = \frac{1.2 \times 10^{57}\ \text{protons}}{3.6 \times 10^{38}\ \text{protons/s}} = 3.3 \times 10^{18}\ \text{s}.$$

This amounts to about 10^{11} yr, or 100 billion yr. The actual burning time for the Sun is more like 10 billion yr (half of which has passed) because only the innermost 10 percent of the Sun's mass is hot enough to burn through the proton cycle.

What Do You Think? Before physicists became aware of nuclear energy generation, they made some predictions of how long the Sun would burn. Make an estimate of the Sun's lifetime assuming that the reactions were chemical rather than nuclear. [*Hint*: Compare typical energies released in chemical and nuclear reactions.]

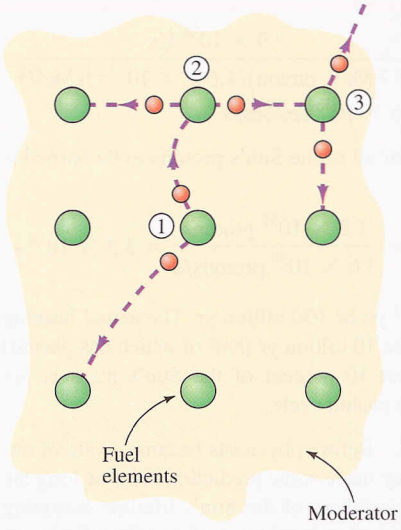
44–6 Applications of Nuclear Physics

Radiometric Dating

The radioactive nucleus ^{14}C can be used to date biological materials. The lifetime involved is 8268 yr, and that is the rough order of magnitude of ages that can be measured with this method. Other radioactive decays, with longer lifetimes, can be used to date longer geologic times, in the range 10^6 yr to 10^{10} yr (Fig. 44–18). For example, rocks form when liquid magma solidifies; after that point, chemically induced separation of elements is more difficult. As long as there is no lead in a sample of rock when that rock forms, any ^{206}Pb found in the rock must be the product of ^{238}U decays (for which τ = 4.5 billion yr). Therefore the ratio of ^{238}U to ^{206}Pb in the rock allows us to find the rock's age. Dating techniques of this type typically use radioactive processes whose lifetimes are comparable to the time scale being probed.

▲ **FIGURE 44–18** The Drakensberg Mountains in South Africa were formed out of hardened lava outflows and are believed to be 190 milion years old based on radioactivity determinations.

Radioisotopes



Radioisotopes, unstable isotopes produced in nuclear reactions, have characteristic lifetimes for decay. Atoms with these nuclides behave chemically like stable isotopes of the same atom. Observation of the location of the decay of a radioisotope helps us to understand where a chemical or physical process has taken the radioisotope. The applications of radioisotopes include the use of ^{153}Gd, ^{67}Ga, ^{201}Pb, and ^{123}I in medical diagnosis—a cancerous tumor, for example, may concentrate one of these elements, and the observed location of α decays indicates the tumor site. Moreover, a nuclide can be placed in a tumor; upon decaying, it deposits large amounts of energy that kills cells there. There are also applications in structural engineering. For example, ^{85}Kr is used in leak detection—krypton can penetrate very small cracks, and observation of decays in certain locations indicate that there are cracks there.

Nuclear Power Generation

Here, we discuss two ways in which nuclei can be used for electric power generation. The first uses the fission process, and it is a proven, well-established technology. The second uses the fusion process, and it is not yet commercially feasible. In both cases, the energy released in the respective nuclear reactions is converted through collisions to thermal energy, which is then used to turn turbines and generate electric power.

Controlled Fission: It is possible to generate energy from fission because the proportion of mass in neutrons is larger for heavy nuclei, such as those of uranium, than for light nuclei. (In Example 44–6, we treated the decay of ^{238}U into two ^{119}Pd nuclei, but in fact the heaviest *stable* isotope of palladium has $A = 110$.) This fact, a consequence of the Coulomb repulsion of protons, implies that when a parent nucleus undergoes induced fission into two fragments, the daughter nuclei have relatively too many neutrons to be stable. They may undergo β decay, or more typically, a few neutrons may be produced along with the two daughter fragments in fission (see Fig. 44–17e).

The induced fission process tends to occur more readily when the bombarding neutrons are slow. Although the neutrons that are *produced* in the fission process generally have too much kinetic energy to induce efficiently the fission of other uranium nuclei, their kinetic energy can be reduced by allowing them to collide within a *moderator*, a material whose atoms have light nuclei: The recoiling neutrons lose a substantial fraction of their kinetic energy in such collisions. Once this has happened, these neutrons can induce other fission processes. Of course, some neutrons do not do so, but in each fission reaction as many as 2 to 3 neutrons are produced, on average. If enough fissionable nuclei (^{233}U or ^{235}U, for example) are present, so that at least one released neutron induces another fission, the process can be sustained. We thereby have a *chain reaction* (Fig. 44–19), which takes place within a *reactor*.

▲ **FIGURE 44–19** A chain reaction, in which the free neutrons produced in a fission process induce the fission of still other nuclei, indicated in the sequence ①, ②, ③. The moderator slows down the released neutrons and increases the likelihood that they will produce another fission.

By increasing or decreasing the relative amounts of either fissionable nuclei or moderating material in the form of "control rods," the reaction process can be either speeded up or slowed down and thus satisfactorily controlled. The problem of disposing of the waste products has proven to be more difficult to resolve. These waste products, which include the fission fragments themselves, are typically radioactive and have lifetimes that are long compared to a human lifespan. Because radioactivity can cause genetic damage and cancer, we must dispose of such waste material in such a way that it is isolated from humans and other living things for many generations.

Controlled Nuclear Fusion: Controlling the processes that power the Sun for direct power generation on Earth is an old idea. Deuterium, a hydrogen atom with a ^{2}H nucleus, which is abundant in seawater, could supply fuel for the fusion reaction, and the radioactive waste problem for nuclear fusion appears to be less acute than that for fission. But the technology of controlling fusion reactions has proved to be a difficult one to master. The essence of the problem is not simply to make nuclei collide with enough energy to overcome the Coulomb repulsion barrier and fuse, but to make such collisions occur in large numbers. A collection of nuclei could in principle be brought to energies

high enough to fuse by heating them, but the temperatures required to do so correspond to energies on the nuclear scale rather than the atomic scale. We can estimate this energy to be $E \cong e^2/4\pi\varepsilon_0 R$, the Coulomb energy between two singly charged nuclei separated by a nuclear radius R, where R is on the order of 10^{-14} m. Upon substituting, we find that $E \cong 150$ keV. This energy corresponds to a temperature of about 10^9K, far higher than any ordinary container could withstand. Indeed, at such temperatures, atoms lose their electrons, and matter breaks down to a fully ionized gas of electrons and nuclei, a *plasma*. Although in the Maxwell distribution there are enough particles with high speeds so that a temperature of some 10^8K is still sufficient to produce reactions, this temperature is still much too high for conventional treatment.

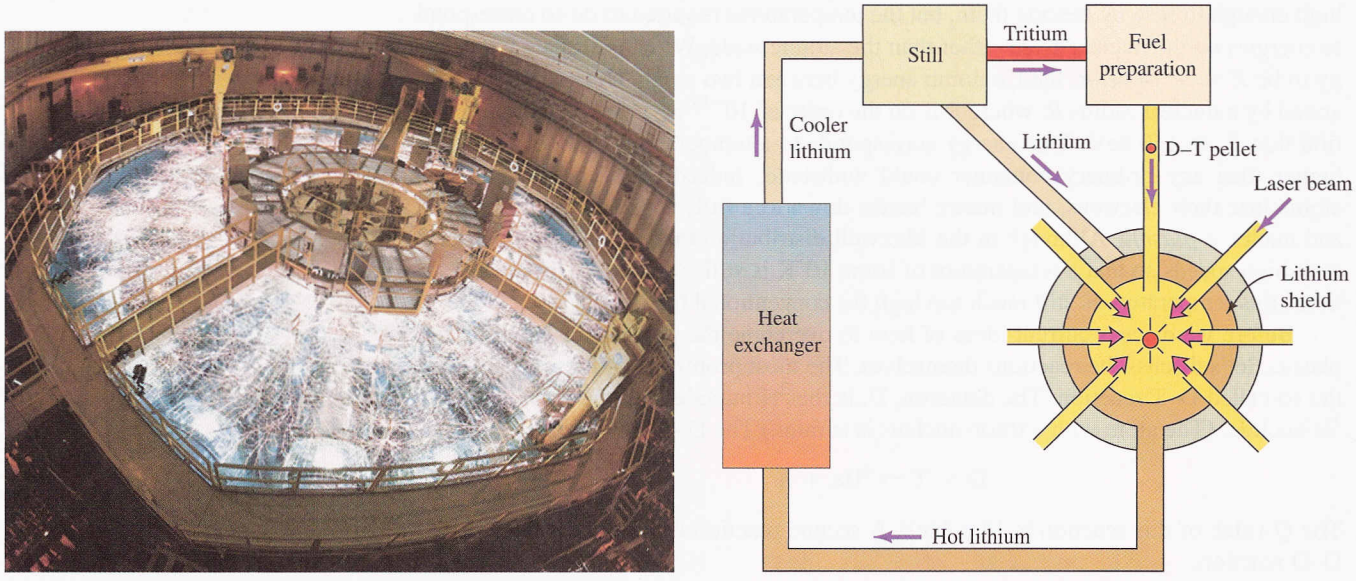
Before we discuss current ideas of how to overcome the problem of handling hot plasma, let's discuss the reactions themselves. The most promising of these reactions is the so-called D–T reaction. The deuteron, D, is the ^{2}H nuclide, and the triton, T, is the ^{3}H nuclide. (The atom with a triton nucleus is tritium.) The D–T fusion reaction is

$$\mathrm{D} + \mathrm{T} \rightarrow {}^4\mathrm{He} + n.$$

The Q value of this reaction is 17.6 MeV. A second reaction of possible interest is the D–D reaction,

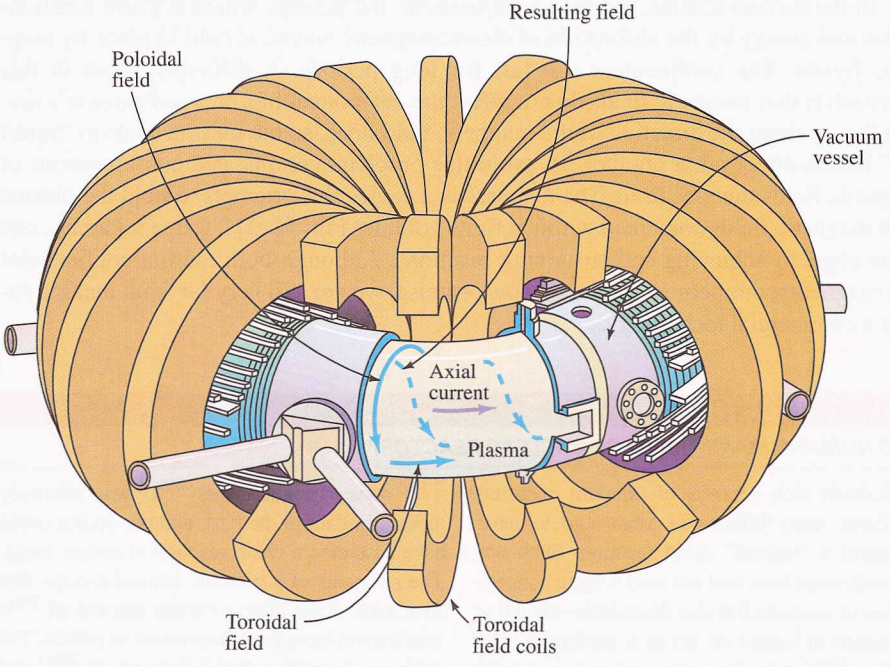
$$\mathrm{D} + \mathrm{D} \rightarrow {}^3\mathrm{He} + n,$$

in which a total of 4 MeV of kinetic energy is produced. If the D–D reaction could be mastered, in particular, a virtually unlimited supply of energy would be available, because deuterium occurs so abundantly in water.



Two rather different approaches have been taken to address the problem of confinement of the hot plasma. The first is *inertial confinement*, a scheme in which tiny pellets of material that contain nuclei suitable for fusion are compressed by powerful laser beams or ion beams until the necessary temperatures and densities are reached (Fig. 44–20). In this scheme, there is no effort to hold the plasma confined for long periods; the beams are fired in pulses, and the pellets are replaced with each pulse. The principal difficulties of this approach are associated with understanding just how the pellets will behave when the energy-supplying beams strike them, with the construction and handling of the pellets, and with the guidance of the beams.

In the second scheme, *magnetic confinement*, the plasma, which is given additional thermal energy by the absorption of electromagnetic waves, is held in place by magnetic forces. The confinement can last for long periods. A difficulty faced in this approach is that magnetic fields do not affect the component of a charged particle's motion that is along the direction of the magnetic field lines, so the plasma tends to "squirt out" in one direction or another. To avoid this problem, complicated configurations of magnetic fields must be used. The *tokamak* is a device that attempts to hold the plasma with magnetic fields contained within a finite volume (Fig. 44–21). Large tokamaks can come close to achieving self-sustaining reactions. Although both inertial confinement and magnetic confinement schemes show promise, we are still very far from making fusion a commercial technology.



THINK ABOUT THIS. . .

DID HUMANS MAKE THE FIRST NUCLEAR REACTOR?

Sufficiently rich deposits of uranium occurred on Earth many billions of years ago to have sustained a "natural" chain reaction. Such ore deposits must have had not only a large concentration of uranium but also deuterium—which is contained in water—to act as a moderator. The ^{235}U-to-^{238}U ratio that exists today is not large enough for a natural reactor to operate. But because ^{235}U decays with a shorter lifetime than ^{238}U does, we know that ^{235}U was relatively more abundant in the past, and ore bodies could have sustained a chain reaction at earlier times. The remnants of a possible *natural reactor* that shut itself down after a certain amount of ^{235}U was burned have been discovered in Africa. The evidence includes a depleted supply of ^{235}U and a characteristic distribution of daughter nuclei descended from fission products.

▲ **FIGURE 44–20** (a) The Particle-Beam Fusion Accelerator II at Sandia National Laboratories in Albuquerque, New Mexico, used for inertial-confinement experiments. (b) Schematic diagram of fusion by inertial confinement with laser beams or particle beams. D–T pellets are sent to a site where momentum from many laser or particle beams implodes them, bringing them to high enough temperatures and densities for significant amounts of fusion to occur. The neutrons from the fusion process produce tritium in the lithium shield, which also becomes hot. The tritium can be distilled out of the hot lithium and used to produce more fuel pellets. Deuterons are abundant in water. Electricity could be made from the thermal energy removed at the heat exchanger.

▲ **FIGURE 44–21** Schematic diagram of fusion by magnetic confinement, containment in the magnetic fields of a tokamak. The so-called poloidal field forms circles around the toroidal field. [After W. M. Stacey, Jr., "Fusion Reactor Development: A Review," *Advanced Nuclear Science and Technology*, **15**: 131 (1983).]

Summary

The nucleus was discovered by means of scattering experiments that showed significant numbers of incident α particles scattered through large angles, which follows if the atom has a small, massive, positive core structure. The nucleus, held together by the nuclear force, is composed of Z protons and $N = A - Z$ neutrons, where A is the mass number. Nuclei with the same Z value but different N values are isotopes of a given atomic species. The masses of nuclei and of atoms are conveniently measured in atomic mass units, u, defined so that the mass of a ^{12}C atom is exactly 12 u. The binding energy, the energy released when a nucleus is formed from its A constituents (nucleons), is significant; a binding energy per nucleon of 7 to 9 MeV is typical of larger nuclei. This binding energy is so large that due to the relativistic equivalence of mass and energy the mass of a nucleus is on the order of 1 percent less than the sum of its constituent masses. To a good approximation, the constituents of the nucleus are closely packed into a sphere of radius

$$R_A = r_0 A^{1/3}, \tag{44–7}$$

with $r_0 \cong 1.2$ fm. The lifetimes of unstable nuclei, the spectrum of states, spins, and magnetic dipole moments all provide useful ways to understand nuclear behavior.

For distances greater than about 1 fm, the nuclear force between nucleons is well described in terms of the Yukawa potential,

$$U(r) = -g^2 \frac{e^{-r/R}}{r}, \tag{44–9}$$

where g^2 measures the strength of the force and R is the range, approximately 2 fm. A useful set of models has been developed to explain nuclear behavior. The shell model is an approach in which individual nucleons move in a central nuclear potential. The resulting spectrum, including the presence of magic numbers—Z and N values for which a nucleus is particularly strongly bound—can be explained by this model. The liquid-drop model treats the nucleus as a continuous medium and is able to explain behavior such as fission, the splitting of large nuclei. The semiempirical mass formula, which is inspired by the liquid-drop model, successfully fits the masses of nuclei.

The strong binding of nuclei has important implications for whether nuclear reactions, including scattering and decay, can occur. Short-lived resonances, excited states of nuclei, are visible in cross sections for scattering, and their widths are inversely proportional to their lifetimes, according to the Heisenberg uncertainty principle.

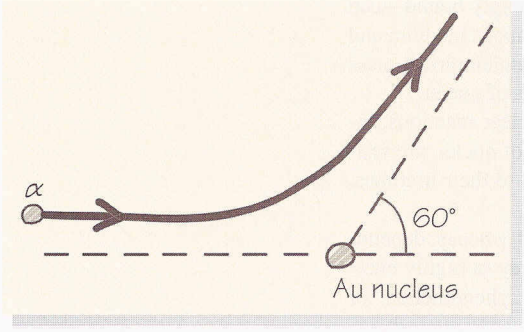
Nuclei can decay through three principal processes: β decay, α decay, and γ decay, depending on whether the decaying nucleus emits an electron, an α particle, or a γ-ray (a highly energetic photon), respectively. Collectively, these processes comprise the phenomenon of radioactivity. The rate of a single decay process is described by the equation

$$N(t) = N_0 e^{-\lambda t}. \tag{44–21}$$

Tunneling is an essential feature of α decay. Natural radioactivity is associated with decay chains, processes in which the products of radioactive decay are themselves radioactive and decay. The presence of such processes supplies us with useful radiometric dating techniques. Certain artificially produced radioactive nuclides have a variety of uses, including radioactive and medical applications.

The systematics of nuclear masses shows that fission, the breakup of large nuclei into smaller ones, and fusion, the combining of small nuclei into larger ones, are energetically favorable. When these processes occur, energy is released. However, both can occur only if a potential energy barrier is overcome. Fusion processes are the means by which the stars obtain energy. Fission induced by neutrons can occur in controlled chain reactions, in which a fissioning nucleus releases neutrons that can initiate other fission reactions. Such chain reactions are a commercially important source of energy.

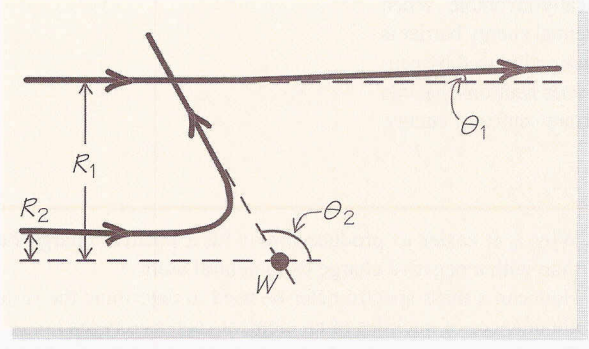
Understanding the Concepts



1. Alpha particles have a charge of $+2e$ and a mass of roughly four nucleon masses. Describe experiments that would allow you to measure these quantities.
2. Neutron stars are stars that have collapsed under the influence of the gravitational force into what are essentially enormous nuclei composed mostly of neutrons. Why do these neutrons not decay?
3. In our discussion of why some nuclei undergo fission, we did not mention the effect of the energy term proportional to A in the liquid-drop model. Why not?
4. Protons and electrons each have intrinsic spins $\hbar/2$. Use the fact that the spin of ^{6}Li is $\hbar$ to show that the ^{6}Li nucleus cannot consist exclusively of protons and electrons.
5. Why is it easier to produce ions with a positive charge rather than with a negative charge from neutral atoms?
6. How can a mass spectrometer be used to determine the isotopic abundances of nuclides of an element such as oxygen?
7. Experiments to measure the inner structures of the nucleus typically use electrons as incident projectiles. Why might electrons be more useful than α particles for such experiments?
8. Of the calcium isotopes ^{39}Ca, ^{40}Ca, ^{41}Ca, and ^{42}Ca, which would you expect to have the smallest neutron separation energy, and why?
9. Of the nuclides ^{15}N, ^{16}O, and ^{17}F, which would you expect to have the largest proton separation energy, and why?

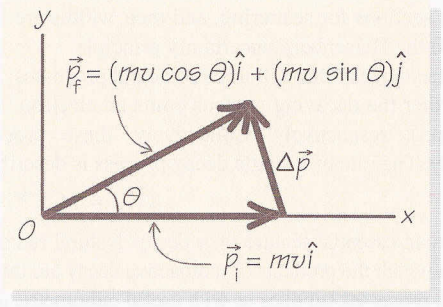
10. The mass conditions for β decay and electron capture are the same. Under what conditions is each one more likely to occur for a given nuclide?
11. Certain chemical elements tend to concentrate in bone marrow. Why should you avoid any such elements that are radioactive?
12. Why are light nuclei more efficient moderators for controlled nuclear fission than are heavy nuclei?
13. Neutrons that have been slowed down by a moderator are unable to induce rapid fission in ^{238}U nuclei. Why?
14. When we gave the (final) kinetic energies of the ^{4}He and neutron products in the D–T fusion reaction, we assumed that the collision takes place at rest. Yet we know there is a Coulomb energy potential barrier to overcome. Why was it possible for us to ignore the initial kinetic energy?
15. Most of the daughter nuclei that result from fission are radioactive. Why?
16. Why might you expect a neutron to penetrate farther into a sample of matter than would an α particle of the same kinetic energy?

Problems



44–1 Static Properties of Nuclei

1. (I) How many neutrons and how many protons do the following nuclides have: ^{9}Be, ^{13}C, ^{22}Na, ^{31}P, ^{57}Fe, ^{72}Ge, ^{107}Ag, ^{131}Cs, ^{208}Pb, ^{241}Am?
2. (I) What is the total binding energy of ^{6}Li? Its binding energy per nucleon?
3. (I) What is the Rutherford collision cross section of a 8.0-MeV α particle ($Z = 2$) on a gold nucleus ($Z = 79$) at a scattering angle of 60° (Fig. 44–22)? Express your answer in units of *barns* (1 barn $\equiv 10^{-24}$ cm^2).



▲ **FIGURE 44–22** Problem 3.

4. (I) Consider the deflection of an α particle of kinetic energy 8 MeV by a tungsten atom, for which $Z = 74$. Estimate the typical angular deflection (a) for $R_1 = 0.01$ nm; (b) for $R_2 = 10$ fm (Fig. 44–23).

▲ **FIGURE 44–23** Problem 4.

5. (II) An α particle with (nonrelativistic) speed v is approaching the center of a nucleus of radius R and charge $+Ze$. Calculate the distance of closest approach. Assume that the nucleus is much heavier than the α particle. For what value of v will the distance of closest approach equal R?
6. (II) Calculate the distance of closest approach that a 5.5-MeV α particle makes when it scatters head-on with tungsten nucleus (see Fig. 44–2). Neglect recoil of the tungsten nucleus. Compare this with the sum of the nuclear radii for helium and tungsten.
7. (II) A proton with 6.0 MeV of energy scatters at a 60° angle from a gold atom. (a) How close did the proton come to the center of the nucleus? (b) To the surface of the gold nucleus? (Assume that the proton is pointlike.)
8. (II) The masses of the stable isotopes of calcium are 41.95863 u for ^{42}Ca, 42.95878 u for ^{43}Ca, and 43.95549 u for ^{44}Ca. Calculate the binding energies of each nuclide.
9. (II) Express the Rutherford collision cross section in terms of the momentum transfer, $\Delta\vec{p}$, of a scattered particle, which has an initial momentum $mv\hat{i}$ and a final momentum $(mv\cos\theta)\hat{i} + (mv\sin\theta)\hat{j}$ (Fig. 44–24).

▲ **FIGURE 44–24** Problem 9.

10. (II) If we want to use an electron to probe distances to the size of a uranium nucleus, what energy should the electron have? What if we want to probe distances to the size of a nucleon, about 1 fm?
11. (II) Use the work–energy theorem to solve Example 44–2. Integrate the work over the distance from infinity to the turnaround distance R, the point at which the Coulomb force has done work equal to the initial kinetic energy of the α particle.
12. (III) *Mirror nuclei* are pairs of nuclei for which Z and N of each nucleus are opposites: For example, $^{23}_{11}$Na and $^{23}_{12}$Mg are mirror nuclei with $Z = 11$, $N = 12$ and $Z = 12$, $N = 11$, respectively. The idea that the *only* difference in the energies of these nuclei is due to a difference in electrostatic energy gives us another way to measure nuclear radii and in particular the constant r_0 in Eq. (44–7). If you solved Problem 24–91, you showed that when a charge Q is distributed uniformly throughout a spherical volume $(4/3)\pi R^3$, the electrostatic energy is $\frac{3}{5}Q^2/4\pi\varepsilon_0 R$. Use this result to express the *difference* ΔE in the electrostatic energies of the pair of mirror nuclei above, and use that expression to find r_0, as defined by $R = r_0 A^{1/3}$, in terms of ΔE.

13. (III) Evaluate r_0 by comparing the binding energy and electrostatic energy of the following pairs of mirror nuclei (see Problem 44–12): ^{7}Li(7.016005) and ^{7}Be(7.016930); ^{9}B(9.01333) and ^{9}Be(9.012183); ^{11}B(11.009305) and ^{11}C(11.011433); ^{21}Ne(20.99385) and ^{21}Na(20.99765); ^{23}Na(22.9898) and ^{23}Mg(22.9941). The quantity in parenthesis is the mass of the particular nucleus in units of u.

44–2 Nuclear Forces and Nuclear Models

14. (I) (a) The energy of the first excited state of the nucleus ^{70}Ge is 1.04 MeV. Calculate the frequency and wavelength of a photon needed to excite this state from germanium atoms at rest. (b) Do the same for the nuclide ^{181}Ta, whose first excited state has an energy of 0.0062 MeV.

15. (I) According to the shell model, closed shells of protons occur for $Z = 2$, $Z = 8$, $Z = 20$, $Z = 40$, $Z = 70$, and similarly for neutrons. Use the shell model to determine whether the following nuclides have a closed shell (magic number) for either neutrons or protons: ^{15}N, ^{39}K, ^{40}Ca, ^{56}Fe, ^{140}Ce. Does your answer correlate to whether the respective nucleus is tightly bound?

16. (I) Use the semiempirical mass formula to find the ratio of the surface contribution to the Coulomb contribution for the nucleus ^{6}Li.

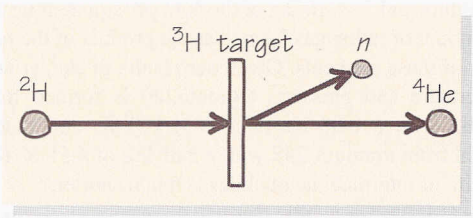
17. (II) Assume that the two protons inside a ^{4}He nucleus are approximately 4 fm apart. (a) Calculate the Coulomb force between them. (b) Use the binding energy of ^{4}He to *estimate* the nuclear force. Compare the two forces.

18. (II) Find the force that corresponds to the Yukawa potential energy, Eq. (44–9). Sketch it as a function of the separation distance; on the same plot, sketch an inverse-square force, assuming that that force corresponds to the same potential energy as Eq. (44–9) for small r.

19. (II) The energy required to assemble Z protons in a uniform distribution throughout the volume of a sphere of radius $r_0A^{1/3}$ is $\frac{3}{5}Z^2e^2/(4\pi\varepsilon_0 r_0 A^{1/3})$. The parameter r_0 is roughly 1.2×10^{-15} m. What fraction of the mass of a carbon nucleus does this energy represent?

20. (II) Use the semiempirical mass formula to determine the neutron, proton, and α-particle separation energies for the nuclide ^{56}Fe.

21. (II) Use the semiempirical mass formula to find the Z value that minimizes the total mass $M(A, Z)$ for fixed A by solving $\partial M/\partial Z = 0$.



22. (III) Use the semiempirical mass formula to determine the relation between A and Z such that spontaneous fission into two identical fragments occurs; that is, for which $M(A, Z) - 2M(A/2, Z/2) > 0$.

44–3 Energetics of Nuclear Reactions

23. (II) The first nuclear reaction ever observed, by Ernest Rutherford, was the reaction $\alpha + {}^{14}\text{N} \rightarrow p + {}^{17}\text{O}$. If 5 MeV α particles are used to bombard ^{14}N at rest, determine the sum of the kinetic energies of the two outgoing particles from the atomic masses in Table 44–2 [$M(^{17}\text{O}) = 16.999131$ u].

24. (II) The α particle Rutherford used to initiate the first observed nuclear reaction (see Problem 23) had to overcome the Coulomb barrier between the protons in ^{4}He and those in ^{14}N. Assume that the α particle must come within 1 fm of a proton in the target nucleus for a nuclear reaction to occur. Calculate the minimum energy the α particle must have to initiate the reaction. Compare your result with the 5.26 MeV energy for the α particle in Rutherford's experiment. Was the reaction likely?

25. (II) One way to produce a beam of energetic neutrons is to bombard ^{3}H with accelerated ^{2}H. The reaction $^{3}\text{H} + {}^{2}\text{H} \rightarrow {}^{4}\text{He} + n$ releases 17.6 MeV. What is the energy of a neutron produced by a 2 MeV ^{2}H beam, assuming that the ^{4}He nucleus moves in the direction of the ^{2}H beam (Fig. 44–25)?

▲ **FIGURE 44–25** Problem 25.

26. (II) Nucleons are not static, but move within nuclei. The approximate energy of a nucleon inside a nucleus is about 20 MeV. Use this kinetic energy and the uncertainty principle to *estimate* the dimensions of a sphere that might contain the nucleon. Is this size approximately equal to that of a nucleus? Interpret your result.

27. (II) The nuclear reaction James Chadwick used in his experiment to identify the neutron was $\alpha + {}^{11}\text{B} \rightarrow n + {}^{14}\text{N}$. Assume that the α particle had energy 5.3 MeV and that the ^{11}B was at rest; $M(^{11}\text{B}) = 11.009305$ u. If the kinetic energy of the ^{14}N is 0.8 MeV, what energy would the neutron have?

28. (II) Is the nuclear reaction ${}^{16}_{8}\text{O} + {}^{24}_{20}\text{Mg} \rightarrow {}^{40}_{20}\text{Ca}$ possible if the nuclei in the initial state are at rest? If so, how much energy is released? If not, how much extra energy is needed in the form of kinetic energy?

29. (II) The most frequently used laboratory neutron source works as follows: A source of ^{226}Ra emits 4.78 MeV α particles that are used to bombard beryllium. Neutrons are produced in the reaction ${}^{9}_{4}\text{Be} + {}^{4}_{2}\text{He} \rightarrow {}^{12}_{6}\text{C} + n$. The atomic mass of ${}^{9}_{4}$Be is 9.012183 u. Find the other masses from Table 44–1 and use these to estimate the maximum kinetic energy of the neutrons.

30. (II) Which of the following reactions are not possible, and why not: (a) $\alpha + {}^{57}\text{Fe} \rightarrow n + {}^{60}\text{Ni}$; (b) $p + {}^{58}\text{Ni} \rightarrow {}^{3}\text{He} + {}^{57}\text{Co}$; (c) $n + {}^{157}\text{Gd} \rightarrow d + {}^{156}\text{Eu}$; (d) ${}^{241}\text{Am} \rightarrow \alpha + {}^{237}\text{Pu}$?

31. (III) A foil made of 20 mg of ^{58}Co (metallic cobalt) is exposed for 1 h to a beam of neutrons with a flux of 5×10^{13} neutrons/cm^2 s. If the *capture cross section* (the reaction ${}^{58}\text{Co} + n \rightarrow {}^{59}\text{Co}$) for such neutrons is 1700 barns (see Problem 3), how many ^{59}Co nuclei are formed? [*Hint*: Find the effective area taken up by the target cobalt atoms.]

44–4 Radioactivity

32. (I) Show that the primary β-decay process, Eq. (44–25), is possible only when the atomic mass of the parent nucleus is greater than the atomic mass of the daughter nucleus.

33. (II) Show that positron emission, Eq. (44–28), is possible only when $M_P > M_D + 2m_e$, where M_P is the atomic mass of the parent nucleus and M_D is the atomic mass of the daughter nucleus.

34. (I) Show that electron capture is possible only when the atomic mass of the parent nucleus is greater than the atomic mass of the daughter nucleus.

35. (I) The number of unstable nuclei $N(t)$ present at time t diminishes with time according to the differential equation

$$\frac{dN(t)}{dt} = -\frac{1}{\tau}N(t),$$

where τ is the lifetime. Show by direct substitution that the solution to this equation is indeed $N(t) = N_0 e^{-t/\tau}$.

36. (I) What is the activity of a 0.03-kg sample of ^{235}U? The half-life of ^{235}U is 7.04×10^8 yr.

37. (II) The upper 0.3 m of soil contains on the average about 10^3 kg of uranium and 3×10^3 kg of thorium per square mile. Calculate the amount of radon gas formed as the product of the radioactive decay of these elements. Give your results in cm^3/yr at standard temperature and pressure. (Radon-220 is formed from thorium-232 with a half-life of 1.39×10^{10} yr, and radon-222 is formed from uranium-238 with a half-life of 4.51×10^9 yr. The half-life of intermediate nuclides is much shorter.)

38. (II) The theory of α decay as a tunneling process allows us to predict an experimental relation between the half-life $t_{1/2}$ and the kinetic energy K of α particles emitted during radioactivity. An approximate version of this prediction is

$$\ln t_{1/2} = \frac{Z(3.97\ \text{MeV}^{1/2})}{\sqrt{K}} - 123,$$

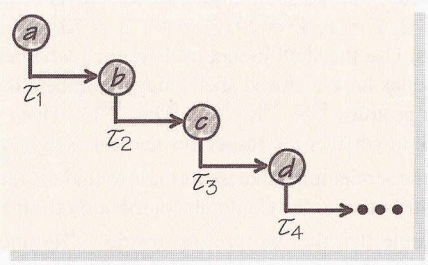
where K is in MeV. (a) Fill in the missing values in the following table:

Nucleus	K (MeV)	$t_{1/2}$
^{215}Ra	?	1.6 ms
^{223}Th	7.7	?
^{244}Pu	?	8×10^7 yr
^{248}Cm	5.16	?

(b) In order to perform an experiment, we need a source of α particles with a half-life of at least 5 days. What is the highest-energy source we are likely to find?

39. (II) By looking up the masses of the neutron, proton, and electron in Appendix II, find the maximum energy, in MeV, of an electron produced in the decay of a neutron.

40. (II) In a sample of $^{211}_{86}$Rn nuclei, 26 percent decay by α decay to $^{207}_{84}$Po and the rest decay by electron capture to $^{211}_{85}$At. What is the ratio of the lifetime for α decay, τ_α, to the lifetime for electron capture, τ_β?



41. (II) The half-life of ^{14}C is 5730 yr, and the tissues of organisms accumulate this isotope from the atmosphere while the organisms are living. The skeleton of a mammoth is found to have 15 percent as much ^{14}C as the atmosphere has. When did the mammoth live? Assume that the concentration of atmospheric ^{14}C does not change.

42. (II) The age of marine sediments can be determined by their thorium-230 content. ^{230}Th is the decay product of ^{234}U and it decays to ^{226}Ra with a half-life of 75,200 yr. Measurements indicate that the ^{230}Th content of a sediment is 6 times larger at the surface than at a depth of 40 m. What is the deposition rate at that location in mm/g?

43. (II) ^{80}Br is one of a small number of nuclides that is able to decay by all three β-decay processes. Show that this is possible. $M(^{80}\text{Br}) = 79.918528$ u, $M(^{80}\text{Kr}) = 79.916376$ u, $M(^{80}\text{Se}) = 79.916521$ u.

44. (II) Suppose that the lifetime for γ decay of a nucleus at rest is so long that, for all practical purposes, the natural width of the spectral line can be ignored (that is, the γ energy takes on a single, fixed value). When the nucleus is part of a collection of atoms at finite temperature, it moves randomly, sometimes toward and sometimes away from a γ-ray detector, and the spectral line width is determined by the Doppler shift of the emitted γ-rays. This phenomenon is known as *Doppler broadening*. Estimate the width due to Doppler broadening for these atoms at a temperature $T = 600$K.

45. (III) A radioactive nucleus a decays with a lifetime τ_1 into nucleus b, which decays with a lifetime τ_2 into nucleus c. The change in the number of nuclei a obeys the relation $dN_a = -(N_a/\tau_1)\,dt$ (see Problem 40–65). The number of nuclei b does not obey a simple equation of this type, because those nuclei are continuously being depleted through decays into nuclei c while they are replenished through decays of nuclei a. Show that the correct expression for the change in the number of nuclei b is $dN_b = -(N_b/\tau_2)\,dt + dN_a$. How will this expression generalize to a chain of decays $a \rightarrow b \rightarrow c \rightarrow d \ldots$ with lifetimes τ_1, τ_2, τ_3, $\tau_4, \ldots$, respectively (Fig. 44–26)?

▲ FIGURE 44–26 Problem 45.

46. (III) We have a chain of decays in a three-level system of nuclei a, b, c with $M_a > M_b > M_c$. Level a decays both to level b (with lifetime τ_{ab}) and level c (with lifetime τ_{ac}), while level b decays to level c (with lifetime τ_{bc}). Thus the number of nuclei at level a at time t obeys the differential equation

$$\frac{dN_a(t)}{dt} = -\frac{1}{\tau_{ab}}N_a(t) - \frac{1}{\tau_{ac}}N_a(t) \equiv -\frac{1}{\tau_a}N_a(t).$$

(a) Show that the solution to this equation is $N_a(t) = N_0 e^{-t/\tau a}$.
(b) Show that the number of nuclei of level b at time t obeys the differential equation

$$\frac{dN_b(t)}{dt} = \frac{1}{\tau_{ab}}N_a(t) - \frac{1}{\tau_{bc}}N_b(t).$$

(c) Show by substitution that the number of level b nuclei is

$$N_b(t) = N_{0a}\frac{\tau_a\tau_{bc}/\tau_{ab}}{\tau_{bc} - \tau_a}(e^{-t/\tau_{bc}} - e^{-t/\tau_a}).$$

(d) Show that there is no need to write an equation for N_c once N_a and N_b are known as functions of time, because $N_c(t) = N_{0a} - N_a(t) - N_b(t)$ if we start with only a collection of N_{0a} nuclei at time $t = 0$.

47. (III) Show that when the rate of decay from nucleus a in Problem 46 is much smaller than the rate of decay from nucleus b to nucleus c, then after a time that is long compared to τ_{bc}, $N_b(t) \cong (\tau_{bc}/\tau_{ab})\,N_a(t)$. (You may use the results derived in Problem 46.)

44–5 Fission and Fusion

48. (I) The energy of nuclear weapons is expressed in terms of megatons of TNT, where 1 megaton of TNT $= 4.3 \times 10^{15}$ J. What minimum mass of ^{235}U is required to produce a nuclear weapon of 200 kilotons? [*Hint*: Each fission of ^{235}U produces about 200 MeV of energy.]

49. (II) The temperature of the interior of stars is about 10^7 K. (a) Estimate the typical kinetic energy of the colliding protons that participate in the proton cycle. (b) Compare your answer to part

(a) with an estimate of the kinetic energy that protons initially distant from one another must have to come within 1 fm of each other, a distance at which the strong forces can lead to fusion.

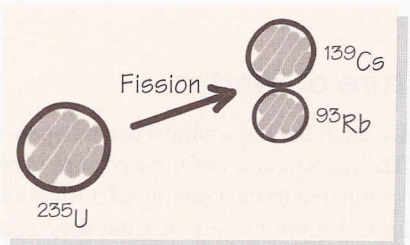
50. (II) Calculate the difference between the Coulomb energy for a parent nucleus (Z, A) and the sum of the Coulomb energies of two daughter nuclei (fZ, fA) and $[(1-f)Z, (1-f)A]$, respectively, where f is some fraction between 0 and 1. Show that this energy difference is maximized when $f = \frac{1}{2}$; that is, from the Coulomb energy terms alone it is energetically favorable for fission to produce two equal-sized fragments.

44–6 Applications of Nuclear Physics

51. (II) A 440-MW (electrical output) nuclear power plant uses ^{235}U as its fuel. The uranium fuel contains 6 percent ^{235}U, and each fission reaction produces 200 MeV of energy. Assume that the power plant is 25 percent efficient in producing electric energy. (a) Calculate the amount of uranium fuel used in 1 yr. (b) Determine the amount of thermal energy released to the environment in that time. (c) How many fission events occur per second?

52. (II) One of the reactions in the proton cycle is Eq. (44–32b), $^2\text{H} + p \rightarrow {}^3\text{He} + \gamma$. Calculate the energy released in this reaction. Use the data given in Table 44–1, but take into account that atoms inside burning stars are completely stripped of their electrons.

General Problems



53. (I) The *carbon cycle*, a stellar burning process secondary to the proton cycle, consists of the following sequential series of nuclear reactions and decays:

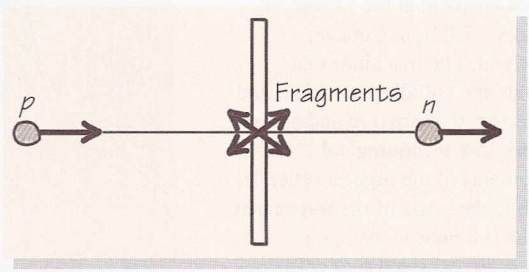
$^{12}\text{C} + p \rightarrow {}^{13}\text{N} + \gamma$, with 1.9 MeV of energy released;
$^{13}\text{N} \rightarrow {}^{13}\text{C} + e^+ + \nu$, with 1.2 MeV of energy released;
$^{13}\text{C} + p \rightarrow {}^{14}\text{N} + \gamma$, with 7.6 MeV of energy released;
$^{14}\text{N} + p \rightarrow {}^{15}\text{O} + \gamma$, with 7.4 MeV of energy released;
$^{15}\text{O} \rightarrow {}^{15}\text{N} + e^+ + \nu$, with 1.7 MeV of energy released;
$^{15}\text{N} + p \rightarrow {}^{12}\text{C} + {}^4\text{He}$, with 5.0 MeV of energy released.

(a) What is the net effect of one cycle, and how much energy is produced per cycle? (b) Consider a star of mass 3×10^{30} kg, consisting mainly of hydrogen, with 0.1 percent of its mass in ^{12}C. The characteristic duration of a carbon cycle in the star is 5×10^6 yr. Estimate the energy produced each year by the carbon cycle, assuming that each carbon nucleus in the star acts as a catalyst for the cycle.

54. (II) (a) Use the semiempirical mass formula to determine an expression for the binding energy of a nucleus. (b) Apply your result to calculate the binding energy of ^{12}C.

55. (II) A fissioning ^{235}U nucleus produces two fission fragments, ^{139}Cs and ^{93}Rb (Fig. 44–27). Assume that the two fragments are spherical in shape and that the charge is uniformly distributed in both of them. What is the Coulomb potential energy of the system if the two fragments are just touching?

▲ FIGURE 44–27 Problem 55.



56. (II) Use the semiempirical mass formula to find the neutron separation energy for the nuclides ^{16}O and ^{17}O. Explain the difference.

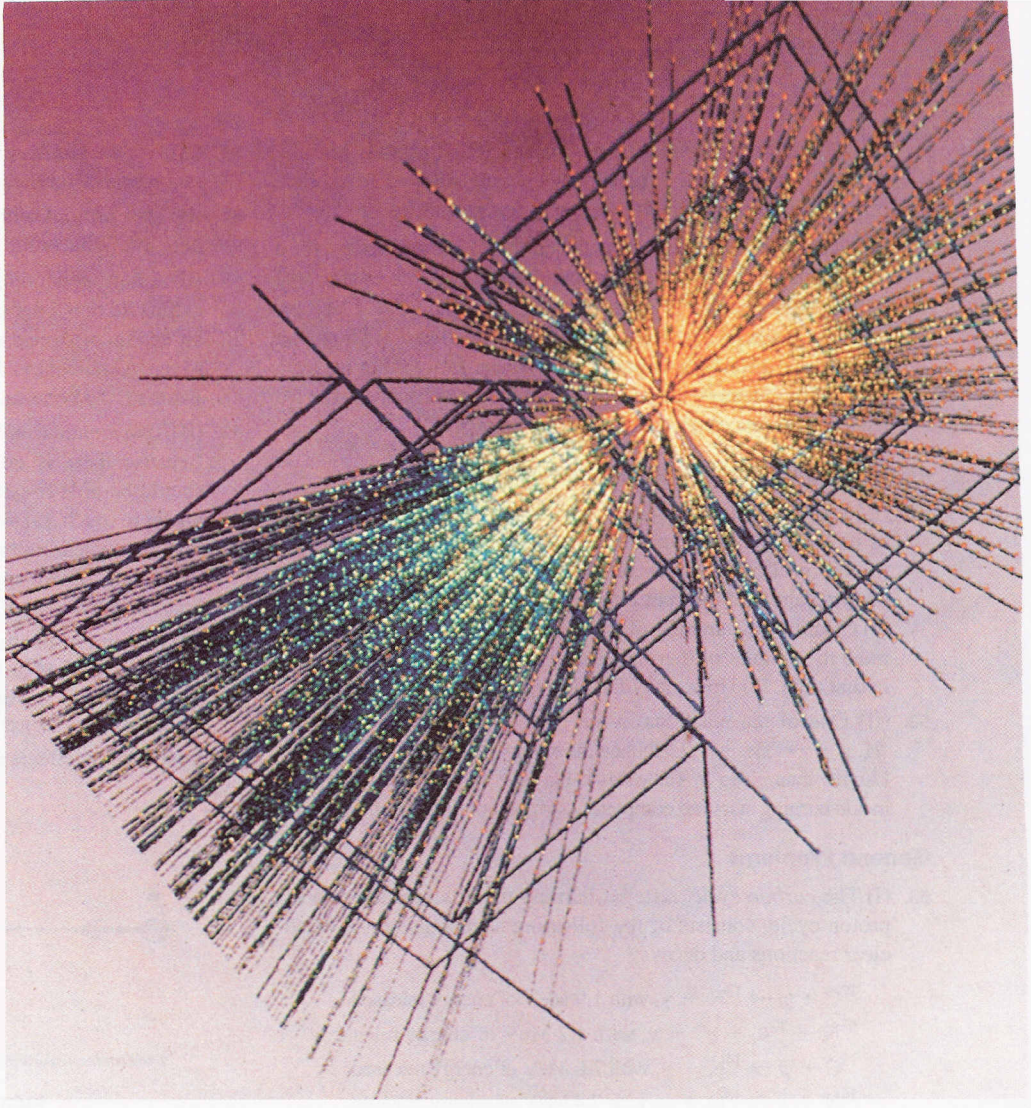
57. (II) Two protons within a star, each with energy 12 keV, collide head-on. What is the distance of their closest approach?

58. (II) A bone containing 20 g of carbon emits β particles from ^{14}C at the rate of 8.5 per second. At the time the ^{14}C is taken from the air and incorporated into bone, the activity of natural carbon due to its ^{14}C content is 15 Bq/mol. The lifetime of ^{14}C is 8268 yr. Estimate the bone's age.

59. (II) Two identical and neutral helium atoms approach each other. Because there is no Coulomb repulsion between them, they should be able to get very close together, close enough for the nuclei to touch. (a) What is wrong with this argument? (b) Given that the nuclear radius of helium is about 2 fm and that the center of mass of two approaching helium atoms is at rest, what energy must the helium atoms have for the nuclei to touch?

60. (II) A beam of neutrons of kinetic energy 3.7 GeV is produced through the bombardment of nuclei by protons. What distance does this beam travel before 5 percent of the neutrons have decayed (Fig. 44–28)? [*Hint*: The neutrons are relativistic, and time-dilation effects are important.]

▲ FIGURE 44–28 Problem 60.



61. (II) One of the early suggestions about the composition of the nucleus was that it contains A protons and A–Z electrons. Use the uncertainty principle to estimate that if an electron is confined to a sphere with a radius of about 10^{-14} m, the size of a nucleus, then its momentum must be larger than about 10^2 MeV/c. Given that β rays emitted by the nucleus have energy on the order of 1 MeV, this estimate rules out the possibility that there are electrons in the nucleus.

62. (II) Calculate the overall kinetic energy produced in the carbon cycle (see Problem 53) after the two positrons produced in the cycle have annihilated against electrons.

63. (II) The energy of a collection of noninteracting fermions of mass m with number density n in a volume V is given by $E = V(\hbar^2\pi^3/10m)(3n/\pi)^{5/3}$. Use this expression to calculate the energy of the protons, E_p, in a nucleus in terms of A, Z, and r_0, where r_0 is the nuclear radius scale in Eq. (44–7). Repeat your calculation for the energy of the neutrons, E_n.

64. (III) Starting with the results of Problem 63, sum the proton and neutron energy terms, using the variables A and $\tau \equiv N - Z$. You will want to make the substitutions $Z = (A - \tau)/2$ and $N = (A + \tau)/2$. Approximate your result for $\tau \ll A$ by using $(1 + x)^p \cong 1 + px + \frac{1}{2}p(p-1)x^2$, an approximation good for $x \ll 1$. Show that this result has one term proportional to A and another term proportional to τ^2/A. Compare the coefficients of these two terms with the corresponding terms in the semiempirical mass formula. What does this tell you about the model of a nucleus as a collection of noninteracting protons and neutrons in a box?

Chapter 45

The results of the spectacular collision of two lead nuclei moving at very high energy, seen in the so-called NA49 experiment at the European laboratory CERN, in Geneva, Switzerland. The machines that accelerate the colliding particles, and the detectors that observe and analyze the debris, are technological achievements of the highest order. In order to make sense of the forces that act at the subnuclear scale, it is necessary to make sense of collisions such as these.

Particles and Cosmology

The "inner-outer connection," by which we mean the coming together of the realms of the very small and the very large, is a new, fertile field of study, barely three decades old. To understand how the fundamental structure of matter and the evolution of the universe affect each other requires some background knowledge of the two areas. The story of these fields and of the connections between them involve the interplay of brilliant experiments and great leaps of imagination in the development of the theories that describe them. The progress that has been made has depended on ever improving observational tools: A series of powerful accelerators have provided knowledge of the structure of matter at the smallest scales, and a series of powerful telescopes have been essential to our understanding of the structure of the universe. In this chapter, we outline how these instruments have led to a deep understanding of the realms of particles and cosmology and of how these realms are described in many ways by the same physics.

45–1 Probing the Structure of Matter

A "Russian doll" is a set of nested dolls; each but the smallest can be opened to reveal a smaller version of itself (Fig. 45–1). The investigation of the structure of matter and of the forces that hold it together can be compared to the opening of a Russian doll. As the investigators of any given era have looked more closely at what they regarded as the fundamental constituents and interactions of matter, they have found at smaller scales within that matter other constituents interacting through other forces. The constituents

and interactions at larger scales can be explained in terms of the physics at smaller scales. The first real step in "opening the Russian doll" was made by John Dalton in 1808. He knew that when chemical elements combine chemically, they do so in precise proportions, and he proposed that the simplest explanation for this phenomenon is that a variety of different types of atoms exist, one for each chemical element. The atoms of the chemical elements supply the building blocks for the construction of molecules. The interatomic forces that supply the "glue" for this construction are electrical in origin.

But atoms are not truly indivisible. We saw in Chapter 41 how an atom is constructed from electrons and a nucleus. The structure of the nucleus and of electrons represents the Russian doll within an atom. The atom is held together by electromagnetic forces between the electrons and the nuclei.

We have seen that nuclei have structure. They consist of nucleons—protons and neutrons. The nucleus is held together by the nuclear, or strong, force. This force differs from the electromagnetic force in that it has finite range. And compared with the electron rest energy, the energy required to remove a neutron or proton from a given nucleus with the help of electrons is so large that relativistic effects—those that relate energy to mass—are significant for the first time in our brief overview of the structure of the matter.

Do electrons and nucleons have structure? If so, what forces hold those structures together? As far as we know today, there is no evidence to suppose that electrons are composed of more fundamental constituents. This is not the case for nucleons and other strongly interacting particles, known collectively as **hadrons**. Scattering experiments carried out with particle accelerators have provided us with powerful evidence regarding their structure and the nature of the interactions involved.

▲ **FIGURE 45–1** Each Russian doll hides inside its larger companion. This toy is a useful analog to the structure of the physical world.

Seeing Subatomic Systems

How do we determine the shape and size of an object in everyday life? We look at it, by which we mean that we observe light (photons) bouncing off the object. Our eyes serve as a detector for observing a pattern of reflected light.

What prevents us from seeing atoms in this way? Light diffraction limits our ability to discern details of small objects, as we learned in Chapter 38. Resolution of details in an object of size d requires light of wavelength $\lambda \leq d$. Thus to study atoms in this way, we would need light of short wavelength. Because of the relation $\lambda = h/p$ [Eq. (40–3)], our light consists of photons with large momentum. The fact that matter has wavelike properties extends this limitation ($p > h/d$) to the case in which we scatter massive projectiles—electrons, for example.

In Chapter 8, we discussed the connection between the momentum (or energy) of a projectile and the size of the target that can be studied. Let's review that subject, using our knowledge of diffraction patterns (Chapter 38). The characteristic angular size of the diffraction pattern made by a projectile of wavelength λ scattering from an object of size d is $\sin\theta \cong \lambda/d$. The size of the momentum transfer in a scattering experiment is characteristically $\Delta p \cong p \sin\theta$, as we learned in Chapter 8. Therefore,

$$\Delta p \cong p \sin\theta \cong p\frac{\lambda}{d} = \frac{h}{d}, \tag{45–1}$$

where we have used the de Broglie momentum–wavelength relation, $p = h/\lambda$, in the last step. Thus an increasing momentum is needed to study ever smaller objects. In the laboratory frame (a moving projectile and a fixed target particle), much of the energy of the system is contained in the motion of the center of mass, which, because of momentum conservation, continues unaltered after the collision. This energy is unavailable for probing the target. The correct statement is that *Eq. (45–1) actually applies to the center-of-mass momentum and momentum transfer.*

The diffraction limit expressed in Eq. (45–1) is essentially contained in the Heisenberg uncertainty relations. Recall that the momentum–position uncertainty relation is $\Delta x\, \Delta p > \hbar$, Eq. (40–12), where $\hbar = h/2\pi$. If we interpret d as the position uncertainty Δx, then the connection is evident.

Let's look at some numerical aspects of Eq. (45–1). An atomic radius is approximately 10^{-10} m. The nucleus is roughly 10^5 times smaller, and we can take the size of a

single proton to be characteristically 10^{-15} m. If we want to see the structure within a region of radius 1 percent of the size of the proton, we want $d \cong 10^{-17}$ m. According to Eq. (45–1), this requires us to have a momentum transfer of magnitude $\Delta p \cong 6 \times 10^{-17}\ \text{kg} \cdot \text{m/s}$ in our collider. This corresponds to a particle energy that can only be produced in a large accelerator. The highest-energy accelerator currently operating is that of Fermilab, near Chicago, and it circulates protons of momenta ten times this amount. In the Large Hadron Collider (LHC), now under construction near Geneva, Switzerland, the colliding protons will have thirty times this momentum. From Eq. (45–1), we see that the distance to be probed at the LHC is on the order of $d \cong 10^{-19}$ m.

EXAMPLE 45–1 Alpha (α) particles with kinetic energy of 2 MeV are scattered by atoms of a heavy element. The experiment shows that a fraction of the α particles are scattered through 90° in the laboratory frame. What can one deduce from this about the size of the target responsible for the scattering?

Setting It Up We shall use Eq. (45–1) to estimate the dimensions of the scatterer, with $\sin\theta$ of order 1. We must therefore calculate the momentum of a 2-MeV α particle, which is a particle with mass very close to 4 times a nucleon mass. We need not worry about relativistic effects, since the kinetic energy is very small compared with the rest mass energy of the α particle, and since the target is an atom of a heavy element, we need not worry about the distinction between the center of mass frame and the laboratory frame. In other words, the scattering may be viewed as from an infinitely heavy atom.

Strategy The relation $p = h/(d \sin\theta)$ allows us to estimate the size of the target, $d = h/(p \sin\theta)$. This equation shows that a large target leads to small-angle scattering for a given p, whereas a small target leads to large-angle scattering for the same p. In terms of the (nonrelativistic) kinetic energy $K = p^2/2M$, we obtain

$$d = \frac{h}{\sqrt{2MK}\sin\theta}.$$

The problem statement states that the scattering can take place at 90°, and we find the smallest value of d—the target size—by replacing $\sin\theta$ by unity.

Working It Out With $\sin\theta = 1$, and the α mass equal to four nucleon masses,

$$\begin{aligned} d &= \frac{h}{\sqrt{2MK}\sin\theta} \\ &\cong \frac{6.6 \times 10^{-34}\ \text{J} \cdot \text{s}}{\sqrt{(2 \times 4 \times 1.67 \times 10^{-27}\ \text{kg})(2\ \text{MeV})(1.6 \times 10^{-13}\ \text{J/MeV})}} \\ &\cong 10^{-14}\ \text{m}. \end{aligned}$$

This number is a factor of about 10^4 smaller than an atomic radius. An experiment of this type was carried out by Rutherford at the beginning of the 20th century and led Rutherford to the conclusion that the particle that was responsible for the scattering of the α particle had to be very much smaller than the atom.

What Do You Think? Could the electrons in the atom have been responsible for the large-angle scattering of the α particles?

*Answers to **What Do You Think?** questions are given in the back of the book.*

EXAMPLE 45–2 The proton has a radius of approximately 1.2 fm. You want to use electrons as projectiles to study the structure of protons on a scale of 0.5 to 1.2 fm. Assuming that the maximum observable electron-scattering angle in the center-of-mass system is 30°, what center-of-mass momentum must the incident electrons have? Is it necessary to use relativistic kinematics?

Strategy The uncertainty relation combined with the de Broglie relation can tell us the relation between the projectile momentum p and the distance scale d of the target observable with a scattering experiment:

$$p \cong \frac{h}{d \sin\theta}.$$

To decide whether this involves relativistic kinematics, we can compare the quantity (momentum × speed of light) with the rest energy of the electron. If $pc > m_e c^2$, the motion is indeed relativistic.

Working It Out Given that $p > h/(d \sin\theta)$, the largest value of p is determined by the smallest value of d, namely, $d = 0.5$ fm:

$$\begin{aligned} p &\cong \frac{6.63 \times 10^{-34}\ \text{J} \cdot \text{s}}{(0.5\ \text{fm})(\sin 30°)} = \left(\frac{6.63 \times 10^{-34}\ \text{J} \cdot \text{s}}{(0.5\ \text{fm})(0.5)}\right)\left(\frac{1\ \text{fm}}{10^{-15}\ \text{m}}\right) \\ &= 2.7 \times 10^{-18}\ \text{kg} \cdot \text{m/s}. \end{aligned}$$

Thus

$$\begin{aligned} pc &= (2.7 \times 10^{-18}\ \text{kg} \cdot \text{m/s})(3.0 \times 10^{8}\ \text{m/s}) \\ &= (8.0 \times 10^{-10}\ \text{J})\frac{1\ \text{eV}}{1.6 \times 10^{-19}\ \text{J}} = 5.0 \times 10^{9}\ \text{eV}, \end{aligned}$$

or 5.0 GeV. Because $m_e c^2 \cong 0.5$ MeV for an electron, the value of pc required is some 10,000 times the rest mass, and the motion is highly relativistic.

Note that an electron with 5 GeV of energy in the center-of-mass reference frame is an electron with much higher energy in the laboratory reference frame, namely about 53 GeV, or 53,000 MeV (see Problem 8).

What Do You Think? The target proton is about 2000 times more massive than the electron. Is its motion also relativistic in the center-of-mass reference frame?

Elastic and Inelastic Scattering

We have confined our discussion to elastic scattering to this point, and elastic scattering has indeed been a fruitful process to study. In Chapter 40, for example, we discussed Compton scattering, in which the scattering of light by electrons provides strong evidence for photons, the particles of light. We also know about Rutherford's experiments on the elastic scattering of α particles by atoms and how they demonstrate the presence and size of an atomic nucleus. The elastic scattering of electrons by protons has helped show that protons are not pointlike and explore their charge distribution.

Inelastic scattering is another type of process that can supply information about the structure of scattering particles. The oldest example arises in spectroscopy: A beam of electrons in a cathode ray tube collides with atoms of a gas that fills the tube, neon atoms for example. The electrons excite the atoms from their ground state to an excited state that then decays into a photon and neon in the ground state. This is an inelastic collision. Depending on which atomic level the electron in the atom is excited to, the photon (symbol γ) in the decay process will have the energy that is predicted by energy conservation. Consider, for example, this process in a neon gas, namely

$$e^- + \text{Ne} \rightarrow e^- + \text{Ne}^* \rightarrow e^- + \text{Ne} + \gamma.$$

We can use the characteristics of the process to study the excited states of neon, denoted by Ne*. The observed energy of the photon tells us the energies of the various Ne* states and how strongly these processes occur helps us discover features such as the angular momentum of these states.

To take a different example, consider the scattering of protons by protons. At low energies we can study the shape of the proton–proton potential energy function with the elastic process

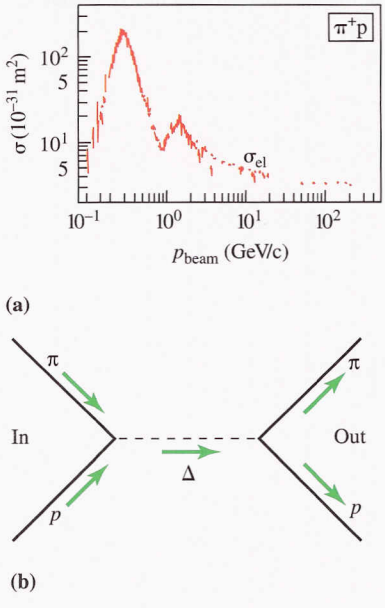
$$p + p \rightarrow p + p.$$

Beyond a certain threshold, in the vicinity of projectile energy 290 MeV with a stationary target, there is a large inelastic component, with a large cross section† for the process

$$p + p \rightarrow p + n + \pi^+.$$

On the right, we have a new particle, the π^+ (positive pion), first seen in this way in the late 1940s, when accelerators powerful enough to produce protons in the 300 MeV range became available. Its discovery was not unexpected, having been predicted by Hideki Yukawa in 1935 (see Section 45–3 for more).

The pions (π^+ as well as its neutral and negatively charged partners π^0 and π^-, respectively) are produced copiously in reactions like those cited above. While not stable, the pion has a lifetime long enough to allow one to form beams of pions by deflecting them and then focusing them with strong magnetic fields. One can then observe how pions scatter from protons, as for example in elastic scattering,



$$\pi^+ + p \rightarrow \pi^+ + p. \qquad (45\text{–}2)$$

The cross section for the process in Eq. (45–2) was found to have a marked peak as a function of the energy in the initial configuration (Fig. 45–2a). This peak corresponds to the production and subsequent decay of the analog of an atomic excited state, or resonance—a state of rest mass 1232 MeV/c^2 and angular momentum 3/2 (in units of $\hbar$)—that we label with the symbol Δ (Fig. 45–2b). The fact that the cross section has a peak of finite width means that the mass of the Δ resonance (and other states like it) has a width that corresponds to a spread in the value of the mass. This is consistent with the energy-time uncertainty principle, in which the lifetime represents the spread in time, and the width of the resonance in energy represents the energy uncertainty (see Section 40–3 and Conceptual Example 45–3).

The sequence of events that produce Eq. (45–2) can be written as

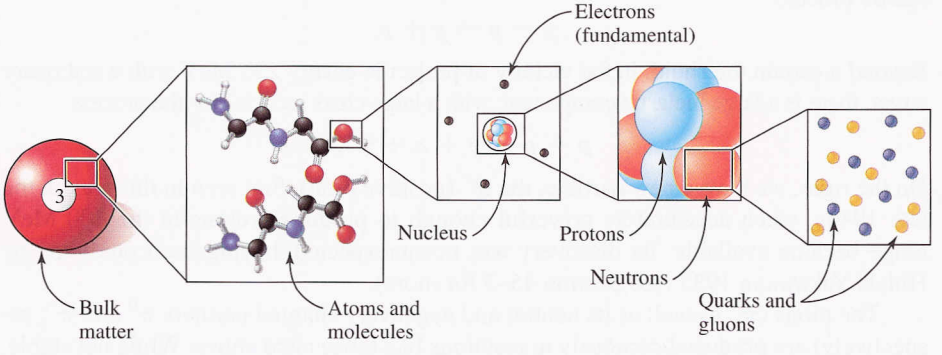
$$\pi^+ + p \rightarrow \Delta; \quad \text{then } \Delta \rightarrow \pi^+ + p. \qquad (45\text{–}3)$$

Just as atoms have many excited states of different quantum numbers, studies of inelastic collisions reveal a very large number of such excited states of the proton analogous to the Δ, but with different spins. We term these states *resonances*, given the shape of the cross section as a function of energy. As for the Δ resonance, the width of any of these resonances is associated with its lifetime.

▲ **FIGURE 45–2** (a) The cross-section for the elastic scattering of positive pions from protons exhibits a peak at a center-of-mass energy of about 1230 MeV. This peak has a substantial width. (b) The interpretation of the peak is that the pion–proton system has a resonant state, or an unstable particle, the Δ. The width of the peak is interpreted according to the uncertainty principle in terms of the lifetime of the Δ.

†See Section 19–7 for a discussion of the cross section.

CONCEPTUAL EXAMPLE 45–3 The rest mass of the Δ resonance, including its width, is given by $Mc^2 = (1232 \pm 60)$ MeV. A more recently discovered particle, the J/ψ, has a mass given by 3096.87 MeV $\pm$ 90 keV. Are both particles unstable? If so, which has the longer mean life?



Answer The very fact that the masses of these "particles" have an uncertainty is an indication of a finite lifetime and hence of instability. The term "resonance" is in fact just another term for "unstable particle." The time-energy uncertainty relation $\Delta E \Delta t \cong h$ shows that the mean life of an unstable system is inversely proportional to the energy spread, which translates to a spread in rest mass. In this case the Δ has a much larger (by a factor of 600) uncertainty in its rest mass, and therefore the Δ has a mean life that is shorter by that same factor.

As we have already argued, pion beams allow us to study processes such as the ones that we used to look at the Δ:

$$\pi^+ + p \rightarrow X^{++}, \quad \text{or} \quad \pi^- + p \rightarrow X^0.$$

The quantity labeled by X can consist of an unstable particle (or as we shall term it, a "state") like the Δ, but with different quantum numbers (see below). The collection of all these states is known as the **hadrons**. The origin of this name is in the Greek word for "strong," appropriate because the particles involved in the reactions are all associated with nuclear forces. Today the hadrons are understood as being composed of a small group of more fundamental building blocks of matter called **quarks**—an example of the "Russian doll" picture. We'll discuss hadrons and quarks further in Sec. 45–3.

In Fig. 45–3 we outline the constituent structure of matter, analogous to the Russian doll. A figure of this type gives us an oversimplified view of the larger picture, and we shall want to look more deeply into that picture.

▶ **FIGURE 45–3** A schematic picture of the hierarchical structure of matter.

45–2 New Quantum Numbers

The Discovery of Antimatter

Relativity, which has thus far entered our discussion only in connection with kinematics, turns out to play a fundamental role in the physics of elementary particles. In 1928 Paul Dirac discovered an equation describing electrons that combines quantum mechanics and relativity. One of the predictions of this equation is that the electron should have a partner which could be called an anti-electron. This new particle, the **positron**, had to have exactly the same mass as the electron, the same spin $\frac{1}{2}$, but a positive charge (hence its name). When a positron makes contact with an electron, the two particles can annihilate each other, with the consequent production of neutral particles. At low energies, the annihilation produces photons, the most common reaction being

$$e^+ + e^- \rightarrow 2\gamma. \tag{45–4}$$

The products of such an annihilation reaction must have total charge zero, since charge conservation continues to hold in quantum mechanics. (Charge conservation is believed to be exact, by which we mean that it is *never* violated.) In fact, in relativistic quantum mechanics *all* particles have their corresponding antiparticles: the proton has its antiproton, the neutron its antineutron, and so on. The photon is truly neutral and is said to be its own antiparticle. (Why then is the neutron not its own antiparticle? We'll discover the answer to this in the next subsection.)

The positron was observed just three years after its prediction, and although it does not persist in nature—we live in a electron-rich world and a positron will sooner or later meet an electron and annihilate—it is easily produced in inelastic scattering processes. It can be slowed down and become bound to an electron for short periods, giving rise to a hydrogen-like neutral "atom" called *positronium* whose presence is signaled by a characteristic spectrum.

It is worth noting that in the description of processes, the "cancellation" of matter and antimatter implies that in a reaction one can transfer a particle on one side of a reaction to the other by replacing it with its antiparticle. (The underlying process is still subject to energy and momentum conservation.) Thus, assuming that there is sufficient energy available in the initial state, a reaction such as

$$e^- + p \rightarrow p + e^- + \gamma \tag{45–5}$$

will be closely related to the following processes:

$$\begin{aligned} e^- + e^+ &\rightarrow \bar{p} + p + \gamma \\ p + \bar{p} &\rightarrow e^- + e^+ + \gamma \\ \gamma + p &\rightarrow p + e^- + e^+. \end{aligned} \tag{45–6}$$

Baryon Number

There are some reactions, or decays, that are never seen. When this happens it may be because of the conservation of quantum numbers. To take an example, we never see the energetically possible decay $p \rightarrow e^- + \gamma$, and you could quickly say that that decay is forbidden because at the least it violates the law of charge conservation. Other examples conserve charge and are energetically possible, yet still do not occur in nature; for example,

$$p \rightarrow e^+ + \gamma, \quad \text{or} \quad p \rightarrow e^+ + e^+ + e^-. \tag{45–7}$$

Similarly, the annihilation process

$$e^- + p \rightarrow \text{photons} \tag{45–8}$$

does not occur—if it did, there would be no atoms in the universe, only photons. Finally, the electrically neutral neutron is *not* its own antiparticle. If it were, then nuclei containing more than one neutron would be blown apart by the energy generated in the annihilation of a neutron with another neutron (= anti-neutron). To explain all this, Eugene Wigner introduced a new quantum number analogous to the electric charge, the **baryon number** B. By assigning appropriate values of B and insisting on *baryon number conservation*, it is possible to explain the absence of these reactions. The following assignments will accomplish the task of ruling out unobserved reactions:

$B = 1$: proton and neutron;
$B = -1$: antiproton and antineutron;
$B = 0$: electrons and positrons, photons, pions.

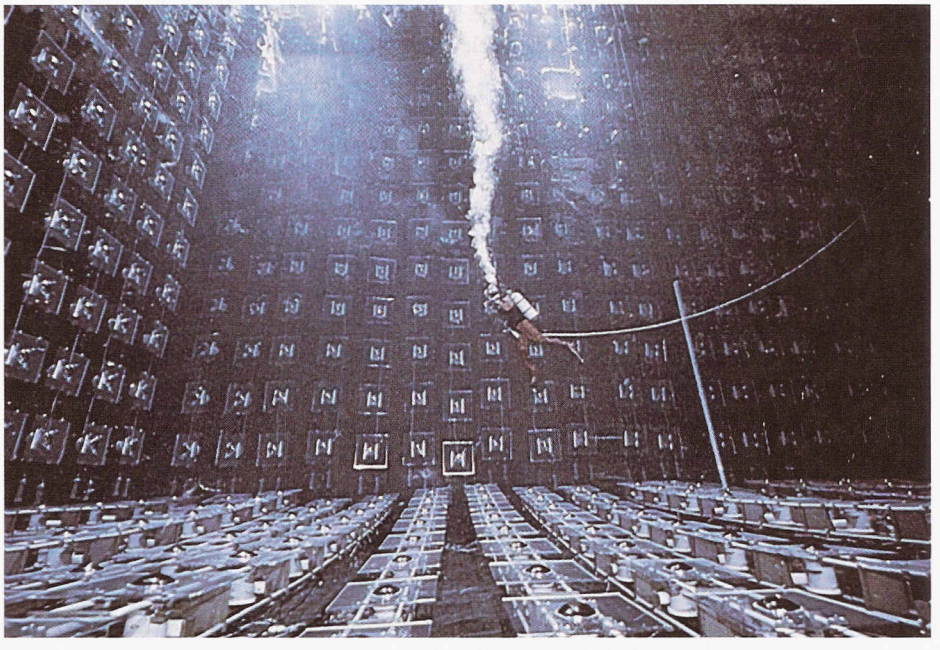
For all practical purposes, baryon number conservation acts exactly like charge conservation in restricting the kind of final particles that can emerge from a given two-particle collision.

CONCEPTUAL EXAMPLE 45–4 Which of the following reactions are allowed and which are forbidden, and why? [*Hint*: Do not forget to pay attention to the conservation of angular momentum.]

(a) $e^+ + \gamma \rightarrow p + \gamma$;
(b) $e^+ + e^- \rightarrow p + \bar{p}$;
(c) $p + \bar{n} \rightarrow e^+ + \gamma$;
(d) $p + \bar{n} \rightarrow \pi^+ + \gamma$.

Answer (a) Forbidden. Baryon number conservation is violated. (b) Allowed. Both charge and baryon number are conserved; furthermore, there are two spin-$\frac{1}{2}$ particles on each side, so that angular momentum conservation is not manifestly violated. In an experiment, the initial energy must, of course, be large enough to create the proton–antiproton pair. (c) Forbidden. Baryon number and charge are conserved. However, the total angular momentum on the left side will always be an integer, while on the right side, which has only one spin-$\frac{1}{2}$ particle, the total angular momentum will always be half-integral, and angular momentum *cannot* be conserved. (d) Allowed. Baryon number and charge are conserved, and there are no manifest angular momentum conservation problems.

THINK ABOUT THIS. . .



HOW WOULD WE KNOW IF THE LAW OF BARYON CONSERVATION WERE VIOLATED?

We should start by saying that the question is badly posed. We can never make an absolute statement about a conservation law such as this; we can only set limits on how small an eventual violation has to be. And based on the remarkable stability of matter, we have very good limits on the conservation of baryon number. Consider the baryon-number violating decay

$$p \rightarrow e^+ + \pi^0. \qquad (45\text{–}9)$$

This decay is forbidden only by baryon number conservation. If it took place on a time scale much less than the age of the universe, it would make our universe atom-free. But might the reaction occur very rarely? This question is one that can only be decided by experiment, and a series of extraordinary experiments designed to measure the reaction show that *if the proton lifetime is not infinite, it is nevertheless greater than* 10^{30} *years*. How can we say this if the universe has existed for only some 10^{10} yr? We can measure such a lifetime by assembling 10^{30} protons and watching them carefully; if the lifetime were 10^{30} yr, we would expect one decay per year. In one experiment, a tank filled with 8000 tons of water (about 10^{32} protons) was surrounded by suitable detectors; no decays like those in Eq. (45–9) occurred over a period of several years (Fig. 45–4). The tank was placed in a salt mine deep underground to avoid interference from high-energy particles coming from outer space.

Although baryon number is conserved like electric charge, baryon number differs from electric charge in that there are no Coulomb-like forces associated with baryon number. Another way in which baryon number differs from electric charge is that according to certain ideas and under certain circumstances, the conservation of baryon number may be very slightly violated. Conditions in the early stages of the universe could have provided these circumstances.

▲ **FIGURE 45–4** The very pure water in this tank, in an underground laboratory in Japan, is surrounded by phototubes, detectors sensitive to the tiniest trace of light. Here the apparatus is being checked by a scientist with scuba equipment. The phototubes are activated after the lights are turned out; they are capable of capturing the tiny flash of light associated with a proton decay somewhere in the tank, if such a decay were to occur.

EXAMPLE 45–5 The discovery of the antiproton was made in collisions of a proton beam with a stationary proton target. What is the minimum energy required for the incoming proton so that an antiproton can be produced?

Strategy First of all, we need to see what reaction requires the minimum energy. In a collision $p + p$, the initial charge is $Q = 2$ and baryon number is $B = 2$. Thus the final state must have $Q = 2$ and $B = 2$. Since the antiproton has $Q = -1$ and $B = -1$, the remaining particles that form part of the final state must collectively have $Q = 3$ and $B = 3$. The smallest such aggregate is three protons, so that we are talking about the reaction

$$p + p \rightarrow p + p + p + \bar{p}.$$

To find the minimum energy necessary to make this process occur, we can first visualize what happens in the center-of-mass frame. There the two initial protons collide head-on, and the total momentum is zero. The lowest-energy state occurs when all the four particles in the final state just sit there, at rest. Any other state would require more energy, the kinetic energy of their relative motion. The picture of four particles all at rest relative to each other looks the same in any reference frame, except that the foursome all move with a fixed momentum. This then means that in the laboratory reference frame, the initial particles have momentum q and 0, respectively, and their energies are $\sqrt{(qc)^2 + (Mc^2)^2}$ and Mc^2, respectively. In the final state, we must again have total momentum q, but there is no internal momentum: The four particles act as if there were only a single particle of mass $4M$. Thus energy conservation implies that

$$\sqrt{(qc)^2 + (Mc^2)^2} + Mc^2 = \sqrt{(qc)^2 + (4Mc^2)^2}.$$

To answer the question posed, we can solve this expression for q, and hence for the incoming proton's total energy, $E_q = \sqrt{(qc)^2 + (Mc^2)^2}$. The kinetic energy is the total energy minus the rest energy.

Working It Out Squaring both sides of the energy conservation equation gives

$$(qc)^2 + (Mc^2)^2 + 2E_qMc^2 + (Mc^2)^2 = (4Mc^2)^2 + (qc)^2.$$

The factor $(qc)^2$ cancels, and we find

$$E_q = 7Mc^2.$$

The minimum proton kinetic energy required to produce an antiproton is then $6Mc^2$, or about 5630 MeV.

What Do You Think? Won't the antiproton sitting on top of three protons annihilate immediately, presenting a serious problem to your hopes of discovering the antiproton?

Leptons and Their Quantum Numbers

Both the electron and the neutrino ν are fundamental constituents of matter. These particles do *not* participate in the strong (nuclear) force and are known as **leptons**. We recall from Chapter 44 that the neutrino has no charge and little or no mass. But along with the electron, it does carry a conserved **lepton number** analogous to the baryon number. Both the electron and the neutrino, each with spin $\frac{1}{2}$, have the lepton number $+1$; their antiparticles e^+ and $\bar{\nu}$ have the lepton number -1. This law explains, for example, why the fundamental beta decay process $n \rightarrow p + e^- + \bar{\nu}$ can occur, while the process $\pi^+ + p \rightarrow e^+ + e^+ + n$ cannot.

The story of the leptons does not, however, end here. Less than a decade after the discovery of the positron, a new particle called the muon (symbol μ^-) was discovered. It has spin $\frac{1}{2}$, it has its own antiparticle (μ^+), and except for its mass (about $207m_e$), it appears to be identical to an electron. However, a certain number of reactions involving the muon are not observed even though they are allowed by charge, energy, and simple lepton number conservation. The most easily observed would be

$$\mu^- \rightarrow e^- + \gamma.$$

To account for the nonobservation of this reaction and of others, one introduces an electron lepton number *and* a muon lepton number, each of which is separately conserved. Neutrinos are associated with muonic processes in the same way that they appear in some electronic ones, and this means that we must put a subscript on neutrinos, with the muon having its own associated neutrino ν_μ, distinct from the electron neutrino ν_e. Each of these neutrinos carries its respective lepton number. The lepton quantum number assignment gives (e^-, ν_e) and (μ^-, ν_μ) electron and muon lepton number $+1$, respectively, with their antiparticles having lepton number -1. Thus for example the reaction $\mu^- + p \rightarrow n + \nu_\mu$ is allowed, while the process $\mu^- + p \rightarrow n + \nu_e$ is not.

Neutrinos interact so weakly that these ideas are hard to test, and it requires careful experiments to confirm the hypothesis. For example, it is possible to make a neutrino beam by using the decay

$$\pi^+ \rightarrow \mu^+ + \nu_\mu.$$

When the beam is directed at a target of nuclei, one learns that negative muons are produced in the (rare) collisions, never electrons. The appearance of an electron would imply the violation of separate muon lepton number and electron lepton number conservation.

CONCEPTUAL EXAMPLE 45–6 A group in a laboratory claims to have discovered a new, stable particle with positive charge. The group states that its mass is approximately 10 times that of the electron, and that when it collides with a proton, it leads to the annihilation of the proton with the production of three positrons and one electron. What can you say about the lepton and baryon number of this particle? Can it form hydrogen-like atoms with electrons? Why can you say with some confidence that such a particle cannot really exist? [*Hint*: All particles have antiparticles.]

(continues on next page)

Answer Let us label the particle by X. It is said to annihilate with a proton according to

$$X + p \rightarrow 3e^+ + e^-.$$

Baryon conservation implies that X has $B = -1$. Furthermore, charge conservation implies that X has unit positive charge. Finally, as far as lepton number is concerned, the lepton number on the right side is $N_e = -2$ and therefore the electron lepton number of the X is -2. Consider now a possible bound state of the X with an electron. While the X and the electron attract each other, they cannot annihilate, because the annihilation product would have to include an antiproton, and this is energetically impossible. Thus a hydrogen-like "atom" could indeed exist.

What is the argument that might lead one to doubt the existence of this state at a mass ten times that of the electron? If X exists, so does its antiparticle $\overline{X}$, which would have $B = 1$ and charge -1. But then the proton could decay through a process that is energetically allowed and charge- and B-conserving, namely

$$p \rightarrow \overline{X} + 3e^+ + e^-.$$

This proton instability would be quite visible.

45–3 The Fundamental Constituents of Matter: Leptons and Quarks

Decades of experiments with electrons and muons, at ever increasing energies, have revealed no evidence that these particles, the leptons, have a substructure. As far as we know, the pairs (e^-, ν_e), (μ^-, ν_μ) and their antiparticles are "pointlike." Pointlike is a good way to describe a fundamental particle; it says that the particle is not "made" of something more basic, in the way that atoms are made of electrons and nucleons. We might say that these particles are the smallest Russian doll, keeping in mind that other particles will also have this description. There is one complication—there is yet a third pair of leptons, denoted (τ^-, ν_τ), with their own conserved lepton number. But there is good experimental evidence that there are *only* three lepton pairs, so that the set of six leptons and their antiparticles make up all the leptons. The neutrinos of each of the three pairs are all much less massive than their charged partners, and indeed than the electron. The charged partners, the e^-, μ^-, and τ^-, have a large range in mass, with the τ some 3500 times more massive than the electron.

The Quark Model

The baryons and the mesons, or in other words the ensemble of hadrons, are certainly not pointlike, and there is evidence of a substructure. This substructure is described in terms of a set of fundamental constituents known as **quarks**.

The large number of hadrons discovered in scattering experiments is reminiscent of atoms and their excited states. The Bohr model of hydrogen allows us to explain all the states of hydrogen in terms of an electron, a proton, and the forces between them. Similarly, the *quark model* economically describes baryons and mesons in terms of a few constituents and their interactions. This model was proposed independently by Murray Gell-Mann and George Zweig in 1964.

In the quark model, neutrons, protons, and pions are composed of quarks, each with spin $\hbar/2$: the *u-quark* ("up" quark) and the *d-quark* ("down" quark). Both types of quarks have an antiparticle, $\overline{u}$ and $\overline{d}$, respectively. The quantum numbers of these (and other) quarks are listed in Table 45–1. The electric charge of the quarks is a fraction of the electron charge. This does not mean that charge is no longer quantized, but that the

TABLE 45–1 • Properties of Quarks

Quark	Charge in units of e	Baryon no.	Spin in units of $\hbar$	Rest energy*
$u, \overline{u}$	$\frac{2}{3}, -\frac{2}{3}$	$\frac{1}{3}, -\frac{1}{3}$	$\frac{1}{2}$	1.5–4.5 MeV
$d, \overline{d}$	$-\frac{1}{3}, \frac{1}{3}$	$\frac{1}{3}, -\frac{1}{3}$	$\frac{1}{2}$	5–8.5 MeV
$c, \overline{c}$	$\frac{2}{3}, -\frac{2}{3}$	$\frac{1}{3}, -\frac{1}{3}$	$\frac{1}{2}$	1.0–1.4 GeV
$s, \overline{s}$	$-\frac{1}{3}, \frac{1}{3}$	$\frac{1}{3}, -\frac{1}{3}$	$\frac{1}{2}$	80–155 MeV
$t, \overline{t}$	$\frac{2}{3}, -\frac{2}{3}$	$\frac{1}{3}, -\frac{1}{3}$	$\frac{1}{2}$	174 ± 5 GeV
$b, \overline{b}$	$-\frac{1}{3}, \frac{1}{3}$	$\frac{1}{3}, -\frac{1}{3}$	$\frac{1}{2}$	4.0–4.5 GeV

*Since individual quarks have never been observed, the values are inferred indirectly, using theoretical input as well as experimental information.

true quantization is in units of $\frac{1}{3}e$. The fact that quarks and antiquarks have spin $\hbar/2$ means that the spin of an even number of quarks plus antiquarks is an integer times $\hbar$ whereas the spin of an odd number of quarks plus antiquarks is a half-integer times $\hbar$.

The proton is a composite of three of these quarks, uud; the neutron has the structure udd. The antiproton is made of the combination $\bar{u}\bar{u}\bar{d}$, whereas the antineutron is $\bar{u}\bar{d}\bar{d}$. A combination of three quarks can have a variety of angular momenta, and these different combinations successfully explain all the baryons thus far discovered. For example, among the observed baryons is a quartet of states, partners of the previously discussed Δ^{++}. All four, Δ^{++}, Δ^{+}, Δ^{0}, and Δ^{-}, have spin $3\hbar/2$ and baryon number $B = 1$. These are formed from the combinations uuu, uud, udd, and ddd, respectively. The quark model also accounts for mesons. Mesons have $B = 0$ and are bosons (their spin is an integral multiple of $\hbar$), and they are properly described as pairs of quarks and antiquarks. In particular, $\pi^{+} = (u\bar{d})$ and $\pi^{-} = (d\bar{u})$, whereas π^{0} is a combination of $u\bar{u}$ and $d\bar{d}$.

Complementary evidence for the existence of quarks is provided by scattering experiments. When electrons with high energy were first used to probe protons in a hydrogen target in the 1950s, the results quite early revealed a distribution of charge within the proton (that is, the proton was found not to be pointlike). Figure 45–5 shows the ratio of the observed distribution to the distribution a pointlike proton would give. If the proton were pointlike, this ratio graph would be a flat line rather than the observed curve. There was widespread expectation that further experiments would continue to verify that the proton's charge is distributed smoothly within it, much as the champions of the "plum pudding" model of the atom would have expected for α particles scattering from the atom. If the proton charge were distributed uniformly, electrons passing through the proton (and possibly breaking it apart) would be deflected very little. To the surprise of the physics community, a series of experiments of this type in 1968 at previously unexplored energies revealed a very different behavior: Electrons were scattered in large numbers at large angles and in a pattern characteristic of a proton constructed of three pointlike particles, each carrying a fraction of the proton charge. These particles are the very quarks that we used to describe the pattern of observed hadrons. The existence of a subset of hadrons related to the proton in a more complicated way was explained by the existence of yet another quark, the *strange* quark s (and its antiparticle). These three quarks are called the light quarks. In addition to the three so-called light quarks (u, d, s), there are three so-called heavy quarks, denoted by the letters (c, b, t). These were anticipated by theorists who found that certain interactions required three families of fundamental particles, and they are elements of still other series of hadrons.[†] We will learn more about what lies behind the quark model in the next section, in our discussion of the fundamental forces.

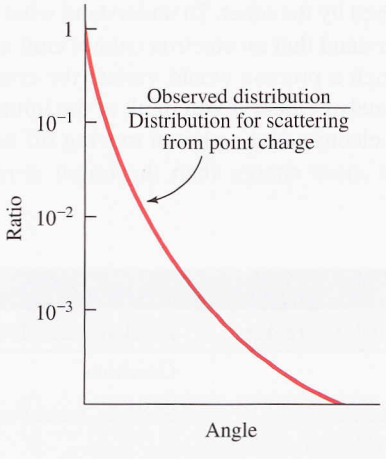


FIGURE 45–5 Elastic electron–proton scattering experiments show that the proton is not pointlike. The horizontal axis is the scattering angle; we have already seen that this quantity measures how closely the target is probed. The vertical axis is the ratio of the measured cross section to the cross section that would follow if the proton were pointlike. This curve would be flat, not decreasing, if the proton were pointlike. We know from other scattering experiments that the corresponding curve for quarks is flat, to the accuracy with which we can measure it.

[†]The $(udcstb)$ labels are often called *flavor* labels. They represent quantum numbers that are conserved in some aspects of the fundamental interactions but not in others.

EXAMPLE 45–7 What is the charge, baryon number, and lowest possible value of the total angular momentum of the following combination of quarks: $(u\bar{s})$, (tsd), $(c\bar{c})$?

Strategy We make use of the quantum numbers listed in Table 45–1. The charge and baryon numbers are additive, and working these out for the three combinations given is straightforward. In the case of angular momentum we note that all the quarks and antiquarks have spin $\frac{1}{2}$. Thus a two-quark system will have a total angular momentum of $\frac{1}{2} \pm \frac{1}{2}$ with possible orbital angular momentum added in as well. This means that for the two-quark system the lowest value of angular momentum will be zero: The spins point in opposite directions, and there is no orbital angular momentum. For a three-quark system, two of the spins can point in opposite directions, but a spin $\frac{1}{2}$ will always be left over. With no orbital angular momentum, that spin determines the lowest value of total angular momentum.

Working It Out

$(u\bar{s}): Q = \frac{2}{3} + \frac{1}{3} = 1; B = \frac{1}{3} - \frac{1}{3} = 0,$
total angular momentum $= 0;$

$(tsd): Q = \frac{2}{3} - \frac{1}{3} - \frac{1}{3} = 0; B = \frac{1}{3} + \frac{1}{3} + \frac{1}{3} = 1;$
total angular momentum $= \frac{1}{2};$

$(c\bar{c}): Q = \frac{1}{3} - \frac{1}{3} = 0; B = \frac{1}{3} - \frac{1}{3} = 0;$
total angular momentum $= 0.$

What Do You Think? Which of these particles can be its own antiparticle?

In spite of the great success of the quark model in classifying all of the observed hadrons, all attempts to find free quarks in collision experiments have thus far failed. The mystery of why single quarks have not been seen lies in the way in which they interact with each other to form nucleons, mesons, and all the hadrons. This is one of the themes of the next section.

45–4 The Fundamental Forces and Their Carriers

We first talked about fundamental forces in Chapter 5. Now we are in a position to add to that discussion. We can identify three fundamental forces acting in nature (Table 45–2): gravitation; the electroweak force, which is a unification of the electromagnetic force and the weak force originally associated with beta decay in nuclei; and the strong, or nuclear, force. There is very little we can say about gravitation beyond what we said in Chapter 12, because we do not know of a way to bring gravitation and quantum mechanics together. There is, however, a great deal more we can say about the other forces, and in order to set the stage for that discussion, let us consider how it is that forces are transmitted in a quantum-mechanical and relativistic world.

The Carriers of Forces: The Yukawa Theory

Our discussion begins with electromagnetism. Classically, charged particles—a pair of electrons, say—interact through the electromagnetic fields they set up. How does this result carry over into the quantum domain? In this domain the electromagnetic field is described by photons, and the interaction between the electrons occurs when one electron emits a *virtual photon* that is then absorbed by the other. To understand what we mean by a virtual photon, it is necessary to understand that an electron cannot emit a real photon and just remain an electron, because such a process would violate the conservation of energy and momentum. This is immediately evident if you think of the initial electron at rest; the final state would consist of an electron and a photon moving off back-to-back, and that configuration necessarily has more energy than the initial at-rest electron.

TABLE 45–2 • Fundamental Forces

Force	Particles on Which Force Acts	Particles that Transmit Force
Gravitation	All particles	Gravitons[†]
Electroweak force	Particles with electric charge or "weak" charge	Photons, weak bosons
Strong force	Quarks, gluons	Gluons

[†]Gravitons have never been observed in any sense, nor has the law of gravitation (general relativity) been satisfactorily integrated with quantum ideas.

But thanks to the uncertainty principle, quantum mechanics allows for our process to occur. The uncertainty relation, $\Delta E \Delta t \geq \hbar$, allows for deviations from energy conservation, but only for times Δt determined by the degree of energy uncertainty. During the period Δt the photon, whose production sidesteps energy conservation, is said to be *virtual*, and as long as the photon is reabsorbed (by the second electron) quickly enough, there is no measurable violation of energy conservation. A quantum-mechanical calculation of the effect of this virtual photon exchange shows that it gives rise to the usual Coulomb force of repulsion between two electrons and attraction between the oppositely charged electron and positron.

This way of thinking about forces in quantum mechanics came out of studies of the nuclear forces by Hideki Yukawa in 1934–35. Yukawa proposed that in analogy with the electromagnetic field responsible for the electron–electron interaction, there existed a new field, the *meson* field, whose quanta would play the role of photons. The characteristics of the nuclear force, and in particular the fact that it is a short-range force (Chapter 44), lead to an important difference between photons and the new quanta: The new quanta had to have a rest mass m. Their *virtual* existence now requires an energy deficit of at least mc^2. This is sustainable, as we argued above, for a time of the order of $\Delta t \cong \hbar/\Delta E < \hbar/mc^2$. The virtual particle could propagate a distance no larger than $c\Delta t$ in that time. Thus its effectiveness as a carrier of force is limited to *the range* of the force,

$$R < c\Delta t = \hbar/mc. \tag{45–10}$$

Yukawa's meson, the carrier particle of the nuclear force, is the *pion* mentioned earlier in this chapter. Using Eq. (45–10), we can estimate its mass, m_π, if we take $R \cong 1.4$ fm, an experimental value for the range of nuclear forces:

$$m_\pi = \frac{\hbar}{Rc} = \frac{1.05 \times 10^{-34}\ \text{J} \cdot \text{s}}{(1.4 \times 10^{-15}\ \text{m})(3.0 \times 10^{8}\ \text{m/s})} = 2.5 \times 10^{-28}\ \text{kg} = 0.15 m_p, \tag{45–11}$$

where m_p is the proton mass. Thus, $m_\pi c^2 \cong (0.15)(938\ \text{MeV}) = 140\ \text{MeV}$. Yukawa also calculated the potential energy as a function of particle separation r for the force associated with meson exchange:

$$U(r) = g^2 \frac{e^{-m_\pi rc/\hbar}}{r}. \tag{45–12}$$

Here g^2 is a measure of the strength of the force between the interacting particles, analogous to $e^2/4\pi\varepsilon_0$ for the Coulomb force. In fact, the Coulomb force fits Yukawa's framework perfectly well if it is regarded as the result of the exchange of a massless particle—the photon.

A couple of comments about Yukawa's idea are worth making:

1. The meson must be a boson; that is, its intrinsic angular momentum (spin) must be an integral multiple of $\hbar$. That is because the particles that emit and absorb the meson—the nucleons—are fermions, and if angular momentum is to be conserved, they cannot themselves emit or absorb a particle with half-integral spin and remain fermions.
2. Nuclear forces occur with nearly equal range between neutrons and neutrons, protons and protons, and neutrons and protons. This is a consequence of the fact that Yukawa's mesons occur in the three charge states π^0, π^+, and π^-, with the three particles having (nearly) the same mass.

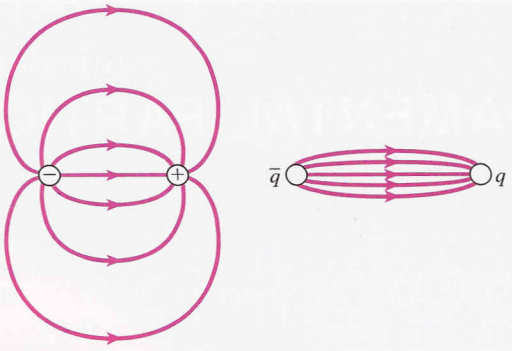
The discovery of pions with all the predicted characteristics had a lasting influence on how we think about the fundamental interactions, even if we no longer think of the exchange of pions as representing a fundamental interaction.

The Electroweak Force

Let us turn back to a discussion of what today we regard as the fundamental forces. Just as electromagnetism is the result of a unification between two forces that were initially thought to be independent, electric and magnetic forces, so the electroweak force is the result of a unification of electromagnetism and the weak force. It will be useful to look first at these pieces of the electroweak force.

Quantum electrodynamics is a quantum version of classical electromagnetism. Quantum electrodynamics describes precisely how charged particles interact through the exchange of photons, massless particles with spin 1 (in units of $\hbar$). By itself, this description is the most accurate theory that we know of. It predicts certain effects of electromagnetism on the magnetic moments of electrons and muons to an accuracy of about one part in a billion, and so far a set of extremely accurate experiments have confirmed every unambiguous prediction.

The **weak interactions** take their name from the fact that their effects are extremely small compared to the effects of electromagnetism or the strong force. They are only visible because they lead to reactions that cannot occur through the other interactions. Among others, the weak interaction governs the muon decay reaction $\mu^+ \rightarrow e^+ + \overline{\nu}_\mu + \nu_e$ as well as beta decay, $n \rightarrow p + e^- + \overline{\nu}_e$, as well as some scattering processes, $\mu^- + p \rightarrow \nu_\mu + n$ for example. We can note that the latter two processes don't involve what we think of as fundamental particles, and indeed these two processes actually occur because the weak interactions operate at the quark level. Thus beta decay of the neutron involves the transformation of a d-quark in a neutron to a u-quark through the weak process $d \rightarrow u + e^- + \overline{\nu}_e$. You can verify for yourself that this is consistent with the quark model description of the neutron and proton.



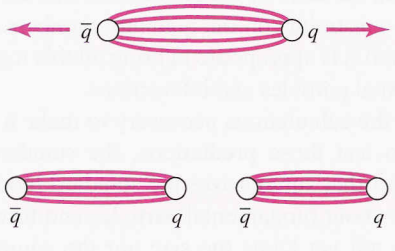
We have spoken of the weak and electromagnetic interactions as separate things. A more fundamental understanding of the weak interaction came about in the late 1960s, when it became clear that the weak interactions were on some level very similar to the electromagnetic interactions. At first, the differences look overwhelming: In addition to differences in strength—manifest in the rate of reactions—the weak force has a very short range. These differences were reconciled by S. Weinberg, A. Salam, and S. Glashow, who recognized that there was a single more fundamental interaction, the **electroweak interaction**. They proposed that at *high* energies, above some critical energy, the weak interactions should be almost identical to the electromagnetic interactions, with a triplet of massless spin-1 particles acting as carriers of the force, much like the photon, with two of them charged and one neutral. These particles are the *weak bosons*, W^+, W^-, and Z^0. Processes involving the weak force can now be thought of in terms of exchange of these particles, subject to the conservation of electric charge, of baryon number, and of lepton number. Thus the underlying basis of β decay, namely $d \rightarrow u + e^- + \overline{\nu}$, can be visualized as a two-step process in which a d-quark within a neutron is transformed to a u-quark with emission of a W^- while the W^- then transforms into ("couples to") two leptons:

$$d \rightarrow u + W^-; W^- \rightarrow e^- + \overline{\nu}_e.$$

At energies below the critical value, the weak bosons W^+, W^-, and Z^0 acquire large masses, some 86 and 97 times the mass of a proton for the W (W^+ and W^- both) and Z^0, respectively. (By saying that a massless particle "acquires" a mass, we mean that the particle behaves as though it had a mass due to its own interactions with other elements of the theory.) The large mass explains the very short range of the weak interaction. The large mass also has the effect of making low energy processes in which exchange is involved occur at a much slower rate, thus explaining the "weakness" of the force. The unification is manifest only at very high energies, beyond our current ability to test directly, but even below these highest energies we can observe effects of the unification coming into play, thus giving experimental confirmation that these ideas are correct. For example, the production and decay characteristics of the W^+, W^-, and Z^0 are predicted, and these have all been well tested. Even more directly, the dramatically increased rate at which reactions such as $\overline{\nu}_e + p \rightarrow n + e^+$ occur at high energies is a consequence of the fact that the "weak" force becomes as strong as the electromagnetic force at high energies. The unification of the electromagnetic and weak forces is an important step in our understanding of the fundamental forces, and to this point, all the predictions of the electroweak unification that have been tested have confirmed that this unification is correct.

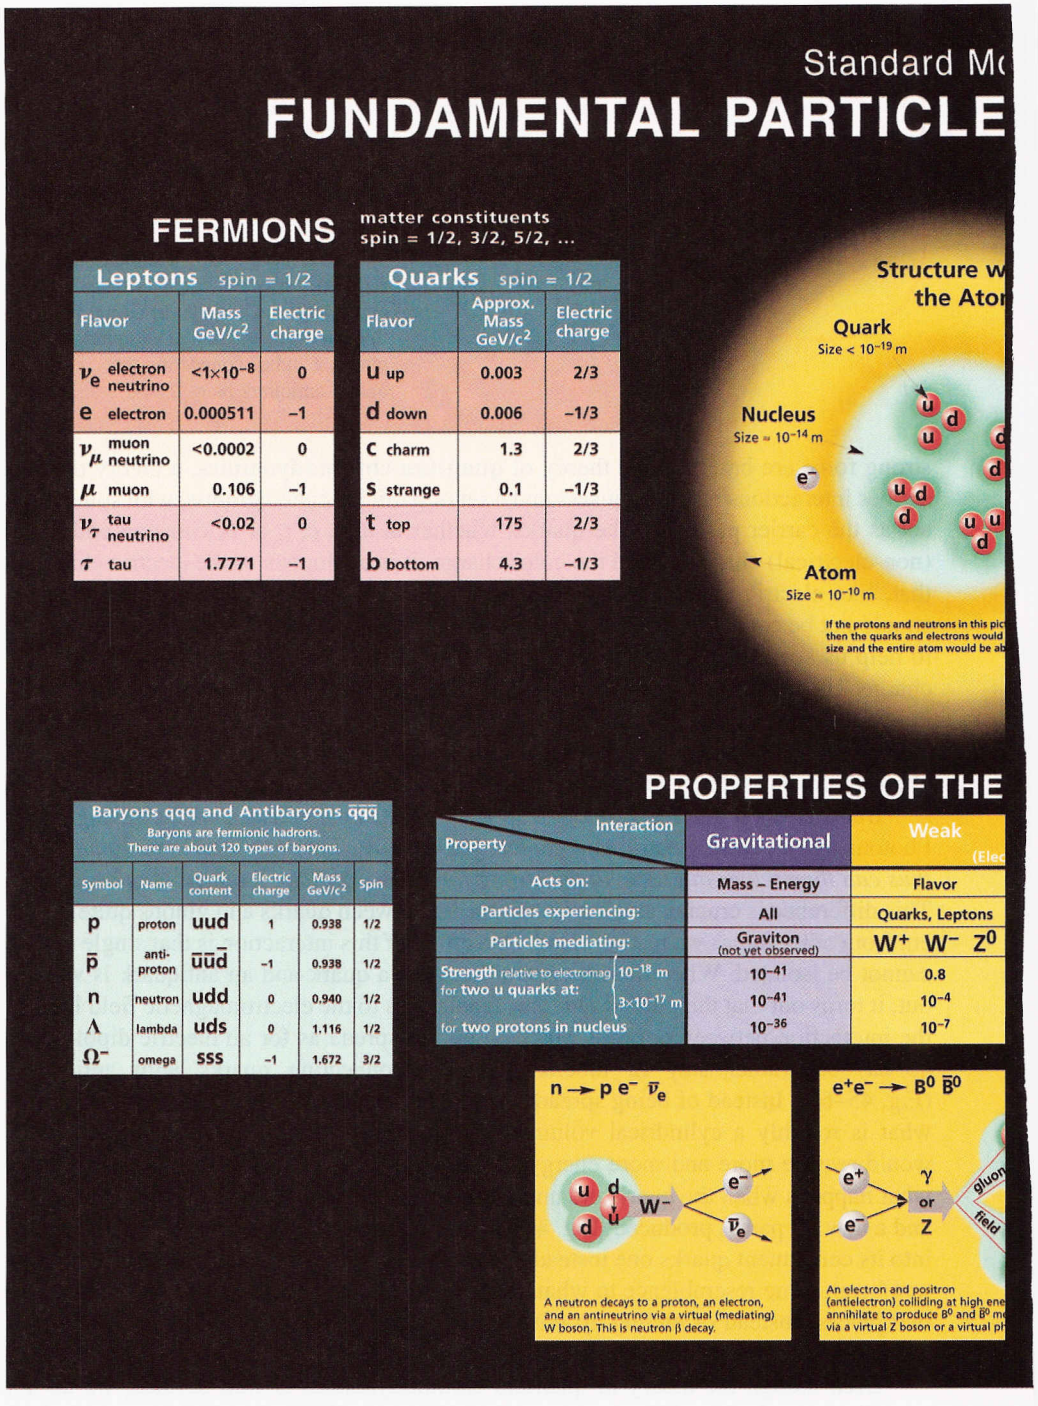
The Strong Force

Yukawa's original ideas concerning the hadrons must be modified to take account of what we now know are the hadronic constituents, the quarks. Thus our ideas about the



(a) (b)

◀ **FIGURE 45–6** (a) Electromagnetic field lines between equal and opposite charges spread widely. (b) Gluon field lines between quark and antiquark remain within a "tube" connecting the quark–antiquark pair.

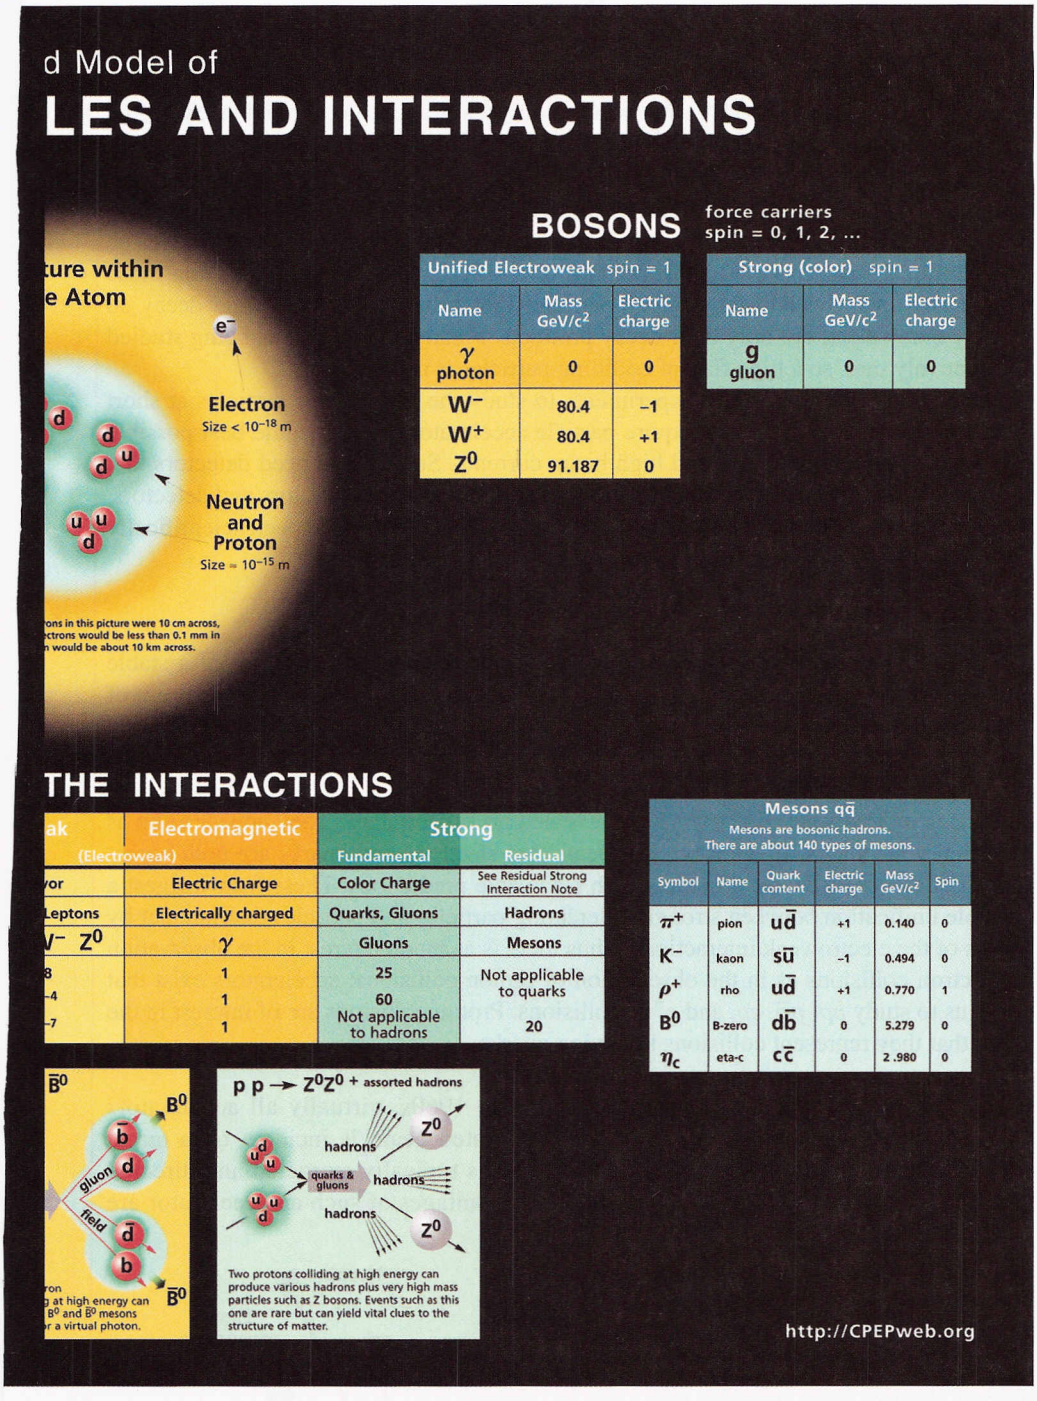


strong force are based on the theory of **quantum chromodynamics**, a theory that describes interactions between quarks and a set of particles called **gluons**, with spin $\hbar$, that act as the carrier particles. The quarks, whether u, d, s, c, t, or b, carry an additional (non-electrical) charge, called the color charge. It is analogous to the electric charge in that, like electric charge, it is both quantized and conserved. The quantum number should not be confused with the colors of the visible-light spectrum; it is merely a label to help us keep track of the charge, much as the label + or − keeps track of electric charge. The label is a bit more complicated than ±, because while electric charge comes in two different types, the color quantum number occurs in three different types. Gluons are emitted and absorbed by particles with a color quantum number (quarks), just as photons are emitted and absorbed by particles with electric charge.

But there is a crucial difference between electromagnetism and the strong force: Photons do not carry electric charge, *but gluons carry the color quantum number and thus can themselves interact via the strong force through the exchange of other gluons*. This difference is crucial, and makes the forces between quarks and gluons quite different from other forces we have studied. One effect of this interaction is that single quarks cannot be isolated. When the interaction between a quark and an antiquark is worked out, it turns out that the gluon field lines (analogous to the electromagnetic field lines in the interaction between opposite charges) do not spread as for an electric dipole (Fig. 45–6a) but rather stay in tubelike regions, connecting quarks with antiquarks (Fig. 45–6b). Instead of being spread out all over space, the field energy is confined to what is roughly a cylindrical volume, and separating the quark from the antiquark would require more and more energy as the separation increases. In fact, a picture of what happens when the quark and antiquark are pulled apart is that the cylinder breaks and a new $q\bar{q}$ pair is produced (Fig. 45–7). Thus if one tries to separate a π-meson, say, into its constituent quarks one instead ends up breaking it up into two mesons. This picture bears some resemblance to what happens when you try to break a bar magnet into two pieces. Instead of ending up with an isolated N-pole and an isolated S-pole, one ends up with two bar magnets.

Even though the theory of quantum chromodynamics is well defined, we do not know how to calculate all the processes that are governed by it, largely because of a lack of mathematical tools. The technical details simplify at high energies, while at low energies some processes are easier to calculate than others. In spite of the calculational difficulties, there seems to be little doubt that quantum chromodynamics is the correct theory of the strong interactions.

◀ **FIGURE 45–7** When an attempt is made to separate a quark from an antiquark by pulling them apart, it is energetically favorable to create a new quark–antiquark pair. This corresponds to the creation of two mesons from one.



▶ **FIGURE 45–8** A summary view of the fundamental particles and their interactions. Electric charges of the particles listed here are given in units of the proton's charge, and spins are given in units of $\hbar$. There are many more fermionic hadrons and bosonic hadrons than are described here, all of which can be accounted for by quantum chromodynamics. More complete copies of this chart can be obtained from Science Kit & Boreal Laboratories, 777 East Park Drive, Tonawanda, NY 14150. (Courtesy of Contemporary Physics Education Project.)

The Standard Model

Above we treated the electroweak and strong forces separately. But the same particles participate in these forces in ways that link reactions and decays. Therefore it is necessary to think about these forces, and the particles that interact through them, together. Additionally, there are self-consistency requirements in the form of the interactions that act between leptons and quarks. All this places strong constraints on the quantum numbers of the fundamental particles and the force carriers, and it is appropriate to bring all this together in what is called a **standard model** of fundamental particles and interactions.

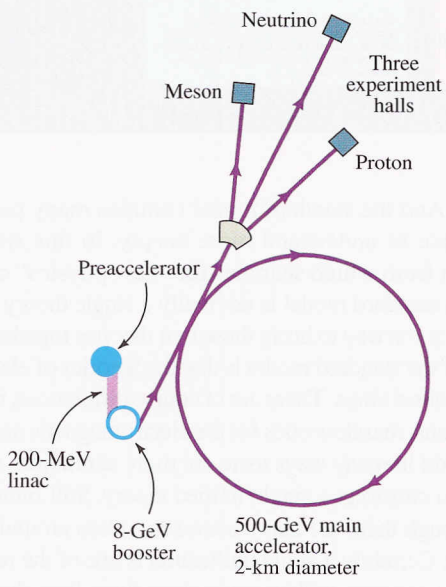
To the extent that we can perform the calculations necessary to make a prediction or perform the experiments necessary to test those predictions, the standard model has passed every test. Figure 45–8 is a chart that summarizes the standard model and hence much of the current state of knowledge about fundamental particles and forces. There are still holes to fill—for example, we do not yet know the size nor the nature of neutrino

masses. And the standard model contains many parameters whose origins and values one would like to understand more deeply. In this way, the standard model sets out a firm platform from which searches for "new physics" can be launched.

The standard model is not really a single theory of both electroweak and strong forces as much as it is a way to bring these two theories together under a single umbrella. One important aspect of the standard model is that the theories of electroweak and strong forces are constructed in identical ways. There are of course differences; these lead to massive carriers for the weak interactions, massless ones for the electromagnetic and strong ones, and to confined gluons and quarks. Yet in many ways there are more similarities than differences, and these have led to attempts to construct a single unified theory. Still more ambitious attempts include gravitation, but although there are many interesting ideas around, there has been little testable progress in this area. Certainly a grand unification is one of the major goals of fundamental research. If we are lucky, progress will be made along these lines during the lifetime of this book!

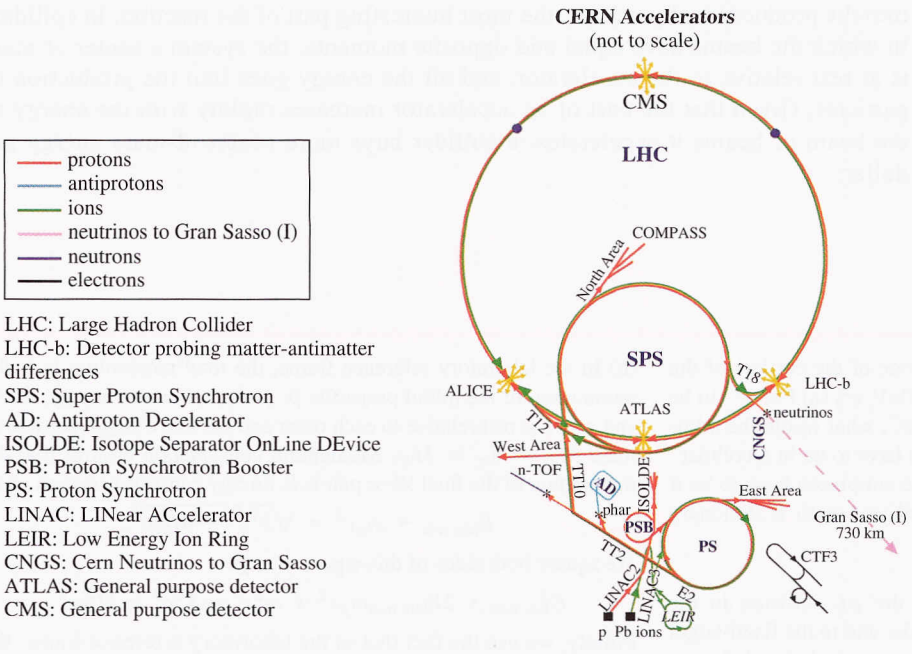
45–5 The Tools of Particle Physics

Richard Feynman compared the process of probing the behavior of elementary particles to seeing how a watch works by throwing two watches at each other and studying the array of gears and springs that come out. Actually, the situation is somewhat worse. We require high energies to see well at short distances, but high energies bring with them relativistic effects such as pair production (pairs of "watches and antiwatches" are produced). In addition, because of confinement, the gears and wheels cannot themselves be final products—just more watches, perhaps of a different design but made from those same gears and wheels. Many of the particles that result are unstable and decay so quickly that we can see only their decay products. Finally, the collisions being studied are relatively rare, so a high flux of colliding particles is necessary.



The problem of designing experiments to study the behavior of particles at short distances is twofold: First, we require particle accelerators that have the best possible combination of high energies and high beam currents. Second, we need detectors that enable us to analyze the results of collisions. In constructing accelerators and detectors, physicists have pushed technologies to their limits. The results have been scientifically and technologically rewarding.

Accelerators



The principle of modern particle accelerators is the repeated acceleration of a stable charged particle by an electric field. A magnetic field controls the path that the beam of accelerated particles follows. Beyond these basic ideas, a variety of techniques are used in different accelerators.

Electrons or Protons: Electrons have revealed no substructure: They appear to be as elementary as quarks. In addition, it appears that electrons and quarks are *both* necessary in quantum mechanical models with calculable predictions. These facts suggest a possible unification between strongly interacting particles and particles that interact by means of the electroweak interactions. Thus there is as much interest in the observation of electron collisions as in the observation of proton collisions; accelerators exist that allow us to study pp, $p\bar{p}$, ep, and e^+e^- collisions. Proton collisions are of interest in the sense that they represent collisions involving quarks.

Fixed-Target Machines or Colliders: Until the 1960s, virtually all accelerators were *fixed-target machines*, in which an accelerated beam is incident on a target (Fig. 45–9). In a fixed-target machine, the beam is typically extracted and directed to a fixed target such as liquid hydrogen. The advantages of such an accelerator are

▶ **FIGURE 45–9** Schematic diagram of a fixed-target machine, in this case an early version of the accelerator at the Fermi National Accelerator Laboratory. Note the several stages of acceleration (beginning with the preaccelerator and a linear accelerator section, or linac) and the extensive target areas (experiment halls), where beams extracted from the ring of the main accelerator collide with fixed targets.

▲ **FIGURE 45–10** Schematic diagram of the various CERN accelerators including the large hadron collider (LHC) currently under construction near Geneva, Switzerland. The entire LHC ring is not to scale—the large ring has a circumference of some 27 km. Protons and antiprotons are injected into the LHC accelerator and travel in opposite directions before colliding.

that a huge number of target particles can be spread throughout any volume and that there is only one beam to manage. These machines have systematically been replaced by *colliders*, in most of which two moving beams of particles with equal but opposite momenta interact in head-on collisions with one another (Fig. 45–10). Table 45–3 lists the characteristics of some advanced colliders. We know that the momentum of the center of mass of a system of interacting particles is constant. When a moving particle collides with a stationary target, the center of mass has nonzero momentum, which is maintained after the collision. Thus a large fraction of the incident energy remains in the motion of the center of mass rather than going

TABLE 45–3 • Characteristics of Some Colliders

Name	Laboratory, Location	Particles	Maximum Beam Energy (GeV)

LHC (under construction) Large Hadron Collider	European Laboratory for Particle Physics, CERN, Geneva, Switzerland	pp	7,000
		Pb-Pb	2760/u

into the production of particles, the most interesting part of the reaction. In colliders in which the beams have equal and opposite momenta, the system's center of mass is at rest relative to the accelerator, and all the energy goes into the production of particles. Given that the cost of an accelerator increases rapidly with the energy of the beam or beams it accelerates, a collider buys more center-of-mass energy per dollar.

EXAMPLE 45–8 The W^+ particle, one of the carriers of the electroweak force, has a mass of about 80 GeV/c^2. (a) For W^+ to be produced in the reaction $p + \bar{p} \rightarrow W^+ + \pi^-$, what would the minimum energy of the proton (and antiproton) have to be in a collider? (b) What would the minimum energy of the antiproton have to be if the same reaction were to occur in a collision with a stationary proton?

Setting It Up Figure 45–11 shows the $p\bar{p}$ collision in the frames of reference appropriate to the collider and to the fixed-target machine, with the momenta and energies appropriately labeled.

Strategy In both cases, we write down the energy and momentum conservation equations. In both cases the minimum energy required is one in which the W^+ and the π^- have no relative momentum, that is, they act as a single particle of mass $M_W + m_\pi$. Since the pion mass is a factor of about 500 smaller than the W mass, we can ignore it in the expressions for energy as a function of momentum.

Working It Out (a) We first express energy conservation in the center-of-mass reference frame, in which the initial particles have the same energy E. This yields $2E = E_W + E_\pi$. The minimum energy, $E = E_{\text{min}}$, corresponds to the W^+ and π^- both produced at rest, so $E_W = M_W c^2$ and $E_\pi = m_\pi c^2$. With $m_\pi \ll M_W$, we have $E_\pi \ll E_W$,

$$E_{\text{min}} \cong \frac{1}{2} M_W c^2 \cong \frac{1}{2}(80\ \text{GeV}) = 40\ \text{GeV}.$$

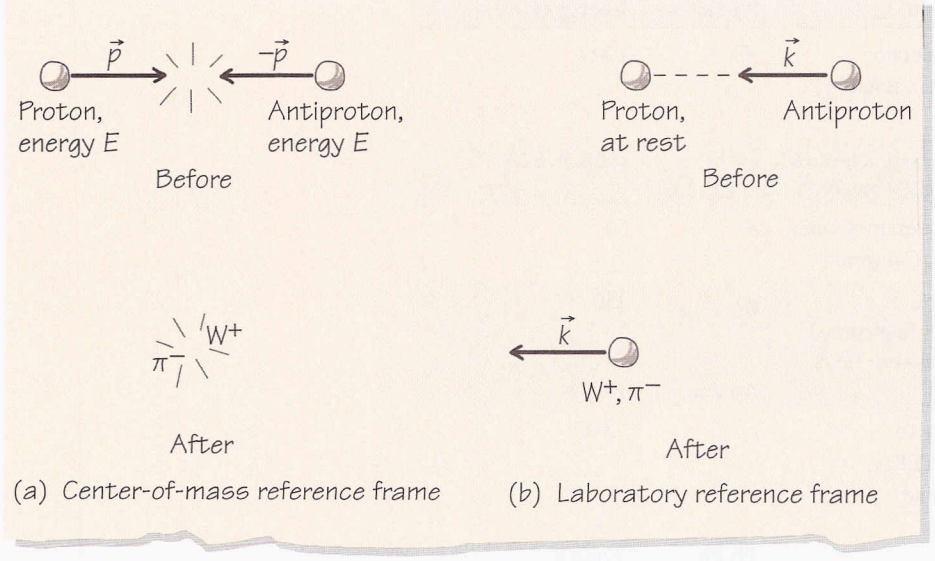
(b) In the laboratory reference frame, the total momentum is k, the momentum of the initial projectile $\bar{p}$. At the minimum energy, the W and π are at rest relative to each other and act like a single particle of mass $M_W + m_\pi \cong M_W$. Momentum conservation ensures that the momentum of the final W–π pair is k. Energy conservation then gives

$$E_{\text{lab, min}} + m_p c^2 = \sqrt{k^2 c^2 + M_W^2 c^4}.$$

We square both sides of this equation to get

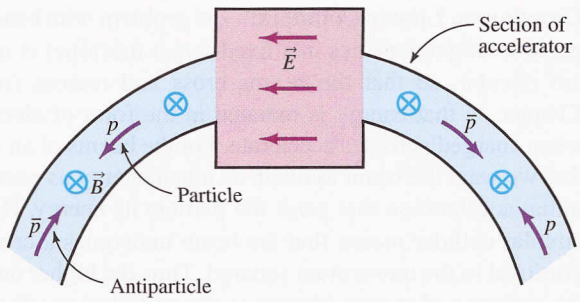
$$E_{\text{lab, min}}^2 + 2E_{\text{lab, min}} m_p c^2 + m_p^2 c^4 = k^2 c^2 + M_W^2 c^4.$$

Finally, we use the fact that in the laboratory reference frame, the energy of the initial $\bar{p}$ is related to its momentum by $E_{\text{lab, min}} = \sqrt{k^2 c^2 + m_p^2 c^4}$. We square this relation and substitute for the term $E_{\text{lab, min}}^2$ in the preceding equation:



$$k^2 c^2 + m_p^2 c^4 + 2E_{\text{lab, min}} m_p c^2 + m_p^2 c^4 = k^2 c^2 + M_W^2 c^4,$$

an equation we can solve for $E_{\text{lab, min}}$. Since $m_p \ll M_W$, we get

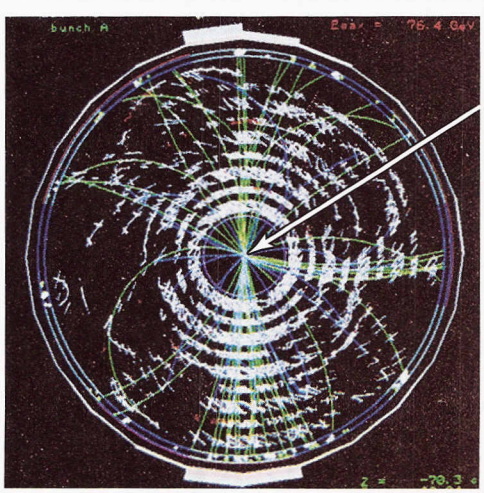


$$E_{\text{lab, min}} = \frac{M_W^2 c^4}{2m_p c^2} \cong \frac{(80\ \text{GeV})^2}{2(0.94\ \text{GeV})} = 3400\ \text{GeV}.$$

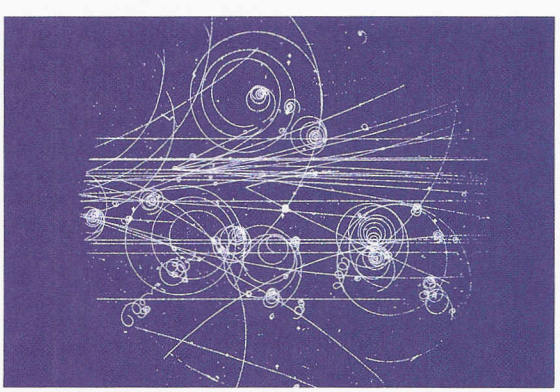
The huge difference between the answers to parts (a) and (b) illustrates the advantage of colliders. It is far cheaper to accelerate two beams to 40 GeV each than to accelerate one beam to 3400 GeV.

What Do You Think? The top quark has mass such that $M_t c^2 = 175$ GeV. Would you expect to need about 175/2 = 88 GeV per particle to produce a top quark in a $p\bar{p}$ collider like that described above?

◀ **FIGURE 45–11** (a) The reaction as seen in the center-of-mass reference frame. (b) The reaction as seen in the laboratory reference frame.



◀ **FIGURE 45–12** In a collider, the same magnetic fields guide both particle p and antiparticle $\bar{p}$, and the same electric fields accelerate both p and $\bar{p}$.



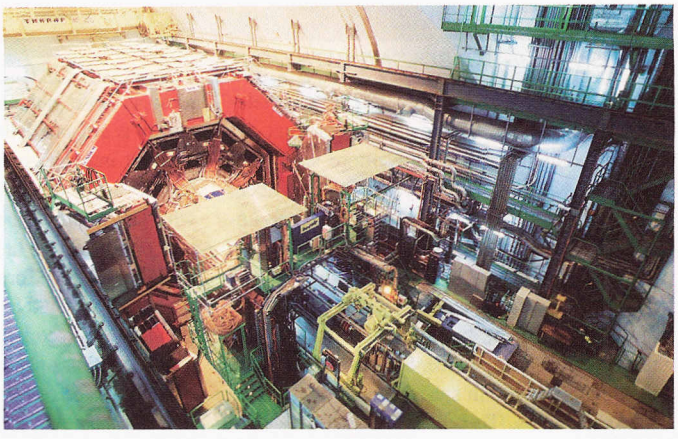
The difficulty in controlling the two beams of a collider is not as great as you might imagine. In the large ring of Fig. 45–10, within which both particles and antiparticles circulate in opposite directions, the same electric field that accelerates particles in one direction accelerates their antiparticles in the other direction, and the same magnetic field that forces charged particles to follow a counterclockwise path also forces their antiparticles to follow a clockwise path (Fig. 45–12). Thus the same fields can be used for a beam of both electrons and positrons, or protons and antiprotons. The major complication is that the two beams must be concentrated and steered so that they only cross at isolated points where the collisions occur; at those points, elaborate detectors, whose locations are marked on Fig. 45–10, monitor the results of the collisions.

We have shown that colliders are energetically advantageous. A second advantage of a collider concerns the distribution of the many particles that are produced in a collision. In the center-of-mass reference frame, the particles produced are spread over all angles (Fig. 45–13), and this is the way the reaction appears in a collider. The fact that the center of mass moves in a fixed-target machine means that the particles produced are carried forward with it and hence concentrated in a narrow cone in the forward direction. As Fig. 45–14 shows, this concentration makes it hard to separate the products.

Each beam of a collider provides a target for the other beam that contains far fewer target particles than does a fixed-target machine. Thus the rate at which collisions occur is much smaller in a collider than in a fixed-target machine. This is not always a disadvantage because the reactions we observe at very high energies produce so much information that even the best computers cannot keep up with data that arrive too rapidly. But when rare reactions are to be studied, a fixed-target machine has advantages.

▲ **FIGURE 45–13** A collision at the TEVATRON collider at the Fermi National Accelerator Laboratory, as recorded in the Collider Detector Facility. The white and green lines are produced in the concentrically oriented cylindrical detectors and indicate the passage of particles. The view is an end-on one—that is, along the direction of the colliding beams. A substantial number of particles are produced at right angles to the beams.

▲ **FIGURE 45–14** This image shows the tracks left in a bubble chamber by the passage of charged particles in a bath of liquid hydrogen colliding with the hydrogen in the chamber. By adjusting the pressure within the chamber, bubbles condense around the ions that are left along the trail of an energetic particle. The chamber is contained within a magnetic field, and the curvature of the tracks due to the presence of the field is evident.



Circular vs. Linear Colliders: The problem with beams that are not very dense (compared to target densities in a fixed-target machine) is in part overcome in colliders that are circular, so that the beams cross and recross frequently. However, recall from Chapter 34 that energy is radiated in the form of electromagnetic waves (or photons) when charged particles accelerate. For the beams of an accelerator, this is undesirable in that we want the beam to retain as much energy as possible. This is unavoidable for the initial acceleration that gives the particle its energy. However, the circular motion in a circular collider means that the beam undergoes a centripetal acceleration that is proportional to the momentum squared. Thus the higher the energy of the beam, the greater the radiation of energy. Moreover, the particles' acceleration is inversely proportional to their mass, so lighter particles, such as electrons, radiate energy at a higher rate than do heavier particles, such as protons. LEP, a now-defunct circular machine that accelerated electrons and positrons to 60 GeV each in a ring of radius 5 km was at about the limit for an electron collider in the form of a ring—at higher energies, the electron beam loses too much of its energy with each turn. The alternative is to construct a linear accelerator in which a new electron beam is repeatedly generated along a straight beam tube without following a circular trajectory. A linear collider—two linear machines with their beams meeting head-on—provides the best solution. The major disadvantage of such a machine, which has indeed been constructed on a demonstration basis (SLC in Table 45–3), is that the beams cross only once, so there is relatively little chance for collision. To overcome this difficulty, the beams are concentrated to only a few microns in size, a tiny fraction of the size of the beams of other accelerators; these beams must then cross with a remarkable precision. Such machines appear to be the only way to construct electron colliders with energies much greater than those of LEP.

Detectors

The devices that observe and analyze collisions in particle accelerators are called *detectors*. Detectors have undergone continual evolution since Joseph J. Thomson first detected the electron in 1897. Subnuclear particles can be detected because they leave a trace of energy as they pass through or decay within a detector. For example, a charged particle that passes through a *photographic emulsion* (a suspension used to coat photographic plates, film, and paper) leaves the same kind of trace that light does. Stacks of photographic emulsion formed the earliest detectors (Fig. 45–15)—most of their use occurred up to the mid-1950s—and allowed scientists to learn much about the charged particles that enter Earth's atmosphere (*cosmic rays*). The resolution of emulsions—their ability to pinpoint a particle track—is less than a micron (10^{-6} m). A similar detection technique uses the fact that a liquid near its boiling point forms bubbles of vapor along

▶ **FIGURE 45–15** This image has been formed within a photographic emulsion. Where charged particles pass, a black line forms. At point *A* a reaction has occurred. One of the reaction products has either come to rest or decayed to neutral products at point *B*. Detailed track analysis can tell which.

◀ **FIGURE 45–16** A large modern detector facility such as the L3 detector in an accelerator at the European laboratory CERN, in Geneva, Switzerland is a huge and complex operation. Collisions of highly energetic beams take place deep within the detector. The multiple layers of detecting devices that surround the collision point analyze the results of the collision. The scale of this detector is impressive—note the catwalks in the photo.

the path of a passing charged particle. In use until the 1980s, *bubble chambers* filled with liquid hydrogen utilized this technique (Fig. 45–14). More modern types of detectors register the passage of a charged particle or of neutral particles, such as photons, by their characteristic effects on the electronic properties of the detector.

A detector may be sensitive to the total amount of energy a particle deposits as it is brought to a stop within the detector (a *calorimeter*), or the rate at which it loses energy as it passes through. In a supplementary technique, the particle's momentum is determined by measuring the amount of curvature in the path of a passing particle in a magnetic field of large, known magnitude within a detection region. Knowing both the momentum and energy, we can calculate the mass, so the particle can be identified. Particle identification is important and not so simple at high energies.

Photographic emulsions record everything that passes through them. Techniques that use electronic *triggers* avoid this difficulty. For example, suppose that you are interested in viewing only those events in which a muon (see Section 45–2) of high energy is produced. Muons pass through matter more easily than do protons or other strongly interacting particles. Then it is possible to surround the interaction region with a great deal of matter—such as many tons of steel—and outside this matter to place a detector that registers electronically the passage of charged particles. This detector emits a signal that the particle is likely to be a muon and thereby acts as a trigger to register the rest of the event. Modern detectors are huge and complex (Fig. 45–16). The electronic registration of the passage of dozens or even hundreds of particle tracks requires vast information storage facilities and powerful computers to extract the most useful information. The computers and analysis techniques developed in these experiments have filtered down to more general use. The World Wide Web is a direct by-product of the need of particle physicists to exchange large amounts of information.

45–6 Cosmology and the Expanding Universe

Giordano Bruno was burned at the stake in 1600 in large part for claiming that the universe is infinite. Although passions have calmed somewhat, people have always had a lively interest in the nature of the cosmos as a whole (*cosmology*). Powerful telescopes have allowed us to see far back into the past, and as a consequence, we know a great deal today about the very early stages of our universe.

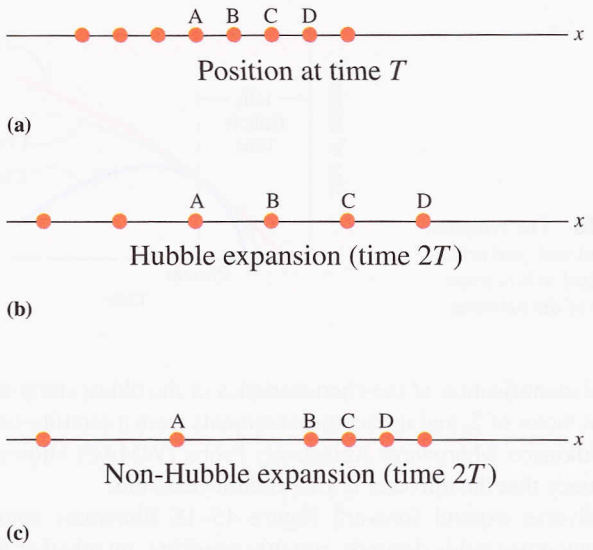
Once Newton discovered the universal law of gravitation, it became possible to ask whether the universe was finite or infinite. Newton pointed out that in a finite universe, the seemingly uniform distribution of stars was unstable. Suppose two stars start moving closer to each other. They get further away from their other neighboring stars, so that any attraction impelling them back to their stable positions is decreased. As they get close together, they create a larger mass, which is then a stronger point of attraction for neighboring stars. You can easily see that there would be a tendency for ever more gravitational clumping of stars. Newton came to the conclusion that the only way to avoid this problem was for the universe to be infinite. This point of view, however, presents its own problems in the form of what is known as *Olbers' paradox*.

THINK ABOUT THIS. . .

WHY ISN'T THE SKY BLAZING WITH LIGHT?

Olbers' paradox was stated in 1823, when telescopic observations had made it clear that the universe contains many, many more stars than are visible with the naked eye. Heinrich Olbers argued that, if the universe were infinite and unchanging, then, regardless of the direction in which we looked, we would see a star and star light would cover the entire sky. We cannot dispute this argument by arguing that distance makes stars too faint to see. Suppose that N stars are contained in a thin spherical shell a distance R away from us. Then, because the area of a sphere increases as the radius-squared increases, there would be $4N$ stars in a shell a distance $2R$ away from us. The intensity of the light decreases as the distance-squared increases, so each star in the more distant shell is only one-fourth as intense as those in the nearer shell, but the total intensity is *independent* of the distance of the shell. The net intensity of an infinite number of concentric shells would be infinite. Yet—and this is what constitutes Olbers' paradox—the night sky is not bright. If the universe were infinite and had been in existence forever, as in Newton's picture, the paradox would be a real problem. But the Big Bang model (see below), in which the universe has existed for only a finite time and is moreover of finite size, resolves Olbers' paradox. If the universe has existed for only a finite time, then any one star has been radiating for a finite time, and there has not been enough time for the radiation from all stars—even if there were an infinite number of them—to have filled the universe and created a bright night sky.

The *science* of cosmology really started after Einstein discovered the general theory of relativity and with it the connection between gravity and the geometry of space. Einstein's starting point was based on the observations that the distant objects in the sky are (a) distributed isotropically—things look more or less the same whatever direction we look in, and (b) are distributed homogeneously—on the average there are the same number of objects in any large volume of a given size that one looks at. These basic assumptions form the **Cosmological Principle**. Einstein's original equations were found by Alexander Friedmann to lead to a nonstatic universe, which meant that the universe would expand, then possibly undergo a subsequent collapse. The Friedmann solutions soon found support in the work of the astronomer Edwin Hubble.



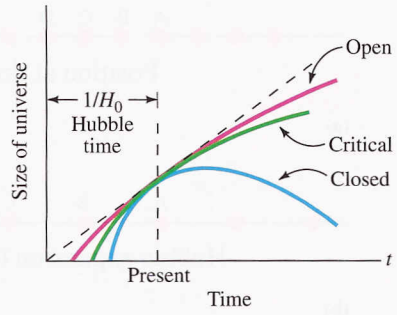
Hubble's Law

Before 1923, nebulae were thought to be glowing clouds of gas within our own galaxy. (It was only a few years before this that Harlow Shapley had determined that what we now know to be our galaxy has a definite shape and that our Sun is far from the galaxy's center.) In 1923, Edwin Hubble identified the nebulae as galaxies like our own and thereby took a giant step toward the understanding of the universe. Hubble used the Mount Wilson telescope in southern California, the first telescope sufficiently powerful to distinguish individual stars in the nebulae. Hubble also measured the spectral lines of stars in the galaxies and showed that, on average, those lines are redshifted, indicating a movement away from us. Hubble's law (1929) relates the average speed u with which another galaxy retreats from our own to a distance D away from us [Eq. (39–17)]:

$$D = \frac{u}{H}. \tag{45–13}$$

H is the *Hubble parameter*, measured to be $H \cong 2.5 \times 10^{-18}\ \text{s}^{-1}$. The redshift gives the speed of recession directly, but how did Hubble know the distance of a given galaxy from our own? He made observations of the cepheids, a class of powerful stars whose systematic waxing and waning was found by Henrietta Leavitt in 1907 to be strongly correlated with their luminosity. The luminosity, or intensity of emitted radiation, of cepheids observed in distant galaxies could be compared with similar cepheids within our own galaxy, and using the inverse square law for the decrease in intensity, their distance could be determined.

There is also *independent* evidence that objects with large redshifts, such as quasars, are very distant: We see some of them through gravitational lenses (Chapter 39). This is possible only if these quasars are much farther than the galaxies that produce their images through the bending of the quasar light. The distances calculated from the lensing effect are consistent with those provided by Hubble's law.



▲ **FIGURE 45–17** (a), (b) Two successive times in a one-dimensional version of Hubble's law. The points (galaxy positions, for example) remain equally spaced along the line. (a), (c) The same two successive times in a (non-Hubble) expansion law in which all the points recede from point A at the same speed, independent of their distance from A. Point A is a special point in the non-Hubble expansion law.

Hubble's law states that *the universe is expanding*. More accurately, we say that *space is expanding*. You might think that Hubble's law places Earth (or our galaxy) in a privileged position in the universe. In fact, it means just the opposite, as the following one-dimensional analogue shows. Figures 45–17a and 45–17b show a line of galaxies at times T and $2T$, respectively, after the moment that the expansion started, which we place at $t = 0$. At time T the galaxies are evenly spaced, and there is no preferred point in this arrangement. We have identified our galaxy (galaxy A) and supposed that Hubble's law holds. Therefore, galaxy C, which is twice as far from us as galaxy B, recedes from us at twice the speed with which galaxy B recedes. We see that at time $2T$, galaxy C is still twice as far from us as galaxy B. The galaxies continue to be uniformly spaced, and no point along the line is preferred. Hubble's law can be contrasted with a law in which other galaxies retreat from ours at constant velocity. While the galaxies may be evenly spaced at time T, this is no longer the case at time $2T$, and galaxy A occupies a special point (Fig. 45–17c). In fact, Hubble's law is the unique law for galactic speeds by which no one galaxy occupies a special point within the cosmos (see Problem 38). A two-dimensional analogue of the situation described by Hubble's law is provided by dots painted on a spherical balloon (Fig. 39–13). When the balloon is blown up, *all* the dots recede from each other, with no dot occupying any special position, and a law like Hubble's law holds. If we lived on the surface of such a balloon, any voyage we took would eventually take us back home, and we would conclude that there is no "outside."

It has taken centuries of discussion for humankind to understand that it is not at the universe's physical center. There *is* no center. It is not as though we are now living in a space in which an explosion once occurred; such a description would imply a privileged point, the position of the explosion itself. Rather, all of space began as a small volume *with no outside*.

Hubble's law with a constant value of H can be used to find the time required for galaxies to separate by given amounts (see Problem 42). Unfortunately, if the law is used as it stands to find the time at which all matter was together, that time is infinite (see Problem 43)! Thus if there was an initial moment when the universe started to expand, Hubble's law with a constant value of H cannot hold all the way back to that time. We can, however, use the law to make an estimate: If we assume that the recession speed is constant, Eq. (45–13) states that the expansion time (the *Hubble time*) is just H^{-1}, some 13 billion years. Other information (for example, theoretical knowledge of stellar evolution

▶ **FIGURE 45–18** The evolution with time of open, closed, and critical universes. The vertical axis is some measure of the size of the universe.

and experimental identification of the characteristics of the oldest stars) confirms this estimate to within a factor of 2, and in fact measurements from a satellite-based experiment known as the Wilkinson Microwave Anisotropy Probe (WMAP) allows us to say with one percent accuracy that the universe is 13.7 billion years old.

Will the universe expand forever? Figure 45–18 illustrates some possibilities. Which of these outcomes holds depends, roughly speaking, on whether the gravitational pull of the energy contained in the universe is strong enough to slow down, and perhaps reverse, the expansion. A serviceable analogy is that of the escape velocity from a massive body. If there is too little mass, then an object hurled out with a certain energy will escape from the body; if the mass of the body is large, then the object will fall back. There is a critical density of energy for which the expansion will go on forever, but will slow down and come asymptotically to a stop at infinite time. This critical energy density is given by the formula

$$\rho_{\text{crit}} = \frac{3H^2}{8\pi G}, \tag{45–14}$$

where H is Hubble's parameter and G is Newton's constant. Less density than this and the expansion goes on forever; more density and the universe recollapses. This information is often stated in terms of the ratio Ω of the density to the critical density. If $\Omega > 1$ the universe will recollapse.

What is the value of Ω? If we look at luminous matter, mainly consisting of the 10^{11} stars in each of 10^{11} galaxies, we find $\Omega \cong 0.02–0.05$ or so. That, however, is not the whole story, since there is much evidence that *dark matter* exists (see Chapter 12), by which we mean matter that does not shine. Estimates of the amount of dark matter can be made in various ways, including the observed rotation profiles of galaxies and the frequency of gravitational lensing, and the conclusion to such estimates is that there is even more dark matter than luminous matter. Nevertheless, inclusion of dark matter boosts Ω only to 0.2–0.3.

A value for Ω of, say, 0.3 is a rather unsatisfactory number; in fact, any number other than $\Omega = 1$ presents problems. We can define a unit of time appropriate to cosmology which involves Planck's constant $\hbar$, c, and Newton's gravitational constant G. This unit is known as the *Planck time* τ_P:

$$\tau_P = \sqrt{\frac{\hbar G}{c^5}} \cong 5.4 \times 10^{-44}\ \text{s}. \tag{45–15}$$

In terms of this unit the universe is 10^{62} units old. This is *very old*, and any random value of $\Omega > 1$ in the early universe would have the universe collapse very quickly, or, if $\Omega < 1$, expand much too rapidly to allow for galactic evolution. In fact, calculations show that the only way to have a value of Ω in the vicinity of $\Omega = 1$ today is to have an early-universe value of Ω equal to one with a precision of one part in 10^{57}! The kind of fine tuning that would be necessary to lead to some value of Ω like 0.3 right now is very unnatural, and it is this kind of thinking that favors Ω *exactly* equal to one both in the early universe and therefore also today.

Current thinking about Ω relies on new observations that seem to suggest that the expansion of the universe, instead of slowing down, is actually accelerating. This can be

interpreted as being due to something called *dark energy* which acts as a form of antigravity. These are new issues, and there are no compelling arguments about what the nature of this dark energy is. With the inclusion of dark energy, it is possible to arrive at $\Omega = 1$. All this is more than theoretical speculation: Measurements from the aforementioned WMAP experiment have led us to the conclusion that to within experimental error, $\Omega = 1$.

The Big Bang Model

The physicist George Gamow was the first to conclude that if other galaxies recede from ours at a speed proportional to their distance from us, then *at some time in the distant past, all galaxies must have been very close together*. This fact defines what is conventionally called the Big Bang model of the history of the universe.

Gamow was interested in how the elements were formed, and he went through the exercise of "running the film of the universe expansion backwards." One would see matter getting denser, and as we know from kinetic theory this would mean a rise in temperature. At some point the temperature would be such that electrons would be stripped from nuclei. At still higher temperatures—earlier times—the nuclei would break up into protons and neutrons, and in due course these would break up into quarks. (Of course, Gamow could not have known about this last step at the time he thought about this.) Let us look more closely at various stages in the lifetime of the universe.

We are currently living in what is called a *matter-dominated* era. The luminous matter in the universe is confined to galaxies and there is much empty space between galaxies. We may speak of an *average density* of matter, and it is small.

EXAMPLE 45–9 Given that at present there are 10^{11} stars per galaxy and on the order of 10^{11} galaxies, *estimate* the density of visible matter across the universe. You may assume that a typical star is like the Sun and that the size of the universe is of the order of 14×10^9 light-years.

Strategy The total mass M of visible matter is estimated by multiplying the number of stars, 10^{22}, by the mass of the Sun, 10^{30} kg. Then to estimate the density, we divide this mass by the volume,

$$\rho = \frac{M}{4\pi R^3/3},$$

with the radius $R = 1.4 \times 10^{10}$ light-years.

Working It Out Note that 1 light-year is the distance light travels in one year, or 3.15×10^7 s. Thus

$$\begin{aligned}\rho &= \frac{3M}{4\pi R^3} \\ &= \frac{3 \times 10^{22} \times 10^{30}\ \text{kg}}{4\pi[(1.4 \times 10^{10}\ \text{ly}) \times (3.15 \times 10^7\ \text{s/y}) \times (3 \times 10^8\ \text{m/s})]^3} \\ &\cong 10^{-27}\ \text{kg/m}^3.\end{aligned}$$

Compare this tiny number with the density of liquid water, 10^3 kg/m^3!

What Do You Think? How would you express your answer in terms of hydrogen atoms per cubic meter?

As we go back in time, the density of matter increases, and with less gravitational potential energy there is more kinetic energy. The temperature thus rises. At temperatures of the order of 1.5×10^5K, atoms ionize, and we enter a period in which matter is in the form of a *plasma* of charged electrons and ions. Charged particles radiate, but the radiation is re-absorbed by the charged particles, and equilibrium between radiation and matter is established. As the temperature rises further and particle energies increase, electron–positron pairs are created. Moving backward in time, nuclei dissociate into protons and neutrons when kT approaches the 8–10 MeV range. Earlier still, the protons and neutrons fall apart into their constituent quarks. We are dealing with a kind of quark–gluon plasma, a state of matter not yet seen in the laboratory. At higher temperatures, quark–antiquark pairs are produced, and all of the particles, antiparticles, and gluons are in equilibrium. We can trace the evolution all the way back to 10^{-11} s after the Big Bang using physics that we understand!

It is instructive to go forward in time from a period when quarks have reassembled into neutrons and protons. This is about *one thousandth of a second* into the existence of the universe, when the temperature is about 10^{11}K. There are protons, neutrons, electrons, positrons, neutrinos and antineutrinos present and, of course, photons. This is a *radiation dominated* era, and the physics that governs the behavior of the fundamental

particles at this temperature is well understood. The number of protons and neutrons is equal, because they can convert into one another through the weak interactions (the leptons must also play a role here). As the expansion proceeds, it takes about a second for the density to drop by a factor of 10^4. Neutrino interactions, which are important at high energies (high temperatures), become much weaker as the temperature falls, and they pretty well stop playing a role in the interconversion of protons and neutrons. It is still too hot for nuclei to form. About 14 seconds later, the temperature has dropped to three billion degrees. There is now not enough energy in collisions to create electron–positron pairs, and when the electrons and positrons that are already present annihilate, they are not recreated. They leave behind photons, and an excess of electrons of one part in 10^9.

It takes a full three minutes from our starting point of one-thousandth of a second after the Big Bang before the temperature has dropped to 10^9K, a number that is about 70 times hotter than that at the Sun's center. This is a significant temperature because below it an initial step in the formation of helium and tritium takes place. The formation of these nuclei must occur in stages in which the reaction

$$n + p \rightarrow \text{deuteron} + \gamma$$

is an essential step. The deuteron is a rather weakly bound state of neutron and proton, and it takes another minute or so before the reactions

$$\text{deuteron} + \text{deuteron} \rightarrow {}^3\text{He} + n$$

and

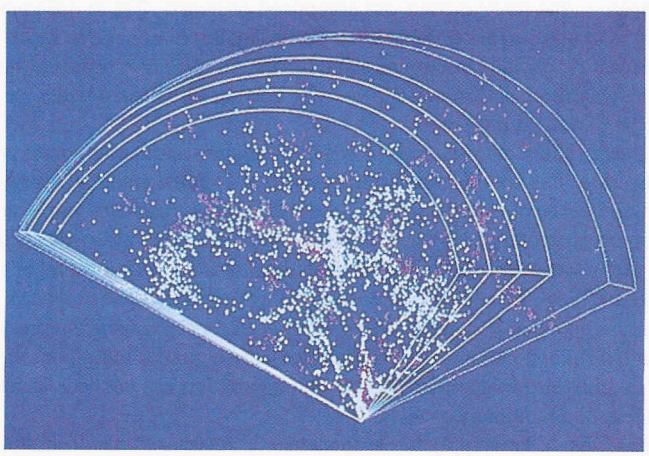
$$\text{deuteron} + {}^3\text{He} \rightarrow p + {}^4\text{He}$$

can occur. By now, pretty much all of the neutrons have either beta-decayed or been bound in the helium nucleus, and *no more nuclear reactions* take place. Detailed calculations show that the nuclei that are formed are 75 percent protons (hydrogen nuclei) and about 25 percent helium.

THINK ABOUT THIS. . .

WHY IS THERE MORE MATTER THAN ANTIMATTER IN THE UNIVERSE?

Looking around us, we observe that *there is an apparent domination of matter over antimatter in the universe*. Although we have no direct evidence that distant galaxies are made of matter rather than antimatter (antimatter would form antiatoms with exactly the same emission spectra as atoms), there is much indirect evidence that the amount of antimatter in the universe is severely limited. For example, even though Earth is continually bombarded from distant space by cosmic rays, these particles consist of matter, not antimatter. The collision and annihilation of antimatter and matter would produce spectacular emissions of radiant energy. Yet if a hot early universe had equal amounts of matter and antimatter, which is a fair assumption given our description, how is it that today there is so little visible antimatter?



Experimental evidence from the weak decays of certain particles indicates that physical processes are not quite symmetric under the reversal of time. This is not a statistical time's arrow, like that discussed in Chapter 20, but rather a real, if tiny in its effect, directionality of physical processes. To use the language of Chapter 20, a film of fundamental physical processes that is run in the forward direction would look slightly different than the same film run backward. Although we do not yet fully understand the origin of this effect, its implications have been explored. One of its consequences is that to a very slight degree matter is preferentially created over antimatter in the ensemble of possible reactions that could have occurred up to time $t = 10^{-12}$ s. For every 10^9 antiquarks created, roughly $10^9 + 1$ quarks are created, and the same ratio has to hold for the electrons. Later, when the universe had cooled to the point where the average collision energy in the cosmic soup was insufficient to make particle–antiparticle pairs, as in the case of electrons and positrons discussed in the text, then production of those pairs no longer took place. The existing particles and antiparticles annihilate each other and are not re-created in collisions. At this point, the slight predominance of matter over antimatter becomes all-important, with the excess matter persisting, even an excess as small as one part in 10^9.

At three minutes it is still far too hot for atoms to form. During the subsequent 700,000 years, any electrons briefly bound to nuclei are immediately knocked away from them, mainly through the absorption of photons—these photons, like all the constituents of the plasma, are in thermal equilibrium at whatever the temperature is at any time, and so they are on average highly energetic. Once the temperature drops enough so that the electrons remain attached to nuclei, atoms can form. The photons are no longer absorbed and can travel easily through what is now a collection of atoms—the universe becomes *transparent to photons*. We say that there is a *decoupling* between matter and radiation at some critical temperature T_c. There is another effect: The photon distribution (the Planck blackbody distribution at $T = T_c$) no longer changes, *except* that the further expansion of the universe leads to a predictable cooling of the photon "gas" as a function of time—Gamow and collaborators predicted that blackbody radiation at a temperature of about 5K would be found today. The distribution of such radiation has a peak in the microwave region. Nobody paid much attention to this prediction until the early 1960s, when Arno Penzias and Robert Wilson of the Bell Laboratories detected microwave radiation of just this type, now known as the *cosmic background radiation*. While the measurement did not find the temperature that Gamow and his collaborators had predicted, more accurate calculations by a group led by Robert Dicke at Princeton University, who at the time were on the verge of measuring this radiation, predicted that the temperature would be closer to 3K. More recent measurements give a value of this temperature of 2.725K $\pm$ 0.001K, an accuracy of 1 part in 10^4. You can read more about this fascinating story in Section 17–5.

The correct prediction of the cosmic blackbody background radiation and of the measured helium abundance in the universe were the "smoking guns" that have led to the acceptance of the Big Bang as the correct description of the evolution of the universe. Nuclei heavier than helium (except for a trace of light nuclei like lithium) are formed in stars. Very detailed calculations using our best knowledge of nuclear physics reproduce the observed abundance of all the elements in the universe.

The Uniformity of the Universe

Matter distribution in the universe is granular, or clumped. Galaxies (clumps of stars) are grouped into clusters, and there are large regions with no visible matter (Fig. 45–19). The granular structure is thought to have developed from small, random fluctuations in a uniform energy density, forming small clumps of higher density. Such clumps act as seeds, gathering matter into them under the influence of the gravitational force. The process is much like the formation of clouds, whose droplets require "nuclei" of some kind. The initial density fluctuations that started the process must have begun at

▲ **FIGURE 45–19** This view of many galaxies reveals a well-developed structure of clumping and voids. One of these features, the roughly horizontal band of galaxies about half-way up from the lower point, has received a name—the "great wall."

a time not too late in the evolution of the universe. The 3K background radiation should contain some "memory" of these fluctuations. High-precision studies of this cosmic background radiation, and in particular of the pattern of tiny fluctuations in it across the sky, have provided evidence in favor of the conjecture that during a very early period known as the *inflation period*, at times of the order of 10^{-35} seconds, the expansion of the universe went through a brief phase of very rapid, *exponential* expansion. This conjecture can be shown to lead to a density of energy given by $\Omega = 1$, which as we described above is very much the value favored by workers in this field.

45–7 A Few Last Words

In the introduction to this text, we spoke of macroscopic and microscopic realms. For centuries, technologies developed through the manipulation of matter in the macroscopic realm on the basis of empirical knowledge. The fact that matter consisted of atoms, and that the behavior of atoms was governed by quantum mechanics, initially had very little impact on the way engineers worked. Scientists, by contrast, have always been interested in the fundamental questions of their own time, many of which seemed to be rather remote from practical application. Today this has all changed. Technology develops to a larger and larger extent on the basis of scientific knowledge. The bulk of today's technology is built on quantum principles and on an understanding of the quantum nature of matter. It is unimaginable that our society could operate without the quantum physics–based circuit elements that make computers or electronic communication possible, or that a chemical engineer could construct new molecules without knowledge of their microscopic structure. While engineers continue to build bridges, those bridges are built on a solid understanding of the microscopic behavior of the materials that comprise the bridges and with the aid of computers that depend on the microscopic realm.

We are still learning how to apply quantum mechanical ideas to bulk materials. We are still in the process of evaluating how to make the best use of our scientific understanding of atoms and nuclei. And we have not yet seen how we can directly apply the knowledge we have gained in the areas of particle physics and cosmology. But we can say with confidence that if our society continues in anything like its present form, we shall certainly use our new knowledge.

Summary

At the microscopic scale, matter exhibits a series of levels, one within the other. Bulk matter is made of atoms and molecules (themselves made of atoms); atoms are built from electrons and nuclei; nuclei are constructed from nucleons (protons and neutrons); and nucleons and other particles that participate in the nuclear force are comprised of quarks. These different levels, which correspond to smaller and smaller distances, are probed by microscopes that must, because of the Heisenberg uncertainty relation between momentum and distance, use beams of higher and higher momenta. This fact implies that special relativity becomes important when we want to probe distances of nuclear size and less.

At higher energies, the conversion of energy into matter–antimatter combinations becomes important. At this stage it is no longer possible to speak of a simple potential energy. Forces themselves are the consequence of the emission and absorption of particles, the force carriers. The fundamental forces are characterized by carriers that share many characteristics. The electroweak force, a fusion of the weak force and electromagnetism, is carried by a triplet of massive spin-1 particles ($W^{\pm}$ and Z^0) and by photons. The strong force that acts between quarks is carried by a set of spin-1 gluons, which also interact among themselves. A consequence of the self-interaction of gluons is that quarks and gluons are *confined*, that is, free quarks and gluons are never seen as isolated particles. The third fundamental force, gravitation, has not yet been successfully reconciled with the ideas of quantum mechanics.

Various conservation laws apply to the fundamental forces and manifest themselves in certain rules for how reactions can proceed. The conservation of electric charge, of baryon number, and of lepton number applies in strong and electroweak interactions.

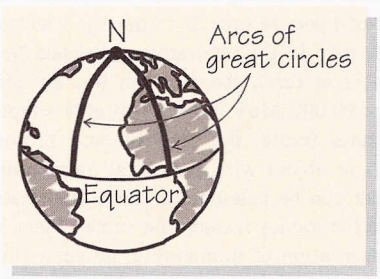


Figure 45–8 summarizes much of what we have studied about the nature of the fundamental constituents and interactions.

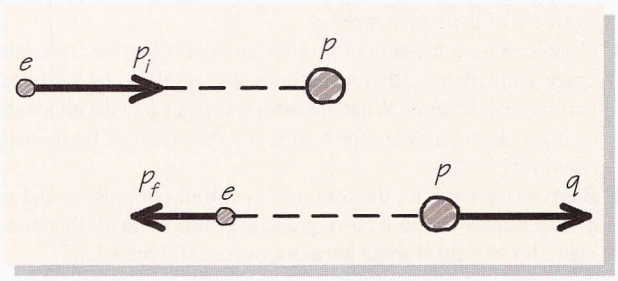
The reactions that occur in high-energy collisions form the most important pieces of evidence for the deduction of the fundamental laws. Colliders, accelerators in which beams of electrons or protons collide head-on, allow us to produce reactions with the highest energies.

Experiments on high-energy reactions share a common ground with astronomical observations. Hubble's law describes an expanding universe that started from a tiny initial volume, at the so-called Big Bang. When the expansion started, the universe was hot and dense, conditions appropriate to the high-energy reactions where the fundamental forces act. As the universe expanded, the temperature dropped, and a succession of energy scales resulted. By applying their knowledge of the behavior of matter at these different energy scales, physicists have successfully accounted for the background blackbody radiation measured to be present as well as the observed amounts of hydrogen and helium in today's universe. The very early evolution of the universe must involve gravitation, but as yet we do not understand how to include gravitation in a way that is consistent with quantum mechanics. Accounting for these earliest times is a formidable challenge for scientists.

Understanding the Concepts

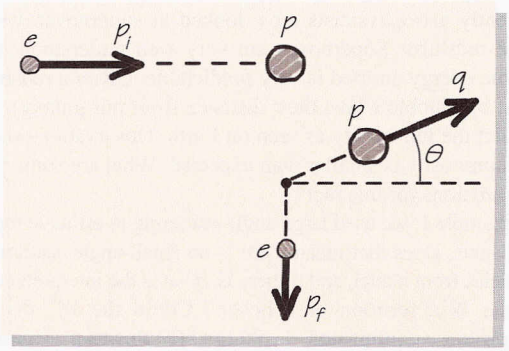
1. Whether a surface has curvature can be determined from certain geometrical properties of that surface. The sum of the angles of a triangle drawn in a flat plane is 180°. Show that this is not the case for Earth's surface by summing the angles of a triangle that links the North Pole with any two points on the equator (Fig. 45–20).



▲ **FIGURE 45–20** Question 1.

2. There are at least three known "families" of leptons. For example, in addition to the electron, there is a particle known as the muon (μ), which behaves in all respects like the electron except that it is more massive. By virtue of the extra mass, the muon is unstable. We also believe that the muon has a muon–lepton number, which, like the lepton number associated with the electron, is conserved. What experiment might tell you that the lepton numbers of the muon and the electron are conserved separately?
3. The lifetime of the proton is at least 10^{30} s, much greater than the age of the universe. Yet it is possible to create and destroy protons in particle reactions. How?
4. Why are electrons rather than protons used to study the charge distribution in the nucleus?
5. What fundamental forces most nearly account for the following phenomena: (a) walking; (b) the structure of gasoline molecules; (c) moonrise; (d) the source of sunlight; (e) the passage of sunlight from the Sun to Earth; (f) neutron stars (stars made mainly of neutrons packed to a density on the order of that of the nucleus)?
6. Can a particle be a lepton and hadron simultaneously? Meson and hadron? Hadron and baryon?
7. If a neutral meson could be made from a $(t\bar{u})$ combination, could such a meson decay *strongly* into a pair of pions? If not, would this mean that the meson is stable?
8. Suppose that electrons could not be removed from atoms, isolated, and studied independently. Would we still have experimental evidence of their existence?
9. Cosmic rays, consisting of protons and nuclei, arrive from outer space with energies that sometimes surpass those of the largest particle accelerators. What are the advantages and disadvantages of using such particles for beams for the study of high-energy reactions?
10. Earth orbits the Sun, the Sun moves within our galaxy, and our galaxy moves within its own galactic group. With all this movement, how could Hubble have discovered Hubble's law?
11. By energy and momentum conservations, an isolated electron cannot emit a photon and remain an electron. Why, then, can this happen in a virtual process?
12. Suppose that an accelerator can accelerate either electrons or protons to a given energy and that these projectiles are to collide with protons at rest. Which type of projectile should be chosen to obtain the greatest center-of-mass energy in the collision?
13. If the proton lifetime is expected to be of the order of 10^{35} s, what size apparatus would you need to see direct evidence of the proton's decay?
14. We know that the early universe was denser than it is now. What are some pieces of evidence that indicate that the early universe was hotter?
15. Recently astrophysicists have looked at supernovae with very large redshifts. Supernovae are very well understood, and the visible energy emitted is very predictable. Given a redshift (and thus, by Hubble's law, their distance from our galaxy), we can predict the luminosity as seen on Earth. Observations show that the luminosity is smaller than expected. What are some possible explanations for this fact?
16. In Example 1, we used large-angle scattering to estimate the size of a nucleus. Does that mean there is no small-angle scattering of α particles from nuclei, and if there is, what is the interpretation of d?
17. Is the W a fermion or a boson? Could the W^+ decay into (a) proton + antiproton + photon? (b) Positron + photon?

Problems

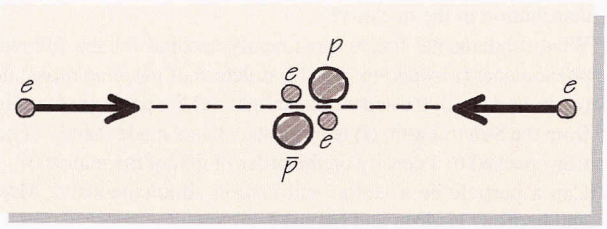


45–1 Probing the Structure of Matter

1. (I) Robert Hofstadter received a 1961 Nobel Prize for experiments in which 500-MeV electrons scattered from stationary nuclei. He found that the nucleus has a fairly constant density but, over a thickness of about 2.4 fm at its surface, the density drops to zero. With what spatial resolution could Hofstadter probe the nucleus with 500-MeV electrons?
2. (I) The Stanford Linear Accelerator accelerates electrons up to an energy of 52 GeV. These electrons can collide with stationary targets. (a) Determine the spatial accuracy with which such a probe can discern details of the nucleus. (b) In the 1960s, experiments performed there with 20-GeV electrons showed that the proton contains pointlike particles, the quarks. What is the best spatial resolution obtainable with such an electron beam?
3. (II) We want to use electrons as projectiles to study the structure of protons by means of the scattering reaction $e + p \rightarrow e + p$. The target proton is initially at rest in the laboratory; we measure those electrons that recoil directly backward. Suppose that all the motion is ultrarelativistic (you can ignore all rest masses except that of the particle at rest). Calculate the momentum transferred to the proton target (Fig. 45–21). If the energy of the incident electron is doubled, how much does the momentum transferred to the proton increase?

▲ FIGURE 45–21 Problem 3.

4. (II) Problem 3 describes the ultrarelativistic collision of an electron with a stationary proton. Compare the final momenta obtained there with the momenta obtained in a similar situation with nonrelativistic kinematics.
5. (II) Consider the ultrarelativistic $e + p$ collision described in Problem 3, but now consider those events in which the electron is scattered at 90° to its initial direction (Fig. 45–22). What is the direction and magnitude of the proton's momentum after the collision?



▲ FIGURE 45–22 Problem 5.

6. (II) (a) Repeat Problem 3, but keep the rest mass of the proton, so that $E = \sqrt{(m_p c^2)^2 + (qc)^2}$ for a proton of momentum q. Continue to treat the ratio of the mass of the electron to that of the proton as zero. (b) Is there an initial electron energy for which the electron motion must be treated relativistically while the motion of the proton can be treated nonrelativistically?
7. (II) Equation (44–2) gives the collision cross section of a *pointlike* projectile of charge $Z_1 e$, mass m, and kinetic energy K scattering from a *pointlike* target particle of charge $Z_2 e$ and mass $M (M \gg m)$ at rest, as a function of the scattering angle θ:

$$\sigma(\theta) = Z_1^2 Z_2^2 \left(\frac{e^2}{4\pi\varepsilon_0}\right)^2 \frac{1}{16} \frac{1}{K^2 \sin^4(\theta/2)}.$$

Suppose that the initial and final momenta of the projectile are $\vec{p}_i$ and $\vec{p}_f$, respectively, with $|\vec{p}_i| = |\vec{p}_f| = p$. Then for large M the magnitude of the momentum transfer $\vec{\Delta} \equiv \vec{p}_f - \vec{p}_i$ in the collision is given by $\Delta^2 = 2p^2(1 - \cos\theta)$. (a) Express the cross section in terms of Δ^2 and plot it as a function of Δ^2. (b) Suppose that the target is not pointlike but spread out over a sphere of radius r_0. Give some qualitative arguments based on the position–momentum uncertainty relation of how the dependence of the cross section on Δ^2 would change.

8. (III) Consider a colliding electron and proton. Show that if in the center-of-mass reference frame the electron has energy 3000 MeV, then in the laboratory reference frame (in which the proton is at rest), the electron has an energy of about 20 GeV, or 20,000 MeV. [*Hint*: You may suppose that in the center-of-mass frame, the electron and proton collide and produce some object with zero total momentum, and with a mass M that can be calculated, given the electron's momentum. In the laboratory frame, that same object is created and, by the conservation of momentum, moves with a momentum p_{lab} equal to that of the incoming electron. The energy of the object in the laboratory frame is then given by $E_{\text{object}} = \sqrt{(Mc^2)^2 + (p_{\text{lab}}c)^2}$. You may then use energy conservation, $p_{\text{lab}}c + m_p c^2 = E_{\text{object}}$, and your calculation of the mass M to find $p_{\text{lab}}c$.]
9. (III) An electron collides with a second electron at rest. What is the minimum energy the incident electron must have to produce a proton–antiproton pair? The reaction takes the form $e + e \rightarrow e + e + (p\bar{p})$. Ignore the electron mass. (See the hint to Problem 8. Figure 45–23 shows the reaction in the center-of-mass frame.)

▲ FIGURE 45–23 Problem 9.

45–2 New Quantum Numbers

10. (I) Use Table 45–1 to find the electric charge, baryon number, and spin of a π^-, which consists of a $d\bar{u}$ quark combination.

11. (I) The K^+ meson (the *kaon*) decays by the process $K^+ \rightarrow \pi^+ + \pi^0$. Assume that in this decay the conservation laws of charge, baryon number, and lepton number are obeyed. What are the values of these quantum numbers for the K^+ meson?

12. (I) Show that the conservation laws of charge, baryon number, and lepton number are satisfied in neutron decay, $n \rightarrow p + e^- + \bar{\nu}$.

13. (I) The reaction $p + e^- \rightarrow \bar{p} + e^+$ does not occur in sensitive experiments designed to observe it. Why not?

14. (II) The π^- meson decays as $\pi^- \rightarrow \mu^- + \bar{\nu}$. What is the baryon number of the μ^-? What is its lepton number? Is it a boson or a fermion? What is its electric charge?

45–3 The Fundamental Constituents of Matter: Leptons and Quarks

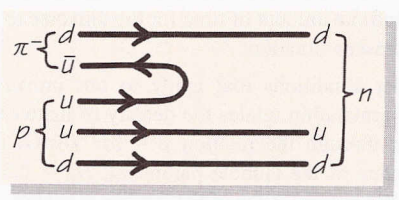
15. (I) Muonium is an atom consisting of a muon and a proton bound to each other. Is it a stable atom?

16. (I) Describe the quark content of a π^+-antiproton system.

17. (II) The pion is the exchange boson for nuclear forces: It is exchanged between two protons or two neutrons and leads to the nuclear force. Given that the transition $n + \pi^0 \rightarrow n$ is possible (virtually), where π^0 is the uncharged pion, describe the minimum quark content for this particle.

18. (II) Positive pions (π^+) can be produced in the reaction $p + p \rightarrow \pi^+ + D$, where D stands for the deuteron, the ^{2}H nucleus. Use this information and the known quark content of protons (*uud*) and neutrons (*udd*) to get the quark content of these pions.

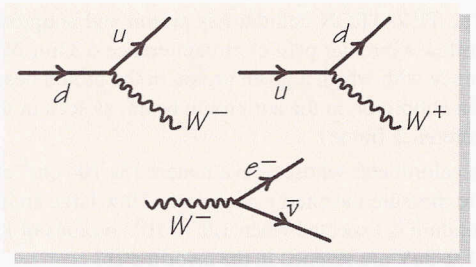
45–4 The Fundamental Forces and Their Carriers



19. (I) The W^+ meson has a mass of 81 GeV/c^2. Calculate the range of the force transmitted by the exchange of the W^+ meson.

20. (II) You have 1.0 kg each of hydrogen (gram-atomic weight 1.0 g/mol) and uranium 235 (gram-atomic weight 235 g/mol). What are the baryon numbers of the two samples of material?

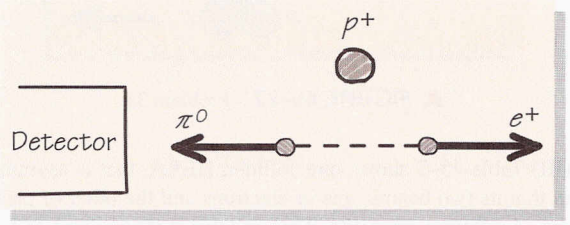
21. (II) There exist mesons like the pion that can be emitted and absorbed by nucleons, but with mass some 5.5 times that of the pion. The exchange of these particles gives rise to a repulsive nucleon–nucleon force. (a) Estimate the range of this repulsive force. (b) Estimate at what energy, in the center-of-mass reference frame of a proton–proton collision, the repulsive force will begin to affect the scattering.



22. (II) Estimate the repulsive force between protons in a uranium nucleus. Compare that force to the attraction between the uranium nucleus and the innermost electron in a uranium atom.

23. (II) The quark contents of some strongly interacting particles are (*uud*) for protons, (*udd*) for neutrons, ($u\bar{d}$) for π^+, ($d\bar{u}$) for π^-, and $(u\bar{u} - d\bar{d})/\sqrt{2}$ for π^0. Figure 45–24 is a sketch of the reaction $p + \pi^- \rightarrow n$ that uses this information. Here all lines represent particles moving to the right, with right-pointing arrows for quarks and left-pointing arrows for antiquarks. Moreover, quark lines never end in such a graph. Use this technique to draw graphs for the reactions (a) $p + \pi^- \rightarrow n + \pi^0$, (b) $p + \bar{p} \rightarrow \pi^+ + \pi^- + \pi^0$, and (c) $p + \pi^- \rightarrow p + n + \bar{p}$.

▲ FIGURE 45–24 Problem 23.



24. (II) Combine the quark-line rules of Problem 23 with the additional graphical rules for emission of a W^- boson by a *d*-quark, emission of a W^+ boson by a *u*-quark, and $W^- \rightarrow e^- + \bar{\nu}$, as drawn in Fig. 45–25. Use these rules to give the graphical representation of the processes (a) $n \rightarrow p + e^- + \bar{\nu}$, (b) $\pi^+ \rightarrow \pi^0 + e^+ + \nu$, and (c) $\pi^- \rightarrow e^- + \bar{\nu}$, all of which proceed with a W boson present at an intermediate stage.

▲ FIGURE 45–25 Problem 24.

45–5 Tools of Particle Physics

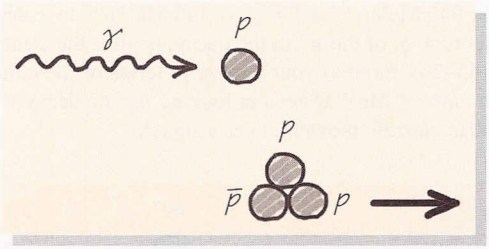
25. (I) According to some theories, a proton at rest can decay (with very long lifetime!) in the mode $p \rightarrow e^+ + \pi^0$. Use $m_p \cong 940\ \text{MeV}/c^2$ and $m_\pi \cong 135\ \text{MeV}/c^2$ to calculate the momentum, q, of the π^0 in the decay; neglect the electron mass (Fig. 45–26). Express your answer in terms of the combination qc, in units of MeV. Detectors looking for the decay would use this characteristic momentum as a signal.

▲ FIGURE 45–26 Problem 25.

26. (II) A proton–antiproton collider is actually a quark–antiquark collider, if we think of each quark in a proton (or each antiquark in an antiproton) as carrying one-third the momentum of the proton (or antiproton). What is the proton (and antiproton) energy in a symmetric $p\bar{p}$ collider that produces quark–antiquark collisions with the same total energy as the collisions produced by an electron–positron collider in which each electron carries a momentum of 11 GeV/c? Ignore the masses of the electron, positron, quark, and antiquark but not those of the proton and antiproton.

27. (II) Calculate the momentum in the center of mass of each incident proton for an accelerator in which 300-GeV protons are incident on stationary proton targets. (See the hint for Problem 8.)

28. (II) Antiprotons of energy 1000 GeV collide with protons of the same energy but opposite momentum in the TEVATRON collider (see Table 45–3). What is the momentum of antiprotons incident on stationary protons if the center-of-mass energy of the $p\bar{p}$ system is the same as that of the TEVATRON?

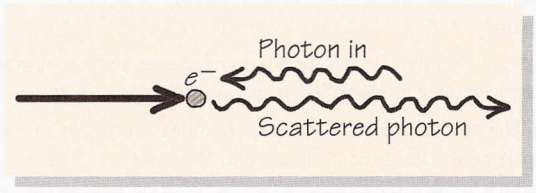


29. (II) An experimenter wants to study the reaction $e^+ + e^- \rightarrow Z^0$, where the Z^0, of mass 91.1 GeV/c^2, is the neutral intermediate boson of the electroweak interactions. The experimenter has a fixed-target machine that accelerates a beam of positrons that can be directed at atoms, which provide a stationary target of electrons. What is the minimum energy of the positron beam for which the reaction can occur?

30. (II) The *luminosity* of a colliding beam machine is the rate at which particles pass in one beam times the number of collisions per unit area of a second beam. The luminosity of the TEVATRON is $10^{37}/\text{m}^2 \cdot \text{s}$. If the total collision cross section for proton–proton interactions is 100 millibarns (1 barn $= 10^{-28}\ \text{m}^2$), how many interactions per second are there at the TEVATRON?

31. (II) The TEVATRON collider has proton and antiproton beams that follow a circular path of circumference 6.3 km. What is the frequency with which a given proton in the proton beam crosses a given antiproton in the antiproton beam, as seen in the laboratory reference frame?

32. (II) A calorimeter whose active material is 100 cm^3 of water is used to measure the energy of protons. How large an increase of temperature is expected when 1.0×10^{12} protons of kinetic energy 1.0 GeV are stopped in the calorimeter?



33. (II) A proton–antiproton pair can be produced in the reaction $\gamma + p \rightarrow p + \bar{p} + p$ (Fig. 45–27). If the target proton is at rest, what is the minimum energy that the photon must have to produce this reaction?

▲ FIGURE 45–27 Problem 33.

34. (III) Table 45–3 shows one collider, HERA, that is asymmetric in that its two beams, one of electrons and the other of protons, are of different momenta. This collider is thus a kind of hybrid between symmetric colliders and fixed-target machines. In the following, neglect the baryon-number and lepton-number conservation laws that must be obeyed in proton–electron collisions. (a) What is the maximum number of neutral pions that can be produced in HERA collisions? (b) What momentum would beams of protons and electrons of equal momentum have in order to be able to produce the number of pions in part (a)? (c) What momentum would a beam of electrons incident on protons at rest have to produce the number of pions in part (a)?

35. (III) Electron accelerators that produce copious quantities of X rays for research on atomic and condensed-matter physics employ electron beams of several GeV. The X rays are produced when the electrons scatter from photons of lesser energy. (For example, the National Synchrotron Light Source at Brookhaven National Laboratory accelerates electrons to an energy of 2.5 GeV and produces photons with energies up to 310 MeV.) Consider laser photons (with wavelength of, say, 590 nm) that scatter head-on from 8-GeV electrons. Calculate the maximum energy of the recoil photon produced in such a (Compton scattering) reaction (Fig. 45–28). At what angle would this photon be produced? [*Hint*: You must keep the electron mass in the relativistic expression for the electron energy, E, even though $E \gg m_e c^2$. You may, however, make the approximation $\sqrt{(pc)^2 + (m_e c^2)^2} \cong pc + \dfrac{(m_e c^2)^2}{(2pc)}$ in this case.]

▲ FIGURE 45–28 Problem 35.

45–6 Cosmology and the Expanding Universe

36. (I) In addition to the Planck time, there is a distance referred to as the *Planck length*. Use dimensional analysis to form a length from the constants $\hbar$, G, and c.

37. (I) In addition to the Planck time, there is a mass referred to as the *Planck mass*. Use dimensional analysis to form a time from the constants $\hbar$, G, and c.

38. (II) Consider the one-dimensional line of galaxies in Figs. 45–17a and 45–17b. Show that an inhabitant of galaxy B would agree that Hubble's law holds, but with the distance being the distance from galaxy B. In this way you confirm that Hubble's law is the unique law consistent with no special central point.

39. (I) Show that the Planck mass, 2.2×10^{-8} kg, is equivalent to an energy of 1.2×10^{19} GeV and to a temperature of 1.4×10^{32} K.

40. (II) The universe is expanding, but the expansion may be slowing down. (a) If R varies with time according to $R = kt^n$, where k and n are constants, find the acceleration of R. (b) The acceleration parameter, q, is defined by $q \equiv -R(d^2R/dt^2)/(dR/dt)^2$. Calculate the value of q.

41. (II) Assume that the size of the universe is determined by a distance scale factor R. This factor is increasing with time t at the rate $R = kt^n$, where k and n are constants. Hubble's law then becomes $dR/dt = HR$. Show that the Hubble parameter H is not constant, and find its time dependence.

42. (II) Use Hubble's law to find the time it would take for the distance from Earth to some galaxy to increase by 10 percent over what it is today. Assume that for the period over which you make your calculation, H is constant. [*Hint*: First find the time interval for the distance to change from x to $x + dx$, assuming that dx is an infinitesimal quantity. Then integrate your result.]

43. (II) By using the techniques of Problem 42, show that if Hubble's law with a constant value of H has held ever since the time when there was no separation between galaxies, it would have taken an infinite amount of time for the universe to have expanded to its present situation.

44. (III) Under conditions that apply to our universe, Einstein's theory of gravitation relates the density of matter to the Hubble parameter through the relation $\rho = 3H^2/8\pi G$. (a) Given the present value of the Hubble parameter, $H_0 = 2.5 \times 10^{-18}\ \text{s}^{-1}$, calculate the present value of the density of matter, ρ_0. Assuming

that matter consists (almost) entirely of hydrogen, with $M_H = 1.7 \times 10^{-27}$ kg, find the number density of hydrogen. (b) Show that the conservation of baryon number implies that the time dependence of the density is given by $\rho(t) = \rho_0[R_0/R(t)]^3$, where R_0 is the current distance scale of the universe and $R(t)$ is the distance scale at a general time t. (c) Combine the result of part (b) with the general relation between ρ and $H \equiv (1/R)\, dR/dt$ to show that $R(t) = kt^{2/3}$, and find k. [*Hint*: Substitute the general form $R(t) = kt^n$ into your equations.]

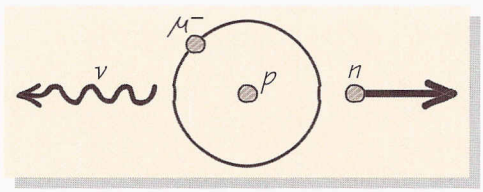
45. (III) Suppose that at the time when stable atoms formed, neutrons and protons were present in the ratio of 1 : 4. (a) Show that if hydrogen and helium formed with these nucleons (plus an appropriate number of electrons), then the number of moles of hydrogen formed was 6 times the number of moles of helium formed. (b) Show that the total mass of hydrogen formed is roughly 1.5 times that of helium formed then. (The actual evolution was such that the neutron-to-proton ratio was 1 : 7 when stable atoms formed.)

General Problems

46. (II) What is the maximum number of antiprotons that can be created in a scattering reaction with 70-GeV protons incident on a stationary hydrogen target?

47. (II) Below what temperature will stable carbon atoms form? He^+ ions? The ionization energies of H and C are 13.6 eV and 11.3 eV, respectively.

48. (II) *Cerenkov counters* are detectors that measure the presence and speed of charged particles by observing the angle of the "wake" of light (Cerenkov radiation; see Fig. 14–36) produced by those particles when their speed through a medium is greater than the speed of light in that medium. What is the minimum energy of electrons that produce Cerenkov radiation in toluene ($n = 1.494$)?



49. (II) Consider a fixed-target machine with protons of momentum 3.2×10^5 GeV/c. If the largest magnetic field we could use to guide the beam in a circular path has magnitude 9.5 T, what is the radius of such a machine?

50. (II) Find a relationship between the de Broglie wavelength and the kinetic energy K of ultrarelativistic particles (particles for which $K \gg mc^2$).

51. (II) In a reaction in which 40-GeV electrons hit 40-GeV positrons head-on (as has been done at the Stanford Linear Accelerator Center), what is the maximum number of π mesons (and antimesons) that can be created for each colliding pair? The mass of a π meson is about 140 MeV/c^2.

52. (II) A pi meson (of mass approximately 140 MeV/c^2) is ejected from a nuclear collision with a kinetic energy of 350 MeV. π mesons at rest have a lifetime of about 2.6×10^{-8} s. Calculate (a) the speed of the pi meson, (b) its momentum, and (c) how far, on average, such a pi meson will travel before it decays.

53. (II) The muon, symbol μ, is for all practical purposes just like the electron, except that it is some 207 times more massive. The muon can be destroyed by a proton in the reaction $\mu^- + p \rightarrow n + \nu$. A muon sent into hydrogen gas slows and is finally captured in a hydrogen-like Bohr orbit. Once it is in the lowest orbit (radius R_0), it will be destroyed by the reaction above if it comes within a distance $L = 0.2$ fm of the proton (Fig. 45–29). The probability that a muon in the lowest orbit will come that close to the proton is estimated from quantum mechanics to be the ratio of the volume of a sphere of radius L to that of a sphere of radius R_0. Suppose that the lifetime for destruction from the lowest Bohr orbit in hydrogen is τ_c. Show that the lifetime for destruction from the ground state of a Bohrlike atom in which the muon orbits a nucleus with Z protons is τ_c/Z^4.

▲ **FIGURE 45–29** Problem 53.

54. (II) Consider muon destruction from the lowest state in a hydrogen-like Bohr atom (see Problem 53). What is the energy of the neutron that emerges from the reaction? If the process occurs when the muon is in orbit around a heavy nucleus, will the reaction look the same as in the hydrogen-like atom?

55. (II) Using energy conservation and momentum conservation, prove that an isolated electron cannot emit a photon and remain an electron (see Question 11).

56. (II) Free neutrons have a lifetime of approximately 890 s. Given that the ratio of neutrons to protons was 1 : 5 when the universe was 1 s old, *estimate* the ratio at 1000 s. Take into account only the loss of neutrons through their decay.

57. (III) When an antiproton slows down by interacting with matter and approaches a proton, it can be captured and form a hydrogen-like atom called *protonium* through its Coulomb attraction to the proton. Find (a) the binding energy of the atom in electron volts and (b) the radius of the atom in its ground state. (Do not forget the reduced-mass effect.)

58. (III) The probability that a proton and an antiproton in the ground state of protonium (see Problem 57) will come within a distance R_1 of each other is estimated from quantum mechanics to be the ratio of the volume of a sphere of radius R_1 to that of a sphere of radius $2R_0$, where R_0 is the ground-state radius of protonium. If the lifetime for annihilation of a proton and an antiproton is 10^{-22} s when they are within 0.2 fm of each other and is infinite beyond this distance, estimate how long the protonium atom lasts in its ground state.

†P. J. Mohr and B. N. Taylor, "The 1998 CODATA Recommended Values of the Fundamental Physical Constants, Web Version 3.1," available at physics.nist.gov/constants (National Institute of Standards and Technology, Gaithersburg, MD 20899, 3 December 1999).

We have given values of the measured constants to six significant figures, even though they may be known to greater accuracy. The error, which expresses the uncertainty in the values of these constants, is in parts per million. Defined constants have no error, and we give their full definition; they are indicated by the notation "exact" in the error column.

APPENDIX III

Other Physical Quantities

III–1.1 SOME ASTRONOMICAL CONSTANTS

Constant	Symbol	Value
standard gravity at Earth's surface	g	$9.80665\ \text{m/s}^2$
equatorial radius of Earth	R_e	$6.378 \times 10^6\ \text{m}$
mass of Earth	M_e	$5.976 \times 10^{24}\ \text{kg}$
mass of Moon		$7.350 \times 10^{22}\ \text{kg}$ $= 0.0123\ M_e$
mean radius of Moon's orbit around Earth		$3.844 \times 10^8\ \text{m}$
mass of Sun	$M_\odot$	$1.989 \times 10^{30}\ \text{kg}$
radius of Sun	$R_\odot$	$6.96 \times 10^8\ \text{m}$
mean radius of Earth's orbit around Sun	AU	$1.496 \times 10^{11}\ \text{m}$
period of Earth's orbit around Sun	yr	$3.156 \times 10^7\ \text{s}$
diameter of our galaxy		$7.5 \times 10^{20}\ \text{m}$
mass of our galaxy		$2.7 \times 10^{41}\ \text{kg}$ $= (1.4 \times 10^{11})\ M_\odot$
Hubble parameter	H	$2.5 \times 10^{-18}\ \text{s}^{-1}$

III–1.2 PLANETARY DATA

Planet	Diameter (in km)	Diameter Relative†	Relative Mass†	Average Density (in g/cm³)	Period of Rotation	Surface Gravity† (in g)	Escape Speed (in km/s)	Semimajor Axis (AU)	Period of Solar Orbit	Average Orbital Speed (in km/s)

III–2 ENERGY SUPPLY AND DEMAND[†]

[†]From the *Physics Vade Mecum,* Ed. Herbert L. Anderson, American Institute of Physics (New York, 1981); and U.S. Congress, Office of Technology Assessment, *Changing by Degrees: Steps to Reduce Greenhouse Gases,* OTA-O-482 (Washington, D.C.: U.S. Government Printing Office, February 1991).

III–2.1 FUEL RESOURCES (1980, ESTIMATED)

Resource	U.S. Resources	World Resources
coal (recoverable)	5×10^{21} J	2×10^{22} J
oil (not including oil shales)	10^{21} J	10^{22} J
natural gas	2×10^{21} J	10^{22} J
hydroelectric	10^{22} J/yr (North America)	6×10^{22} J/yr

III–2.2 ANNUAL USAGE OF RESOURCE (2001, PERCENTAGE OF TOTAL) *Source:* www.energy.gov

Resource	U.S. Usage (total = 1×10^{20} J)	World Usage (total = 4×10^{20} J)
coal	23	24
oil	40	39
natural gas	24	23
nuclear	8	6
hydroelectric	2	7
biomass	3	1

III–2.3 ENERGY CONTENT OF FUELS

Fuel	Energy Content (in J/kg)
bread	10×10^6
glucose ($C_6H_{12}O_6$)	16×10^6
white pine wood	20×10^6
methyl alcohol (CH_4O)	23×10^6
anthracite coal	31×10^6
domestic heating oil	45×10^6
propane (C_3H_8)	50×10^6
natural gas (96% CH_4)	51×10^6
fission of U^{235}	5.8×10^{11}
perfect mass-energy conversion	9×10^{16}

III–2.4 SOLAR ENERGY OUTPUT

total radiated power from the Sun	4×10^{26} W
power per unit area at the top of Earth's atmosphere	1.4 kW/m^2
average power per unit area delivered to an average horizontal surface in the United States in 1 yr	0.2 W/m^2

III–2.5 ENERGY CONSUMPTION IN TRANSPORTATION

Mode	Energy Consumption (J/passenger · km)
bicycle	5×10^4
foot travel	1.5×10^5
automobile	1.9×10^5
intercity bus	6×10^5
intercity train	9×10^5
747 jet airplane	2.3×10^6
snowmobile	6×10^6

III–2.6 ENERGY CONSUMPTION OF ELECTRICAL APPLIANCE (*See* http://www.ianr.unl.edu/pubs/consumered/heg94.htm)

Appliance	Power (in W)	Energy Use per Year (in kWh)
window air conditioner	3750	3750
clock	2	17
dishwasher	1200	363
window fan	200	170
hair dryer	750	38
iron	1000	144
microwave oven	1450	190
radio	71	86
refrigerator-freezer	615	1830
stove	12,200	1175
color television	200	440
vacuum cleaner	630	46
washing machine	512	107

APPENDIX IV

Mathematics

IV–1 SOME MATHEMATICAL CONSTANTS†

Constant	Value
π	3.14159
e (Euler's constant)	2.71828
$\sqrt{2}$	1.41421
$1/\sqrt{2}$	0.707107
ln(10)	2.30259
ln(2)	0.693147
1 rad	57.2958°
1°	0.0174533 rad

†To six significant figures.

IV–2 SOLUTION OF QUADRATIC EQUATIONS

Quadratic equation:

$$ax^2 + bx + c = 0$$

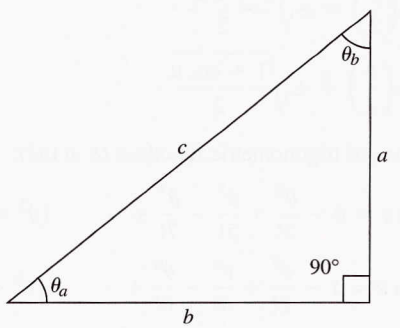
Two solutions:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

IV–3 BINOMIAL THEOREM

$$(x + y)^n = \sum_{k=0}^{n} \binom{n}{k} x^{n-k} y^k$$

where



$$\binom{n}{k} = \frac{n!}{(n-k)!k!}$$

The factorial $m! \equiv 1 \cdot 2 \cdot 3 \ldots \cdot m$; $0! \equiv 1$. Some particular cases of the binomial theorem:

(1) $(x \pm y)^2 = x^2 \pm 2xy + y^2$;
(2) $(x \pm y)^3 = x^3 \pm 3x^2y + 3xy^2 \pm y^3$;
(3) $(x \pm y)^4 = x^4 \pm 4x^3y + 6x^2y^2 \pm 4xy^3 + y^4$.

IV–4 TRIGONOMETRY

1. For a right triangle with sides a, b, and c (the hypotenuse), where the angle opposite side a is θ_a (Figure A–1),

▲ FIGURE A–1

$$\text{sine of } \theta_a = \sin\theta_a \equiv \frac{a}{c};$$

$$\text{cosine of } \theta_a = \cos\theta_a = \frac{b}{c};$$

$$\text{tangent of } \theta_a = \tan\theta_a = \frac{a}{b}.$$

2. The cosine function is even, $\cos(-x) = \cos x$; the sine function is odd, $\sin(-x) = -\sin x$.

3. (1) $\tan\theta = \dfrac{\sin\theta}{\cos\theta}$

(2) $\sec\theta = \dfrac{1}{\cos\theta}$

(3) $\operatorname{cosec}\theta = \dfrac{1}{\sin\theta}$

(4) $\cot\theta = \dfrac{1}{\tan\theta}$

4. (1) $\sin^2\theta + \cos^2\theta = 1$
(2) $\sec^2\theta - \tan^2\theta = 1$
(3) $\operatorname{cosec}^2\theta - \cot^2\theta = 1$

5. (1) $\sin(\theta_1 \pm \theta_2) = \sin\theta_1\cos\theta_2 \pm \cos\theta_1\sin\theta_2$
(2) $\cos(\theta_1 \pm \theta_2) = \cos\theta_1\cos\theta_2 \mp \sin\theta_1\sin\theta_2$
(3) $\sin\theta_1 \pm \sin\theta_2 = 2\sin\left(\dfrac{\theta_1 \pm \theta_2}{2}\right)\cos\left(\dfrac{\theta_1 \mp \theta_2}{2}\right)$
(4) $\cos\theta_1 + \cos\theta_2 = 2\cos\left(\dfrac{\theta_1 + \theta_2}{2}\right)\cos\left(\dfrac{\theta_1 - \theta_2}{2}\right)$
(5) $\cos\theta_1 - \cos\theta_2 = -2\sin\left(\dfrac{\theta_1 + \theta_2}{2}\right)\sin\left(\dfrac{\theta_1 - \theta_2}{2}\right)$
(6) $\tan(\theta_1 + \theta_2) = \dfrac{\tan\theta_1 + \tan\theta_2}{1 - (\tan\theta_1)(\tan\theta_2)}$
(7) $\cos\left(\theta \pm \dfrac{\pi}{2}\right) = \mp\sin\theta$
(8) $\sin\left(\theta \pm \dfrac{\pi}{2}\right) = \pm\cos\theta$
(9) $\sin\theta_1\sin\theta_2 = \dfrac{1}{2}[\cos(\theta_1 - \theta_2) - \cos(\theta_1 + \theta_2)]$
(10) $\cos\theta_1\cos\theta_2 = \dfrac{1}{2}[\cos(\theta_1 - \theta_2) + \cos(\theta_1 + \theta_2)]$
(11) $\sin\theta_1\cos\theta_2 = \dfrac{1}{2}[\sin(\theta_1 - \theta_2) + \sin(\theta_1 + \theta_2)]$

6. (1) $\sin(2\theta) = 2\sin\theta\cos\theta = \dfrac{2\tan\theta}{1+\tan^2\theta}$

(2) $\cos(2\theta) = \cos^2\theta - \sin^2\theta = 2\cos^2\theta - 1 = 1 - 2\sin^2\theta$

(3) $\tan(2\theta) = \dfrac{2\tan\theta}{1-\tan^2\theta}$

(4) $\sin\left(\dfrac{\theta}{2}\right) = \pm\sqrt{\dfrac{1-\cos\theta}{2}}$

(5) $\cos\left(\dfrac{\theta}{2}\right) = \pm\sqrt{\dfrac{1+\cos\theta}{2}}$

7. Expansions of trigonometric functions (θ in rad):

(1) $\sin\theta = \theta - \dfrac{\theta^3}{3!} + \dfrac{\theta^5}{5!} - \dfrac{\theta^7}{7!} + \cdots \quad (\theta^2 < 1)$

(2) $\cos\theta = 1 - \dfrac{\theta^2}{2!} + \dfrac{\theta^4}{4!} - \dfrac{\theta^6}{6!} + \cdots \quad (\theta^2 < 1)$

(3) $\tan\theta = \theta + \dfrac{1}{3}\theta^3 + \dfrac{2}{15}\theta^5 + \dfrac{17}{315}\theta^7 + \cdots \quad \left(\theta^2 < \dfrac{\pi^2}{4}\right)$

IV–5 GEOMETRICAL FORMULAS

1. (circumference of a circle of radius r) $= 2\pi r$

2. (area of a circle of radius r) $= \pi r^2$

3. (area of a sphere of radius r) $= 4\pi r^2$

4. (volume of a sphere of radius r) $= \frac{4}{3}\pi r^3$

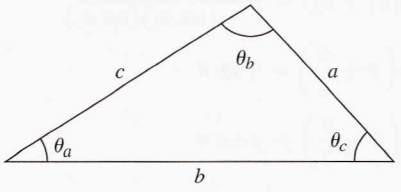
5. (area of a rectangle with sides of lengths L_1 and L_2) $= L_1 L_2$

6. For a right triangle with sides a, b, and c and angles θ_a and θ_b opposite the sides a and b, respectively (Fig. A–1):

(1) $a^2 + b^2 = c^2$ (the Pythagorean theorem)

(2) area $= \frac{1}{2}$(base)(height) $= \frac{1}{2}ab$

7. For a triangle with sides a, b, and c opposite the angles θ_a, θ_b, and θ_c, respectively (Figure A–2):



(1) $\theta_a + \theta_b + \theta_c = 180° = \pi$ rad

(2) $a^2 = b^2 + c^2 - 2bc\cos\theta_a$

(3) $\dfrac{a}{\sin\theta_a} = \dfrac{b}{\sin\theta_b} = \dfrac{c}{\sin\theta_c}$

(4) $a = b\cos\theta_c + c\cos\theta_b$

(5) area $= \dfrac{1}{2}$(base)(height) $= \dfrac{1}{2}ab\sin\theta_c = \dfrac{1}{2}a^2\dfrac{\sin\theta_b\sin\theta_c}{\sin\theta_a}$

▲ FIGURE A–2

8. volume of a right cylinder of height h and radius $r = \pi r^2 h$

IV–6 SOME PROPERTIES OF ALGEBRAIC FUNCTIONS

1. General properties

(1) $a^x a^y = a^{x+y}$

(2) $a^0 = 1$

(3) $(ab)^x = a^x b^x$

2. Properties of exponential of x, $\exp(x)$ or e^x:

(1) $\exp(\ln x) = x$

(2) $\exp(x_1)\exp(x_2) = \exp(x_1 + x_2)$

(3) $\exp(0) = 1$

(4) expansion: $e^x = 1 + x + \dfrac{x^2}{2!} + \dfrac{x^3}{3!} + \cdots$

3. Properties of the natural logarithm of x, $\ln(x)$:

(1) $\ln(e^x) = x$

(2) $\ln(x_1 x_2) = \ln(x_1) + \ln(x_2)$

(3) $\ln(x_1/x_2) = \ln(x_1) - \ln(x_2)$

(4) $\ln(1) = 0$

(5) expansion:

$$\ln(1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \cdots \quad (x^2 < 1)$$

IV–7 DERIVATIVES

In the following, b and p are constants, and u and v are functions of x:

1. $\dfrac{db}{dx} = 0$

2. $\dfrac{d}{dx}(bu) = b\dfrac{du}{dx}$

3. $\dfrac{d}{dx}(u+v) = \dfrac{du}{dx} + \dfrac{dv}{dx}$

4. $\dfrac{d}{dx}(uv) = v\dfrac{du}{dx} + u\dfrac{dv}{dx}$

5. $\dfrac{dx^p}{dx} = px^{p-1}$

6. Chain rule: If u is a function of y, and y is in turn a function of x, then $\dfrac{du}{dx} = \dfrac{du}{dy}\dfrac{dy}{dx}$.

7. $\dfrac{d}{dx}(\sin x) = \cos x$

8. $\dfrac{d}{dx}(\cos x) = -\sin x$

9. $\dfrac{d}{dx}(\tan x) = \dfrac{1}{\cos^2 x}$

10. $\dfrac{d}{dx}(e^{bx}) = be^{bx}$

11. $\dfrac{d}{dx}\ln(x) = \dfrac{1}{x}$

IV–8 TAYLOR EXPANSION

If $f(x)$ is well behaved near point $x = x_0$,

$$f(x) = f(x_0) + \left.\frac{df}{dx}\right|_{x=x_0}(x - x_0) + \frac{1}{2!}\left.\frac{d^2f}{dx^2}\right|_{x=x_0}(x - x_0)^2 + \cdots$$

IV–9 INTEGRALS

In the following, b and p are constants, and u and v are functions of x:

1. $\displaystyle\int \frac{du}{dx}\,dx = u$

2. $\displaystyle\int_{x_1}^{x_2} \frac{du}{dx}\,dx = u(x_2) - u(x_1)$

3. $\displaystyle\int bu(x)\,dx = b\int u(x)\,dx$

4. $\displaystyle\int (u + v)\,dx = \int u\,dx + \int v\,dx$

5. $\displaystyle\int u\frac{dv}{dx}\,dx = uv - \int v\frac{du}{dx}\,dx$ (integration by parts)

6. If u is a function of y and y is in turn a function of x, then

$$\int u\,dy = \int u\frac{dy}{dx}\,dx$$

7. $\displaystyle\int x^p\,dx = \frac{x^{p+1}}{p+1} \qquad (p \neq -1)$

8. $\displaystyle\int \frac{dx}{x} = \ln x$

9. $\displaystyle\int (\sin x)\,dx = -\cos x$

10. $\displaystyle\int (\cos x)\,dx = \sin x$

11. $\displaystyle\int e^{bx}\,dx = \frac{1}{b}e^{bx}$

12. $\displaystyle\int xe^{bx}\,dx = e^{bx}\left(\frac{x}{b} - \frac{1}{b^2}\right)$

13. Some definite integrals:

(1) $\displaystyle\int_0^\infty x^n e^{-x}\,dx = n!$

(2) $\displaystyle\int_0^\pi (\sin^2 x)\,dx = \int_0^\pi (\cos^2 x)\,dx = \frac{\pi}{2}$

(3) $\displaystyle\int_0^\infty e^{-b^2x^2}\,dx = \frac{\sqrt{\pi}}{2b} \qquad (b > 0)$

(4) $\displaystyle\int_0^\infty xe^{-x^2}\,dx = \frac{1}{2}$

(5) $\displaystyle\int_0^\infty x^2e^{-x^2}\,dx = \frac{\sqrt{\pi}}{4}$

(6) $\displaystyle\int_0^\infty \frac{b}{b^2 + x^2}\,dx = \begin{cases} \frac{\pi}{2} & (b > 0) \\ 0 & (b = 0) \\ -\frac{\pi}{2} & (b < 0) \end{cases}$

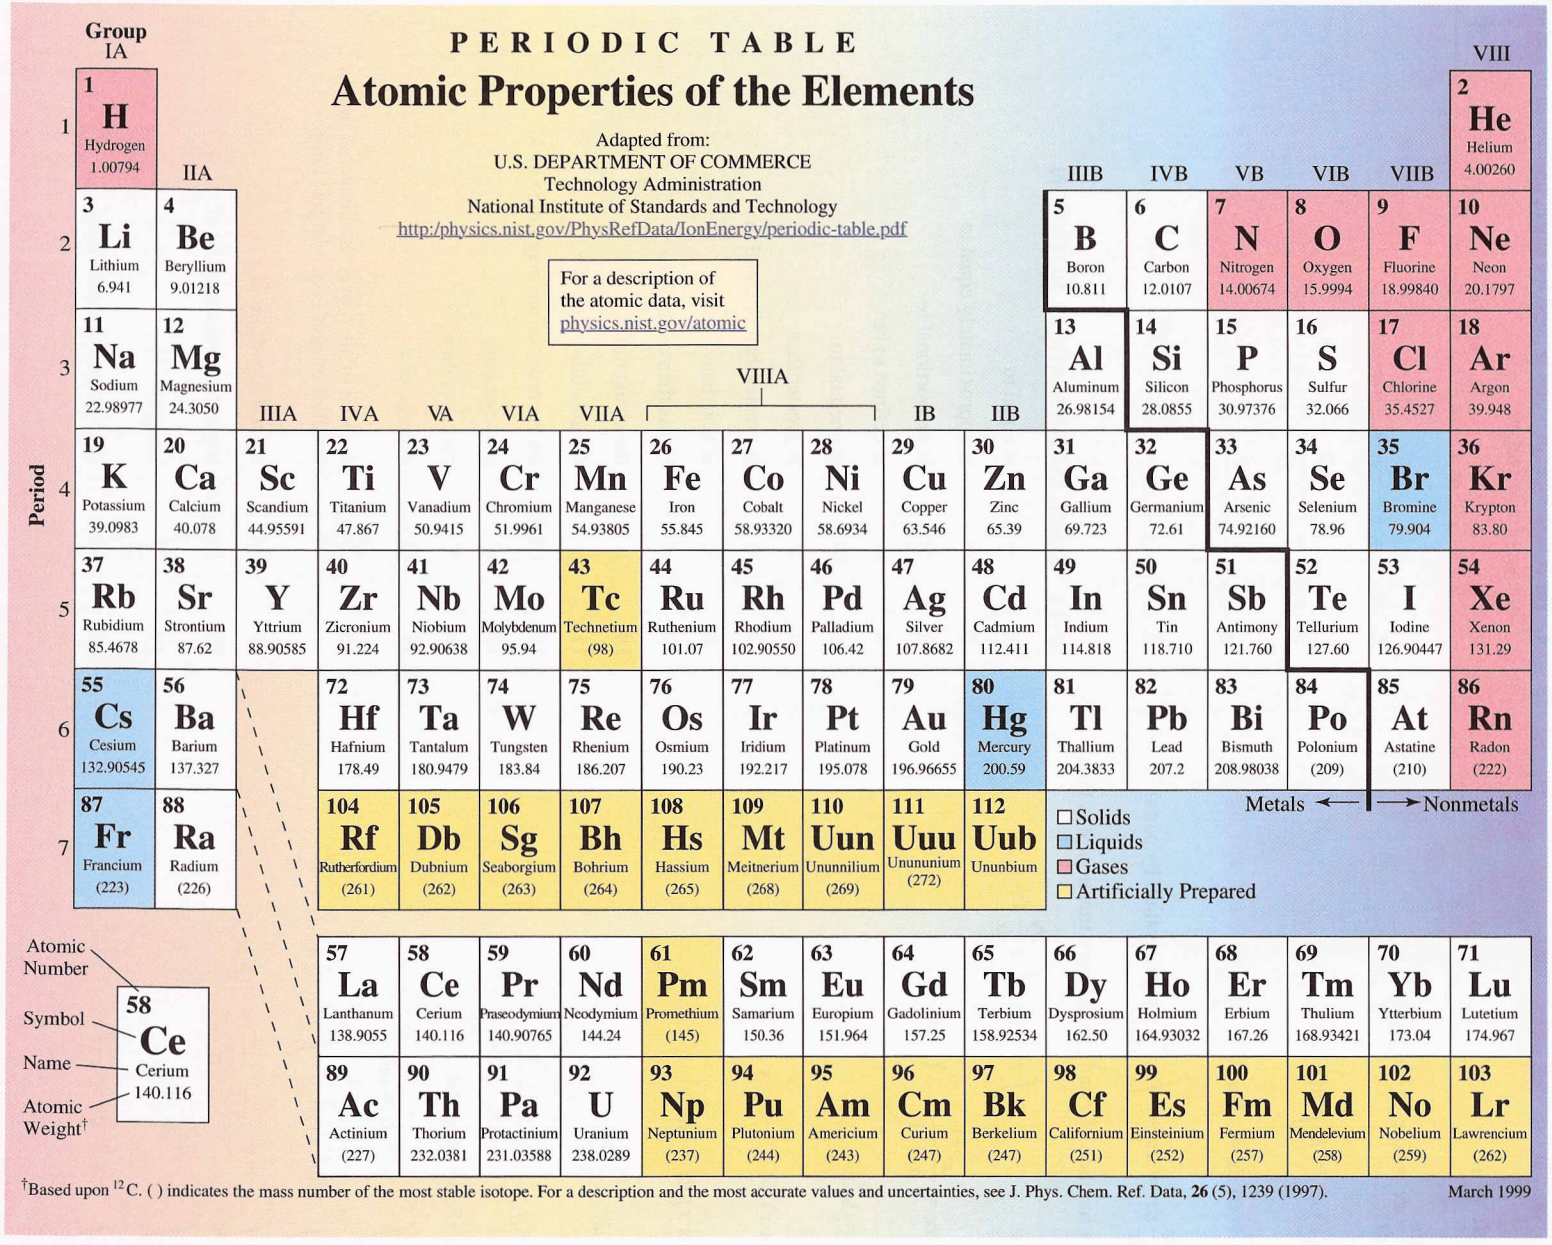
IV–10 SOME EXPANSIONS APPROPRIATE FOR $x^2 < 1$

1. The following expression is good for any n, positive or negative, integer or noninteger:

$$(1 + x)^n = 1 + nx + \frac{n(n-1)}{2!}x^2 + \frac{n(n-1)(n-2)}{3!}x^3 + \cdots$$

2. $\displaystyle\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} + \cdots$

3. $\displaystyle\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} + \cdots$



4. $\displaystyle\tan x = x + \frac{x^3}{3} + \frac{2}{15}x^5 + \cdots$

5. $\displaystyle e^{ax} = 1 + ax + \frac{(ax)^2}{2!} + \frac{ax^3}{3!} + \cdots$

IV–11 SOME MATHEMATICAL NOTATION

1.	$=$	is equal to
2.	$\cong$	is approximately equal to
3.	$\propto$	is proportional to
4.	$\equiv$	is defined to be
5.	$\neq$	is unequal to
6.	$>$	is greater than
7.	$\geq$	is greater than or equal to
8.	$<$	is less than
9.	$\leq$	is less than or equal to
10.	Δx	the change in x
11.	$\lvert x\rvert$	the absolute value of x
12.	$O(N)$	on the order of the magnitude of N
13.	$\pm$	plus or minus
14.	$\mp$	minus or plus
15.	$\langle x\rangle$	average of x
16.	$\displaystyle\sum_{i=i_1}^{i_2} f_i$	the sum of all f_i over the integers i from a smallest integer i_1 to a largest integer i_2
17.	$\ln(x)$	natural logarithm of x
18.	$\log_{10}(x)$	logarithm to the base 10 of x
19.	$\displaystyle\int$	integral
20.	$\displaystyle\oint$	line integral around a loop

Periodic Table of the Elements

APPENDIX VI

Significant Dates in the Development of Physics

History can rarely be stated as a simple series of dates, and the history of science is no exception. Throughout the text we have alluded to important discoveries in physics. The list below is a personal choice and should be thought of as a guide. It oversimplifies some of the history, including stories that are covered more thoroughly in the text. Some of the dates are to be taken with a grain of salt, because discoveries are rarely made in a single identifiable moment. Our list includes some names (and discoveries) not mentioned in the text. Far more numerous are the names not listed, the names of those who built the experimental foundations, those who explored the false paths and cleared the way for those whose names we remember today, or those who verified the speculations that are now called laws.

1583	Galileo	Pendulum motion
1600	Gilbert	Study of magnets
1602	Galileo	Early statement of Newton's first law
1602	Galileo	Laws of falling bodies
1609	Kepler	First two laws of planetary motion
1619	Kepler	Third law of planetary motion
1620	Snell	Law of refraction
1648	Pascal	Atmospheric pressure
1650	Grimaldi	Diffraction of light
1661	Boyle	Chemical elements
1669	Newton	Light dispersion in prisms
1678	Huygens	Wave propagation
1687	Newton	Laws of motion; universal gravitation
1760	Black	Calorimetry
1785	Coulomb	Coulomb's law
1789	Lavoisier	Conservation of mass
1798	Cavendish	Measurement of G
1800	Volta	Electric battery
1801	Young	Interference of light
1801	Dalton	Laws of chemical combination
1802	Charles; Gay-Lussac	Ideal gases
1807	Dalton	Atomic theory
1812	Fourier	Decomposition of waves
1815	Fraunhofer	Discrete spectral lines
1819	Fresnel	Wave picture of light
1820	Oersted	Magnetic fields from currents
1820	Biot; Savart	Law of magnetic field produced by current
1824	Carnot	Second law of thermodynamics
1827	Ohm	Ohm's law
1827	Ampère	Ampère's law
1831	Faraday; Henry	Magnetic induction
1842	Joule	Mechanical equivalent of heat
1847	Helmholtz	Conservation of energy
1849	Fizeau	Direct measurement of the speed of light
1865	Maxwell	The laws of electricity and magnetism; light waves
1877	Boltzmann; Gibbs	Statistical mechanics
1879	Stefan	Blackbody radiation
1885	Osmond	Crystalline structure of metals
1887	Hertz	Electromagnetic waves
1887	Michelson and Morley	Constancy of the speed of light
1896	Becquerel	Radioactivity
1897	Thomson	Charge-to-mass ratio of the electron

1900	Planck	Quanta in blackbody radiation
1903	Rutherford; Soddy	Isotopes
1905	Einstein	Special relativity; quanta in photoelectric effect
1908	Kammerlingh Onnes	Superfluidity
1911	Kammerlingh Onnes	Superconductivity
1911	Rutherford	Nuclear structure of atom
1911	Millikan	Quantization of charge
1912	von Laue	X-ray diffraction in crystals
1912	Bragg and Bragg	Analysis of crystal structure with x-rays
1913	Bohr	Atomic structure
1916	Einstein	General relativity
1922	Compton	Scattering of x-rays
1923	Hubble	Discovery of galaxies
1924	de Broglie	Wave nature of particles
1925	Pauli	Exclusion principle
1925	Heisenberg	Formulation of quantum mechanics
1925	Goudsmit and Uhlenbeck	Electron spin

Answers to "What Do You Think?" Questions

CHAPTER 1

1. Nothing is special about a year. One year refers to an astronomical accident in a sense, since if Earth traveled a slightly different orbit, the year would be different. The second is just as arbitrary. The importance of these or any units is that they establish a common standard with which we can all agree. A light-year is the same to anyone anywhere in the world.

2. Just because this answer is an exact one does not mean that you are obliged to use all the figures in application. It would in fact be an unusual situation for you to want to use the exact answer. You can always round off if fewer digits are called for.

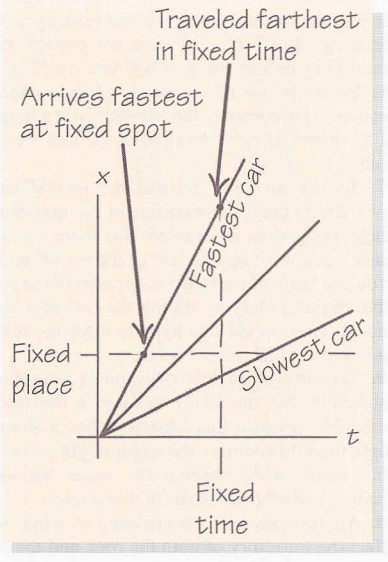
3. The conversion between the millimeter and meter involves a definition, so no new uncertainty is introduced in the conversion.

4. If your calculator does not have enough digits, you might have to use a larger computer or you might have to be clever and use mathematical approximations. In fact, we could have used the approximation $\sin\theta \cong \theta - (\theta^3/3!) + \cdots$, correct if θ is small, to arrive at our numerical answer. But don't throw your calculator away; for almost all applications it will suffice.

6. No, you have a choice of any units you like with the right dimensions. For example, you could take the mass in slugs, the time in minutes, and the length in furlongs, in which case the units of G would be cubic furlongs per slug per minutes squared. But we would more normally use mks units.

7. If the radius of a sphere increases, so does the area of the sphere's surface. Thus there would be more area available for the same number of people, and the area available per person would increase.

8. The estimate l for the size in the example is in fact the cube root of the space taken up by each molecule. The only difference is that with the conditions stated the linear size of a molecule—the length of the side of a cube of the molecular volume—is $\frac{1}{10}l$. In other words, answer (a) is the correct one.



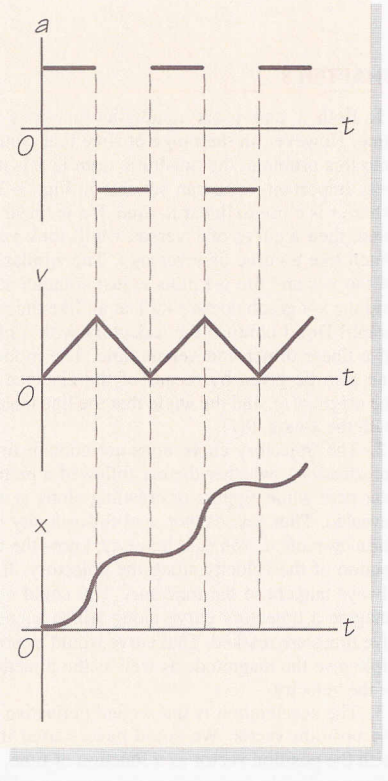
9. It would be unchanged. Displacements don't depend on the choice of origin. You can very easily check this explicitly in this case.

10. How the displacement is broken into components *can* differ according to the coordinate system. But the vector itself, that is its magnitude and direction in space, is independent of its description in a particular coordinate system.

CHAPTER 2

2. See Fig. 2–38.

3. You could certainly take the data in the table and plot it. The plot would contain no more and no less information than the table. When you draw a smooth line connecting the points of the plot, then you are interpolating (guessing, with an assumption of smoothness) between the points. You could use the interpolated curve to find the velocity: The instantaneous velocity at a given time (or position) is given by the slope of the curve of position versus time at the given time. You would draw the straight line tangent to the curve at the given time, then just measure the slope of that straight line. Since the line is straight, you can measure its slope by examining any two points on it, just as we did in our discussion of Fig. 2–5. However, you should keep in mind that when you are taking the slope of a plot that is just a guess (an interpolation between points), you cannot *guarantee* that you have a precise value.



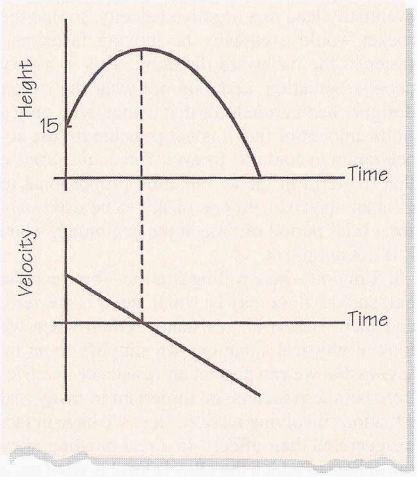
▲ **FIGURE 2–38** Discussion, What Do You Think? Example 2–2.

5. (1d) The ball first moves to the right, then to the left, and so on. When does any acceleration occur? Is it large? (2b) The two runners have different speeds, and the handoff occurs in an idealized fashion, with runners at their top speed. When is the acceleration of the baton? (3a) When the ball is first tossed, it has a large positive velocity; it slows down, passing through $v = 0$ at the top of its toss, at which point it falls with an increasing negative velocity. Since the acceleration is the slope of this curve and the slope is constant (and negative), the acceleration here is constant (and negative). (4c) The car is stopped, accelerates to a constant velocity, then has to stop again for another red light, and so on.

7. The last term in dv/dt is proportional to t^2 and therefore dominates the formula at large values of t in comparison to either the constant term or the term linear in t. Since its coefficient is negative, the expression for the acceleration will eventually become negative. This will in turn eventually lead to a negative velocity, so that the rocket would eventually be moving faster and faster in the backward direction. This is a very peculiar situation, certainly not what the rocket designer had in mind; for that matter, with only a finite amount of fuel it is not possible for the acceleration to continue forever. You could surmise that the term in the acceleration proportional to t^2 is an approximate one meant to be used only for a brief period of time at the beginning, when it is not dominant.

8. Friction—here rolling friction—between the ball and the floor may be small, but it is not zero, and there is also air resistance. Often when we look at physical situations we simplify them by saying that we can neglect air resistance and friction, but these factors are important in many real situations involving motion. Here we have in fact exaggerated their effects. In a real bowling alley the degree to which the alley is level is what most influences the ball's motion.

10. See Fig. 2–39.



▲ **FIGURE 2–39** Discussion, What Do You Think? Example 2–10.

11. (b) The acceleration due to gravity is constant and downward with magnitude g, regardless of initial conditions, which here happens to be a positive (upward) initial velocity.

13. Under constant acceleration, the ball would fall four times as far in the first two time intervals as it did in the first time interval. (We are assuming that all the time intervals are the same.) This is a measurement that could easily be made on the photo in Fig. 2–23 and we encourage you to try it.

14. Refer to the sketches in Fig. 2–40. The acceleration is a constant, the same at the beginning of the motion, the end of the motion, and anywhere in between, including at the top of the trajectory (see Fig. 2–19).

▲ **FIGURE 2–40** Discussion, What Do You Think? Example 2–14.

CHAPTER 3

1. Both x and y are quadratic functions of time. However, in the range of time that comes into this problem, the quadratic term in x is not very important—you can see this in Fig. 3–3b, where x is close to linear in time. If x is linear in time, then a curve of y versus x will look very much like a curve of y versus t. The similarity of the y–x and the y–t plots is just coincidence, and the x–t graph doesn't look at all like the x–y graph! Don't confuse the trajectory with a plot of a linear dimension versus time. The motion can also be given by means of the distance to the origin $r(t)$, and the angle that the line makes with the x-axis, $\theta(t)$.

2. The trajectory curve does not contain time information—whether the car followed a particular path while zipping or crawling along is not revealed. Thus you cannot read full velocity information off it. You can, however, know the direction of the velocity along the trajectory: It is always tangent to the trajectory. You could also imagine a trajectory curve along which successive times are marked. That curve would in principle give the magnitude as well as the direction of the velocity.

3. The acceleration is the second derivative of the position vector. We could have started this with the position vector as a function of time, as taking a double derivative is the same as taking two single derivatives, so we would have "passed through" the calculation of Example 3–2 in any case.

5. The motion in the x- and y-directions are independent of each other. The horizontal travel distance is determined by a combination of things: how fast it moves horizontally (a constant given by the initial condition) and how much time it has to travel (also determined by initial conditions, but this time by the initial vertical component of velocity, zero in this problem). Of course, if the cliff were higher, the ball would be in flight for a longer time and would fall further out in the ocean.

6. The parabola describes the motion for a given acceleration and with the condition that the tee is at the top of the cliff and the velocity at the tee is $\vec{v}_0$. But if the cliff were not present, one could imagine that the golf ball was hit 57 m to the *left* of the tee and at sea level in a manner such as to have exactly the velocity $\vec{v}_0$ at a height of 52 m and 57 m to the right of the new tee-off point.

7. To see why the fact that the ground isn't level affects the θ_0-dependence of the maximum range, imagine as an example that there is a 6-ft fence a couple of feet in front of the tee-off point. (You can think of the fence as a model of the possible terrain.) Only by hitting the ball at a high enough angle could one hope to clear the fence and have the ball travel further.

9. The answer to this question is somewhat subjective, but the likely answer is the lower angle 36° because this trajectory has a shorter flight time. In addition, the target might conceivably more easily observe the water balloons heading toward them at the higher angle.

10. Air resistance or the presence of wind will affect the trajectory of both the rock and the coconut, as we'll discuss in more detail in Chapter 5.

11. Definitely not. If the automobile were rounding a curve with a larger radius of curvature, the acceleration would be less; as for the ramps onto an interstate highway, the car can negotiate a circular arc with a larger radius without danger. The extreme case is straight-line motion, for which 54 mph would pose no problem whatsoever. We'll see in Chapter 5 why too much acceleration can be dangerous, but you know from experience that it has something to do with the car skidding out.

12. The expression $a = \omega^2 r$ shows that the outermost parts of the top move with the largest acceleration. The angular speed is the same for all parts, so $a \propto r$.

13. (b) The rower would say that there is less current to fight, that he or she wouldn't have to row partly upstream just to stay even with the point across the river from the dock. With no current, the frames are identical; $u = 0$, so that $\cos\theta = u/v' = 0$, and the boat should be directed straight across. It would move across with speed v', rather than $v'\cos\theta < v'$. The crossing time is $(0.15\text{ km})/(4\text{ km/h}) = 0.04\text{ h} \cong 2\text{ min}$.

14. It is the solution to Example 3–13 that supplies the answer to this one. In effect, the flight path of the airplane must be longer (the hypotenuse of a right triangle) through the air in order to hold the north–south direction relative to the ground (a side leg of the right triangle). Thus the jet stream adds to the flight time even if is not directly opposed to the motion. You may want to think about the relative angles of flight direction and jet stream direction for which the jet stream can actually help.

CHAPTER 4

1. Not always. Following our rules for addition of vectors (tail to tip, as discussed in Chapter 1), the sum of the five forces for the fixed rods will end up as a single vector pointing somewhere in the three-dimensional space. We can get a zero net force if the two adjustable force vectors—the ropes—can add up to give a vector equal and opposite to this single vector. This is equivalent to asking whether three straight lines of fixed length can form a triangle, and this is only possible if the sum of the lengths of the adjustable force vectors is equal to or larger than the vector representing the sum of the fixed forces.

3. For a constant force, and therefore a constant acceleration, the final velocity is equal to $a\,\Delta t = F\,\Delta t/m$ and is therefore inversely proportional to the mass. If M is the mass of the box and m that of the bowling ball, the ratio of the final speed with one ball to the final speed with n balls is $(M + nm)/(M + m)$. The ratio of the speeds could still be used to count balls, but you would have to know the ratio, not necessarily an integer, of M to m. Notice that if $M \gg nm$, then the ratio is very nearly unity.

4. During the brief contact between the hand and the spaceship the astronaut exerts a force on the spaceship, and the spaceship exerts an equal and opposite force on the astronaut. They are both accelerated in opposite directions (inversely proportional to their masses) and move away from each other until a tether stops their separation by exerting forces on both of them. As the astronaut has less mass than the spaceship, she will have greater acceleration.

5. We can easily imagine that the passenger accelerates forward along with the sled. If he accelerates, there is a force on him. This force must be a contact force coming from the sled. But then, by the third law, the passenger must be exerting a force on the sled, and it must be backward. Why doesn't the sled accelerate backward as a result? That is because there is an additional force on the sled, one that comes from the person who is doing the pushing. The net force on the sled is forward.

7. Professor A would see her own tennis ball bounce on the floor and rise up vertically to her hand. She would conclude that the ball suffers no horizontal acceleration and that there is no horizontal force acting on the ball. Professor B would see that his ball does *not* bounce back into his hand. The reason is that the ball as it leaves the hand has the same instantaneous velocity as he does. While it falls, it maintains that velocity, whereas the professor and the train are accelerating. Thus, by the time the tennis ball comes back up, professor B has moved a little away from the ball. Professor B thinks that the same mysterious force—it has no visible source—that makes professor A accelerate backward also acts on the tennis ball.

8. The glue here ensures a sufficient amount of friction between the blocks. As long as these friction forces are large enough, nothing changes. If, however, the forces between the two blocks along the direction of motion are significantly reduced—for example, the blocks sliding past one another in the absence of friction—then there would be no way to transmit the pull from block 2 to block 1, and block 1 would be not be affected by the force acting on block 2—it would be left behind. As we shall see in the next chapter, friction has an "adjustable" quality up to a certain point.

11. During the contact time, the ball is indeed accelerated both horizontally and upward and acquires its initial velocity for its subsequent motion, during which only the force of gravity acts.
12. Look at Eq. (4–23): The x-position changes in time in a way that depends not only on the acceleration but also on v_{0x}. So we cannot make a rule about how far the nugget goes based on acceleration alone.

CHAPTER 5

2. Either fishermen are eternally optimistic about the size of fish they will catch or, more likely, fish can use their muscles and exert a force on the line much larger than their own weight, and the fishermen don't want the fish to be able to break the line.
3. Absolutely nothing would be different. The acceleration, Eq. (5–12), is independent of the mass of the sliding object. Everything placed on the ramp would slide down in the same way. Without friction neither the golf ball nor the car would roll. We are assuming the ramp will not collapse under the weight of a car.
4. If the ropes are not massless, we must include the gravitational force on them in the force equation. We would have to lift them! If the pulleys are not frictionless, then the tension throughout all the ropes is not the same, and it is no longer true that $T_1 = T_2 = T_3 = T_4$. The entire problem would become more complicated. All these effects reduce the ease with which the person could lift an object with the block and tackle, and for real machinery we wish to minimize these effects so that lifting is easier.
5. The masses would have to be equal. If $m_1 > m_2$, then m_1 will rest on the scale, and the scale would still have a nonzero reading.
6. The critical angle is determined by the *ratio* of the masses [Eq. (5–20)]. In part (a), the masses have the same ratio as in the example, and the system will remain motionless. (b) The mass m_1 will fall down pulling m_2 up the ramp. (c) The mass m_2 slides down the ramp and pulls m_1 up.
8. A force F_{hand} directed into the surface of the ramp would be added to the free-body diagram for the box. To balance this, we would have to increase the normal force from the ramp to the value $F_N = mg\cos\theta + F_{\text{hand}}$, and if the normal force increases, so does the maximum value of static friction and hence the angle at which slipping will start. This makes good sense; we know we can keep an object from sliding down a ramp by pushing down on it.
9. No, the y-component of the force will have a term mg down, which will complicate the last two equations in the example enough to lead to an angle that is not independent of F_{prof}. In effect, we have included a new dimensional quantity that has the same dimensions as F_{prof} and thus allows F_{prof} to enter through the dimensionless ratio mg/F_{prof}.
10. There is more weight on the front tires because the engine is in front. With more normal force pressing on the snow, the maximum static force is larger for the front tires than for the rear tires. This makes a significant difference in traction when μ_s is small and means that if the drive power is coming from the front, it can be larger than if it were at the back without the drive wheels slipping.
12. Gas efficiency for a given velocity would improve if the drag coefficient of the car is reduced, and for racing cars speed can be increased for a given engine power in this way. Drag coefficients for the boxy cars of years ago were as high as 0.7, whereas modern streamlined cars have C_D near 0.3. Gas mileage increases by 5 percent for every 10 percent improvement in drag coefficient. (Of course, the popularity of SUVs is evidence that gas efficiency may not be an important factor for some drivers.) Airplane wings have drag coefficients as low as 0.05.
13. Oil becomes "thicker," or more correctly more viscous (a word that describes the size of the coefficients in drag force—the higher the viscosity, the larger these coefficients), at low temperatures, and the marble in this example would move more slowly. Oil is a much better lubricant when it flows more easily, that is, at higher temperatures. But with today's multi-viscosity oils, car owners don't worry so much about warming up the engine before driving off.
14. From experience we know that the book will move toward the outside of the merry-go-round and fall off. It would move in a combination of radial and tangential directions because once static friction is replaced by kinetic friction (typically smaller than the largest value of static friction), the book will tend to continue motion in its current direction, which is initially tangential but as it moves out also attains a radial component.
15. To the inhabitants of the station, "up" is radially inward, opposite to the "force" that keeps them on the outer wall. Walking on the innermost wall would be like your walking on the ceiling, and walking on the side walls would be like walking on the side walls of your room! In both cases there would be no force to keep them accelerating centripetally toward the center of the wheel, and they couldn't walk on any surface except the outermost wall.
16. We can say that because static friction acts within a range, there will be some leeway for error that is not present when there is no static friction. There will be a range of speeds within which the car can negotiate the curve. See Problem 51, which treats this topic in some detail.
18. A skater will slow down when he or she hits the rough patch. The coefficient of friction of 0.10 in this example is small. A more realistic value, perhaps three or four times larger, would cause the speed to drop quickly enough to present a real danger: The skater might not be able to slow his or her upper body as quickly as his or her legs are slowed by the sand, and the skater may topple over! We are touching here on effects due to the finite size of the body that go beyond the motion of pointlike or perfectly rigid objects that are the main topics of our attention in these early chapters. Later in the book we'll come back to this point in much more detail.

CHAPTER 6

2. As we have not yet dealt with energy other than kinetic energy, we can only answer this question with our intuitive knowledge. We have the work–energy theorem, so we know that a change in kinetic energy implies that there is work done. The furniture mover has the ability to do work because his muscles have the ability to do work. The muscles are able to do work as they have an energy source they can call on—chemical energy from the metabolism of nutrition. The depletion of the chemical energy in the mover's body is measured by the kinetic energy acquired by the sofa.
3. For (i), the answer is (a): The work done is proportional to the force and the force of gravity is proportional to the mass, so that the work done by gravity is doubled. For (ii), the answer is (c): The relation between velocity, acceleration, and displacement is a kinematic one, which does not involve the mass of the object, so that the velocity is the same.
4. Initially the elevator (with its contents) is at rest. The downward force of gravity is exactly canceled by the upward force of the friction of the brakes and the tension of the cable. When the brakes are released and the tension of the cable is increased, there is a net force upward. The net work done is positive, giving rise to the kinetic energy of the elevator and contents. When the brakes grab and the tension decreases, the net work done is large and negative, canceling the kinetic energy possessed by the elevator before it stops.
5. The "pushing" force is unchanged, but the friction force that acts against it slowly increases. Since work done on the box depends on the *net* force, contributions to it become increasingly negative so that, by the theorem, the kinetic energy decreases until it reaches zero. The box comes to rest. At this point the static friction is just large enough to balance the external force and the box does not move.
6. We assume that when the box hits a downward slope, the push is still parallel to the floor. The force of friction is reduced because it is proportional to the normal force, which on the slope only involves the component of weight perpendicular to the slope. There is also an accelerating force due to the component of the force of gravity parallel to the floor. The result is that the net force is no longer zero, and the kinetic energy (and therefore the speed) of the crate increases as it goes down the slope.
7. The component of the force perpendicular to the ramp increases, so that the force of friction increases. The component of the force along the ramp decreases, so that the *net* force along the ramp decreases. There will be an angle at which the net force will go through zero and the crate will start slipping down.
9. Friction is certainly not a spring force. But in this case the friction force varies linearly with distance, so that the integration necessary to find the work done by it takes the same form as the integration necessary to find the work done by a spring force.
10. The circular motion itself implies that a centripetal force must also be acting. It is supplied by a tension in the rod that holds the ball. It does no work because the force is perpendicular to the motion; hence the scalar product that appears in the work is zero. Because it does no work, it cannot increase the speed; only a force with a tangential component can do that. Gravity also acts, but it is canceled by the contact force at the pivot that keeps the rod moving in the horizontal plane.
12. If the work done is independent of the path, then $W(A, B) = W(A, C) + W(C, B)$. This is equivalent to $\int_A^B F(x)dx = \int_A^C F(x)dx + \int_C^B F(x)\,dx$. This, however, is a general property of one-dimensional integrals (see the box Integration), so it is true for the spring force with the variable spring constant.
13. When an object slides on a rough surface, the motion is impeded by irregularities in the surfaces in contact. When these push past each other, energy is dissipated in bending them or in

breaking them off (abrasion). In addition, bonds may be formed between atoms coming from the two different materials, and these bonds break when the object moves (see Section 5–2). In molasses, the object, in order to move, must push the fluid out of the way. Molasses is "hard to move" (liquids such as molasses are said to be viscous, and there are strong electrical bonds between neighboring molecules), while water, say, takes less energy to move it.

14. The horsepower is a rate, an energy per unit time. This can change from instant to instant, and it is therefore an "instantaneous" quantity. If the rate changes slowly, then an average rate over some interval of time may give a good approximate value for the instantaneous rate of delivery of energy.

CHAPTER 7

2. The shift $y \rightarrow y + y_0$ is just a shift in the coordinate system, nothing more. After you make this shift, you are measuring height y from the top of your building: $y = 1$ m in the new system is $y = 101$ m in the old system. If the expression for U in the old system is Mgy, its expression in the new system is $Mgy + mgy_0$. In the new system $U = 0$ at $y = -100$ m. This is a perfectly sensible result. You have not changed the *location* of the zero of U; that remains at sea level. But in the new coordinate system sea level is located 100 m below the building top, at $y = -100$ m.

3. One way to look at this is to note that the reverse process could be represented by a movie of the initial process *run backward*. Time does not enter into energy conservation equations, and for the square of the velocity (i.e., kinetic energy), it does not matter whether the movie runs backward or forward. We can conclude from this that the speed of the brick at roof level would have to be 15 m/s.

4. We have moved from one equilibrium situation to another, with no motion and hence no kinetic energy involved. The potential energy has, however, changed: the spring is compressed so that it has acquired a positive potential energy, while on the other hand the kilogram mass is now *lower*, so that the gravitational potential energy is lower. The total energy has changed because displacing the mass and compressing the spring involved work.

5. When the system is initially at rest, the spring has been extended to its equilibrium point, whose location is determined by the spring constant and *the sum of the masses attached to it*. This is not changed by the motion of the masses and so that motion will be the same. In terms of free-body diagrams we may enclose the pulley and the masses in a box, and then the relative positions of the masses and their motion are a matter that is internal to the box.

6. A sketch of the energy diagram shows that the $E = 0$ line just touches the top of the potential energy hill at $x = 0$. Our object may start at rest at the leftmost turning point, but in sliding down into the first valley it speeds up, reaching its maximum kinetic energy at $x = -2$. In climbing back up the other side of the first valley it loses kinetic energy, that is, it slows down, until at the top of the hill at $x = 0$ it has zero velocity. Will it go on to the right-side valley or will it slide back to the left-side valley? Actually it gets to the top and stays there since there are no perturbing forces that move it to one side or the other.

If you are inclined to worry how a solution of a perfectly well-defined $F = ma$ equation can have a solution that describes motion (the falling into the valley floor) and then at some later time describes a mass at rest, the answer turns out to be that it takes an infinitely long time for the mass to creep up to the very top of the hill. Remember, time information is something you cannot get from energy considerations; for that you need the full apparatus of Newton's second law.

7. No, we cannot tell. The speed would be the same in either case.

8. We see that as r becomes very large (approaches infinity), $U(r)$ goes to zero. The masses are very far apart, and since the force falls off with distance, it is reasonable that there be no potential energy where the force itself is zero. The total energy at large r ("at infinity") is just the kinetic energy.

9. Since the energy of the pendulum systematically decreases, its speed decreases. For example, at the bottom of the swing the energy is equal to the kinetic energy there, so the speed at the bottom of the swing will systematically decrease. The period of the clock, which is what marks the time, is the time for the pendulum to get back to its maximum elevation. After each swing both the speed and the distance that has to be traveled by the mass decrease, so it is conceivable that the period may be unchanged. This is indeed exactly what happens as long as the swing angle is small. The fact that the period is independent of the angle (for small starting angles) is what makes the pendulum a good clock. For more details, see Chapter 13.

CHAPTER 8

2. This is a matter of counting unknowns. The final state is formed of two balls each moving in the same plane. That means that the final state is specified with four pieces of information, the two velocity components of each ball. Originally we knew two pieces of information about the final state (the two components of the final velocity of the cue ball), and that was just enough to allow us to find the two components of the final velocity of the struck ball. Now we are replacing two pieces of information with one, the conservation of kinetic energy. This is no longer enough to allow us to find the final velocity of the struck ball.

3. We can suppose that the force applied to a ball has to do with your stroke and therefore is the same for either the strung rackuet or the solid bat. The strung racket is the choice to make because the ball remains in contact with it for a longer period as the strings "give." The impulse is then larger from the strung racket because of the larger Δt.

4. The more inelastic the better. In an elastic collision relatively more energy goes into the recoil of the car (as opposed to its distortion in collapse), the momentum change of the car is larger, and hence the impulsive force acting is greater. In other words, the acceleration of the occupants is greater in an elastic collision.

5. (b) Energy is lost as the boater and dog "give" in order to bring the dog to rest with respect to the boat—as they change their shape there is heating in the muscles and so forth. The collision was inelastic—the dog and boat have "coalesced" by means of friction between them. The answer cannot be (a) because all the motion is horizontal; it cannot be (c) because there is no friction between the boat and the ice.

6. We can often simplify a situation by using an approximation. In many situations a large quantity plus a small quantity can be closely approximated by the large quantity alone. Thus in the equation for v we can replace the denominator by m_{block}. But care must be taken—we certainly cannot ignore the mass of the bullet in the numerator; we would find $v = 0$ in that case!

7. With the initial object at rest, the momentum conservation equation reads $0 = m_{\text{light}}v_{\text{light}} + m_{\text{heavy}}v_{\text{heavy}}$, with solution $v_{\text{light}} = (m_{\text{heavy}}/m_{\text{light}})v_{\text{heavy}}$; the coefficient of v_{heavy} is greater than 1, so the answer is (b). None of this depends on details of the explosion.

8. With equal masses, the target ball moves off with the speed of the ball that struck it, while the projectile comes to rest in the place of the target ball. The struck ball then can rise to exactly the height from which the projectile started. The motion is symmetric and repetitive.

11. (b) The size of each of the orbs is taken care of by first recognizing that their center of mass lies at their respective centers, by symmetry. The center of mass of the entire system is then that of two *point* masses making a dumbbell. The center of mass is between the two ends of the dumbell, relatively closer to the more massive end. There is no reason that point could not lie within Earth's radius.

12. Certainly. The calculation of a center of mass is additive, and you can do addition in any combination you like. Try the suggested combination to show that this is the case.

13. Allowed angles in the laboratory frame are determined by the possible angles made by the vectors $\vec{p}' + \vec{p}/2$ and $\vec{p}' - \vec{p}/2$. To take a concrete example, suppose that nearly the maximum amount of energy were lost. This corresponds to the final two objects moving off arbitrarily slowly (i.e., very nearly sticking together—see Section 8–3). Then $\vec{p}'$ is very nearly zero, and the direction of $\vec{p}' \pm \vec{p}/2$ is that of $\vec{p}$ itself. In the laboratory frame the objects continue to move, nearly together, along the x-axis. They will not make a large angle with the direction of the projectile.

14. There are many objects that have an external center of mass. Some simple ones are a jackknife folded at a 90° angle—the center of mass will be somewhere within that angle—or a ring donut, which has the center of mass in the middle of the hole.

15. Symmetry places the center of mass at the center of the sheet, that is, $\left(\frac{1}{2}\text{ m}, \frac{1}{2}\text{ m}\right)$. If the mass density had not been constant, the calculation would have been more complex.

16. As we will learn in more detail in Chapter 12, the acceleration of gravity at the surface of the Moon is much smaller than its value at Earth's surface. It is possible to reach higher speeds far away from the Moon (and Earth) with a launch from the Moon, and some have proposed a Moon base just for this purpose.

CHAPTER 9

1. Not at all. The definition of the *average* acceleration depends only on the initial and final angular speeds, not on how they were reached.

2. This is a rotating rigid body: The angular acceleration is the same for all the points within it. We are of course repeating here what was used in the answer to the original question.

7. No. All the integrals would look the same. Of course, because the mass per unit area is just the total mass divided by the area, the correct total mass M would have to appear in the answer.

8. The rotational inertia "weights" points in an object according to their distance squared from the reference axis. Points in our object can be farther from the reference axis when the axis is at a corner than when it is at the center of mass.

10. True, as the equation for ω (the next-to-last equation of the example) shows; it contains the factor $F \times t$. This echoes the analogous result for linear velocity.

11. (c) Since the direction of both quantities is the same, the kinematic equation (9–34) becomes an equation for the magnitude of the angular velocity in terms of the magnitude of the angular acceleration. One doesn't know the time dependence of the change until the time dependence of α is known. In this case Eq. (9–33) shows that α is constant, and this will lead ω to change linearly with time.

13. Friction acts, and it is a nonconservative force, so energy is not conserved. This collision is analogous to the perfectly inelastic linear collision of Chapter 8, in which two objects collide and stick. That is in fact the most inelastic linear collision possible, and a similar remark holds for this "rotational" collision.

14. All points on the wheel have the same angular speed ω about the contact point. Because the top of the wheel is at a distance $2R$ from the point of contact, $v_{\text{top}} = 2R\omega = 2v$.

15. The ratio of the energy in rotation to the energy in linear motion is of the form $I\omega^2/(Mv^2)$. But for a fixed R the factor ω/v is fixed in rolling. Thus the percentage of the energy in rotation is greater for larger I given the same mass and radius.

16. The C factor for a thick cylinder lies in between its value for the solid case $\left(C = \frac{1}{2}\right)$ and the thin-walled case $(C = 1)$ From Eq. (9–52), the thick-walled cylinder will finish the race ahead of the thin-walled cylinder but behind the solid cylinder. The same equation reminds us that the results are independent of the radius.

CHAPTER 10

2. Crucially, there would no longer be a radial component to the angular momentum. This can be seen in our equation for L_{radial}: The angle θ would be $90°$, $d = R \sin\theta = R$, and hence $L_{\text{radial}} = 0$. When the rod lies in the plane of motion, its tension, which maintains the circular motion, is directed to the attachment point and hence exerts no torque.

3. It is unchanged. The instantaneous motion of the ball is the same, even if later the ball will go off as a projectile moving under only gravity. Since its motion looks the same at the moment the rope breaks, its angular momentum is the same.

4. As we had remarked in the "What do you think?" question for Example 10–2, the angular momentum is in this case purely vertical, and unchanging. One would then expect the torque to vanish, and it does because the radial component of tension (which is still present to maintain the circular motion) lies parallel to the radial vector; hence the cross product is zero.

5. (d) Answers (b) and (c) are closely related; as the moment arm is independent of distance fallen, it translates into a moment arm independent of time. Note that this problem involves no rotations at all, yet there is a torque and hence there is an angular momentum. As we argued right at the beginning of Section 10–1, even a linearly moving point mass will generally have an angular momentum about some/any origin.

7. (c) The linear momentum transfer to the center of mass—the linear impulse—is independent of where the impulse is applied. This is not the case for the angular impulse.

9. (b) The angular momentum depends only on the mass of the comet, the speed at closest approach, and the distance of closest approach. The shape of the orbit is not a direct indication of the angular momentum.

11. The stool will stop rotating. Angular momentum is conserved, so two flips, bringing the wheel back to its original orientation, gets us back to the original situation, with the student and stool at rest.

12. Spool B has relatively more of its mass at larger radius and thus will have a larger rotational inertia than spool A. (The general form of I for a spool of mass M and radius R is CMR^2, where C is a geometrical factor, larger for spool B than for spool A.) Thus v is larger for spool A than for spool B.

13. The infinitesimal work done by the impulse is zero, because the scalar product of the angular impulse and the change in angle is zero. Thus the magnitude of the angular momentum is unchanged, although its direction is not.

CHAPTER 11

3. The mass density of the book must not be constant, because the book's center of mass must be somewhere directly over the table in equilibrium. This could be possible if, for example, the spine side were on the average denser than the side that opens.

4. The same fact that gravity acts on the center of mass tells us that if the map is placed with its center of mass on the point it will be in equilibrium; if not, it will rotate off the point.

5. (a) The coefficents of mg in the expressions for both F_A and F_B determine the answer to this question. If L decreases, then both F_B and F_A decrease.

6. If the crane is not fixed to the ground, the crane could pivot about the front tires and tip over! The torque that could make this happen would come from the suspended mass.

7. (b) As the window washer moves up the ladder the lever arm of the washer's weight with respect to the contact point with the ground increases. The torque due to the washer's weight about the contact point with the ground increases, until the torque about this point due to the normal force with the wall can no longer counteract the effect of the torque due to the weight. Note that (d) is in fact a consequence of (b).

8. Doing pull ups requires the lower arm to be rotated about the elbow to bring the body upwards. Thus the attachment distance x may be smaller for the person who cannot do pull ups as easily. Smaller x leads to a smaller torque about the elbow (xF_B).

9. The mass density is constant, so the volume V does not change. Therefore, $V = AL = A'(L + \Delta L)$ where A' is the new cross section. We see $A' = AL/(L + \Delta L)$; the new area will be smaller by 1.2×10^{-3} or 0.1%. This is indeed a small correction, and the assumption that there was no change in the cross section was valid.

CHAPTER 12

2. (a) Look at the equation for the sun's mass M in this example. If, on the right hand side of the equation, we have a larger r, we must also have a larger T. This is independent of Mars' mass.

3. No. Once again a sketch is helpful. The centripetal force on the satellite always points to Earth's center, so that its orbit must be a circle in a plane that contains that point. The plane of a "great circle" passing though Washington makes an angle with the axis of Earth's rotation. This means that if at a given time the satellite is above Washington, a little later Washington will have moved along a circle at a fixed latitude, while the satellite will have moved to a different latitude and longitude.

4. The definition of a stable point can help us devise a test for this problem. We could imagine that $x = x_0 + \delta$, where $\delta \ll x_0$, and see whether the resulting (small) net force points back to x_0. In doing so one would want to use approximations based on the fact that $\delta/x_0 \ll 1$. This would be a test for stability along the line between Earth and the Moon. One could think about stability for motion perpendicular to this line in a similar way, with the vector aspect of the forces playing a more important role. The zero-point is in fact unstable: if, for example, the satellite is a little to the right of the zero-point, it tends to continue moving that way. See Problem 12–70.

You can also respond to the question by thinking about the potential energy as a function of the position on the line between Earth and the Moon. A graph of the potential energy would form a hill, and the zero-point is the top of the hill. The fact that you have a hill rather than a valley means that the equilibrium at the top of the hill is unstable; if the satellite goes a little off the top of the hill, it goes all the way off.

5. From Eq. (12–10), the escape speed depends on the ratio of M/R, which is a factor of 22 less for the Moon than for the Earth, so the escape speed from the Moon is significantly less than from Earth. This is why some people have proposed a moon base for initiation of longer voyages in space.

6. (d) The total energy is negative for a bound system, as in this example, and positive for an unbound system.

7. You cannot answer this without some algebraic thinking. Kepler's relation gives $R^3/T^2 =$ a constant. The orbital speed $v = 2\pi R/T$, and we can invert this to give $T = (2\pi R)/v$. This in turn implies that $R^3 \times v^2/(2\pi R)^2 =$ a constant, or $Rv^2 =$ a constant, or $v^2 \propto 1/R$, therefore as R increases the orbital speed *decreases*.

8. Keep in mind in thinking about orbital motions that all the conic sections described at the beginning of Section 12–2, and drawn in Fig. 12–4b, are possible. We can see from that figure that orbits can be elliptic $(E < 0)$, parabolic $(E = 0)$, or hyperbolic $(E > 0)$. Information that a comet's orbit grazes the Sun is not enough to distinguish these.

9. (d) You can answer this one by thinking of the extreme case: If all the mass were concentrated right at the center, then the force would have the $1/r^2$ dependence characteristic of a point mass.

CHAPTER 13

2. The acceleration is proportional to the displacement; it has maximum magnitude where the displacement has maximum magnitude, at $z = z_{\min}$ and $z_{\max}$. By the same reasoning the acceleration has minimum magnitude, namely 0, where $z = 0$.

4. (b) The time is still a quarter period, and the period does not depend on the speed at $t = 0$.

5. Simple harmonic motion is repetitive. The mass moves back out to $x = -X$, then returns to the origin, and the same maximum speed, a half period later. For this system, with an ideal spring, the pattern repeats forever. The times when $x = 0$, and hence the speed is a maximum, are at $t = T/4, 3T/4, 5T/4$, etc.

6. One would still expect simple harmonic motion. Although the springs may not be in a relaxed state in the stable equilibrium position, the restoring forces will always bring the mass toward this position as long as the spring is not stretched to the point that it no longer acts like a spring. As we saw earlier, any small motion about a stable equilibrium is harmonic, barring special circumstances.

7. The validity of an approximation such as the one we use for pendula depends on whether the first term of a mathematical expansion comes close enough to the exact answer. How close that is is a numerical question which can only be answered by first specifying a criterion for "close enough." In the case of the pendulum, the expansion is Eq. (13–32), and hence whether $\theta_{\max}^3/3! \ll \theta_{\max}$, or more usually whether the ratio $(\theta_{\max}^3/3!)/\theta_{\max} \ll 1$. For example, you may insist that $(\theta_{\max}^3/3!)/\theta_{\max} < 0.05$. In this example, $\theta_{\max} \cong (5.0\text{ cm})/(2\text{ m}) = 0.025 \cong 1.5°$, so that your criterion is satisfied.

9. (a) The monkey makes three things change: The total mass increases, the length increases, and the distribution of the mass over the new length has shifted to the monkey's end. The period is independent of the mass, so the first change is irrelevant. But the period increases with increased distance to the center of mass as well as with increased mass distribution toward the end (so that rotational inertia is increased.). Both the second and third changes increase the period.

10. At first sight we might say we can tell nothing whatsoever; the frequency of oscillation (and hence the period) is modified by the damping parameter b, but it depends on more than b alone. A little thought shows that there is something interesting we can say. You may know that sound is an oscillatory phenomenon, and the fact that one can continue to hear the gong even as its loudness decreases means that this system is not critically damped or overdamped. This establishes what you may already know: Sound involves oscillations that are much more rapid than the time scale associated with the damping of this gong.

CHAPTER 14

1. No. One of the inputs necessary to satisfy the wave equation is that the displacements can't be too large. If the string is infinitely long, then no matter how small a is, there will be x-values (positive and negative) for which the distortion is large. Of course, the function we gave could describe only a portion of a propagating distortion. No matter; this function displays the feature we are interested in here: It moves with speed v.

2. Greater. The relation $v = \lambda f$ shows this. If the system is really the same—for example, if water depth remains the same—v is unchanged. Then if λ decreases, f must increase to compensate.

4. The velocity will approach zero as either $T \to 0$, or $\mu \to \infty$, or both. The first condition of no tension implies that there is no force acting on any element of the wire. This implies no acceleration in the vertical direction and therefore no displacement of the wire from its equilibrium position. The second condition implies that the wire is more and more massive, and in order to get a transverse acceleration, the force (tension) would also have to get larger and larger. For a fixed T we get no acceleration in the limit.

6. Gravity causes the rope to sag, and the hand and attachment point will both have to supply a vertical component of force to allow for a vertical component of tension. We know from experience that if the rope is not too long, then the sag will be small, so that locally the rope will be straight and the conditions that went into our derivation of the wave equation will continue to be satisfied: The tension magnitude will be roughly the same, and the waves will be unchanged to first approximation.

8. We now have two separate situations. On the left we have a string whose length is 0.2 m, so that our expression for the wavelength changes because $L \to L/5$. Thus the wavelengths on the left side take the values $\lambda = \dfrac{2}{n_L}\dfrac{L}{5}$, that is, each allowed wavelength is shortened by a factor of 5. On the right side the length is changed from L to $4L/5$. Thus the wavelengths take the value $\lambda = \dfrac{2}{n_R}\dfrac{4L}{5}$—that is, they are also shortened, but only by a factor of 5/4. Now we can certainly find values of n_L and n_R such that the wavelength has a common value. For example, $n_R = 4$, $n_L = 1$ have the same wavelength as the original string for $n = 5$ (which has a node at the newly clamped point). Nevertheless, these modes will not necessarily match the appearance of an unclamped string, because the amplitudes and the phases on either side of the clamping point have to match.

9. Our expression for the relation between f and T shows that f is proportional to $T^{1/2}$. Thus an increase of 1% in f means that $T^{1/2}$ must increase by 1%, and therefore T must increase by 2%. (To see this, use the fact that $(1 + x)^{1/2} \cong 1 + \frac{1}{2}x$ for x small.) Piano strings differ from one another in mass density as well as tension. T is proportional to f^2, so if strings of different mass density were not used, the range of tensions in a piano would be enormous.

10. This is most easily answered by considering a long pipe with a rectangular cross section. Then it is clear that there can be standing waves across the height, as well as across the width of the pipe, since there is a wave equation for disturbances in those directions, and since the boundary conditions are the same as for the ends of the closed pipe. If the pipe is much longer than it is wide or high, then the wavelengths of the standing waves across the pipe are much smaller, and the frequencies much higher than for the waves along the pipe axis. Therefore they do not enter into the answer to this question. If the cross section is circular, then the standing waves in the directions perpendicular to the axis of the pipe look like Fig. 14–6. Again the distance between crests is much smaller than the wavelengths of quite a large number of harmonics for waves along the pipe axis.

11. As we shall see in Chapter 16, blowing air across the opening of the bottle causes a change of pressure across the top of the bottle, which can set up a standing wave. This wave is analogous to the one-end-open organ pipe wave, so that the fundamental wavelength is roughly four times the length of the bottle. This is a fairly long wavelength, and therefore a fairly low frequency, or deeply pitched, wave. For a tube open at both ends, we have the situation shown in Fig. 14–27. These boundary conditions produce their own harmonic series.

13. Since the pitch does not change on reflection, we may view the process as the arrival of a sound wave at the cliff, and the subsequent emission of a sound wave with the same pitch by the cliff. The pitch as received by the cliff is raised from f_0 because the source is moving toward the receptor. As far as the reflected wave is concerned, we now have a moving observer dealing with a *raised* frequency of emission (but a stationary emitter). Thus the overall effect will again be a raised frequency. For a numerical evaluation

$$f_{\text{final}} = \left(1 + \frac{v_{\text{car}}}{v}\right) f_{\text{refl}}$$

$$= \left(1 + \frac{v_{\text{car}}}{v}\right) \frac{f_0}{1 - v_{\text{car}}/v} = \frac{v + v_{\text{car}}}{v - v_{\text{car}}} f_0.$$

CHAPTER 15

1. We have set the wall separation so that the (fundamental) wavelength is fixed. The relation to this wavelength and the frequency with which the string vibrates is determined by the speed of waves on the string, i.e., by the tension and mass density of the string. There is no reason why this speed is the same as the wave speed in the medium. Thus there is no reason why the frequencies of the wave and the medium must match.

2. If we think of the vibrations of the prongs of a tuning fork as a harmonic oscillator, we recall that $\omega = \sqrt{k/m}$, where k is the spring constant, characteristic of the structure. Thus an increase in mass (such as the additional mass of the tape) reduces the frequency, and that is what happens when the tape is added.

3. In the first case, the different starting time would just reflect a different phase. *Nothing* is changed if we define a new time $t' = t - 5\text{ s}$ and write the same equations that we wrote down with t replaced by t'. All we are doing is resetting the clock. In the second case we note that generically $\cos(kx - \omega t) = \cos\omega(t - x/v)$. Since the traveling waves move with the same velocity, a shift in the location where we observe the mutual maximum merely changes the origin of the t variable, and nothing really changes.

4. The motion is in a radial direction so that the angle θ does not change. The listener will still be at the first maximum. There are other effects: There is a Doppler shift, but this is very tiny since the shift is of magnitude $v/v_{\text{sound}} = 3/330 \cong 0.01$. The main effect is the loudness, since that falls off as $1/R^2$. This means a reduction of the sound intensity by a factor of 4.

5. Assuming constructive interference, the first maximum occurs on the center line with $\theta = 0$. The largest value of θ for an experimental setup as described is 90°, and this will be the limiting case of a "completely" spread-out pattern if that

value of θ corresponds to $n = 1$. This occurs when d decreases to the size $d = \lambda$.

6. This wave is a standing wave in that at a given value of x the displacement varies between limits with a time dependence given by $\sin \omega t$. Since the wall was chosen to be at $x = 0$, the standing wave pattern holds for all values of $x < 0$. This pattern is identical to one in which a string is fixed at $x = 0$ and at $x = -2\pi/k$, for example, but its existence does not depend on having *two* ends fixed.

7. If we think in terms of a string attached to a second string, then the *continuity* of the strings—that is, the absence of a break at the connecting point (e.g. $x = 0$) provides a condition relating the incident wave, the reflected wave, and the transmitted wave at that point. Since this holds for all values of t, we will get another equation relating the three amplitudes. Unlike the energy condition we used here, which is quadratic in the amplitudes, this will be linear. We'll have enough information to solve for the amplitudes of the reflected and transmitted waves in terms of that of the incident wave.

CHAPTER 16

1. (a). The radius doubles, so the volume increases by a factor of 8. For density, which is mass per unit volume, the numerator (mass) doubles while the denominator (volume) goes up by a factor of 8; the density therefore drops by a factor of 4.

3. As in the example here, when the valve area is small it takes much less force to obtain a significant pressure across it, because $p = F/A$. This pressure is then transmitted everywhere within the fluid—in this case within the tire tube.

4. It is the difference in pressure between inside and outside the tube that gives rise to the force that pushes the mercury up inside the evacuated tube. If the top of the tube were open to the outside, the mercury would not rise at all. If there were, say, a third of an atmosphere above, then the net force up would be 2/3 of an atmosphere, and the height would be 2/3 of 760 mm.

5. The same reasoning that explains why the column of water (less dense) is higher than the column of amyl bromide also explains than the column of heptyl ether would be higher than the water column. A quick repeat of the calculation with heptyl ether would give $h_{he}/h_w = 1.23$.

7. (a) The density of salt water is greater than that of fresh water, and the final answer for the density would therefore be larger by a few percent according to the last equation in the example.

8. In contrast to the completely submerged sphere of Example 16–7, a floating object has a buoyant force that cancels the weight completely. The scale would read zero.

9. To reach a further distance, the water should come out of the nozzle at a higher speed—a projectile fired with a larger initial speed will go further. Thus a smaller nozzle diameter is required.

10. If the area changes, then the conservation of flux vA shows that the speed must change as well, increasing as the artery narrows. The full conservation law, Eq. (16–22), applies. A look at that equation shows that if both v and h increase as we go to the head, then p at the head will decrease even more than it did when only h increased. In turn, the pressure at the heart would have to be still higher to compensate. Narrowed arteries are dangerous, as blood flow to the body is reduced and the heart has to exert more effort.

11. An algebraic calculation as in the example would allow you to find the stream speed as a function of hole height. This could then be converted into an algebraic calculation of the horizontal distance carried by the stream as a function of hole height. One could then maximize this by setting the derivative of the horizontal distance with respect to height to zero. You can see that neither a hole near the top nor one near the bottom would give the farthest distance from the tank. For a hole near the top, the water will exit with a low speed, because the pressure is low. For a hole near the bottom, the interior pressure and hence the initial speed will be large, but the stream hits the ground very soon. Fig. 16–25b shows the trajectory of fluid for a variety of hole positions.

CHAPTER 17

2. Temperatures cannot be measured with this type of thermometer when the temperature and pressure are extremely low, because gases liquefy or freeze in this region of extreme cold. There are, however, other kinds of thermometers that we can use in this region, as we'll discuss later.

5. At the higher temperature the bridge would have expanded to fill up the 50-cm gap. At the lower temperature the bridge would have a 50-cm gap, enough to swallow small children if there were only a single joint. With many joints this is less of a problem! In any case, the joints tend to be closed in summer when it will be more pleasant to cross.

6. The inequality of the β-values states that the gasoline will shrink more than the container when the temperature goes down. You can safely fill to the brim on the hottest summer day, and when you look inside the container in winter, the container will not be full.

9. Air consists primarily of oxygen (molecular weight 32.0), nitrogen (molecular weight 28.0), and argon (molecular weight 39.9). The number 29.0 is a weighted average of the constituents' molecular weight according to their percentages in air: oxygen (21%), nitrogen (78%), and argon (1%). We have $M(\text{air}) = 0.21(32.0) + 0.78(28.0) + 0.01(39.9) = 29$.

11. None of them. The constant temperature line is shown on Fig. 17–13, while constant p is a horizontal line and constant V is a vertical line.

13. As it works its way to the surface, the radiation emitted from the Sun's interior is absorbed and reradiated at wavelengths characteristic of the successive temperatures of successive distances from the center.

CHAPTER 18

1. Because the temperature is constant, the transformation would be represented as a straight line parallel to the p axis as the pressure changes. The line would be at the fixed value of T.

3. One of the most common misunderstandings about thermodynamics is the incorrect assumption that heat and temperature are practically the same thing. Just because the temperature is unchanged does not mean there is no heat flow! In fact, there will generally be heat flow at constant temperature if other thermodynamic variables change.

4. (a) higher. The specific heat of aluminum is higher than that of iron (see Table 18–1). That means that for a given heat flow the temperature of the aluminum would change less, and that corresponds to a larger system temperature.

6. If the latent heat of fusion were much larger, then the freezing of lakes would be much rarer, since the air would have to extract a great deal more thermal energy from the lakes. Once a lake froze, melting would correspondingly be much more difficult. Ice cubes would not melt in drinks. (But they would still make them cold!) On the other hand, if the latent heat of fusion were very very small, the lakes would essentially have the same temperature as air, freezing quickly when air temperature fell below the freezing point, with the delay coming only from the time it takes water to conduct heat. Ice cubes would still have a cooling role, although a smaller one, and they would quickly melt and dilute your drink.

7. The rate of heat loss is proportional to the surface area, and a sphere has the smallest area for a given volume.

8. An examination of Eq. (18–12) shows that any term with a small R-value has a big effect. See the discussion following this example.

9. Yes. Kinetic energy will be converted to thermal energy when the containers crash on the road below. It does not matter how the containers receive the kinetic energy.

10. You are not reversing the entire process; in fact you are adding energy, whose source is your muscles, raising the weight and heating the water still further. We'll see in Chapter 20 that the impossibility of reversing the results of chaotic processes such as the churning of water is the basis of the second law of thermodynamics.

11. (b) You can see from the figure that the area enclosed is more than doubled. If you prefer an algebraic solution, the ratio of the new work to the old is $(2p_2 - p_1)/(p_2 - p_1) = (2p_2 - 2p_1)/(p_2 - p_1) + p_1/(p_2 - p_1) = 2 + p_1/(p_2 - p_1)$, a result larger than 2.

12. Because the cycle is closed, the internal energy over one cycle is unchanged, and the net heat flow in will always equal the work done. The heat flow in is positive if the path is clockwise and negative if it is counterclockwise.

13. The heat flow has to come from the thermal reservoir. The reservoir is, by definition, so large that you can take as much heat flow from it as you like without changing its temperature.

14. Since the temperature is constant, the internal energy does not change. Since the gas does work, thermal energy had to flow in, the same amount as the work done, so that positive thermal energy comes out of the reservoir.

CHAPTER 19

1. The internal energy enters in the expression for the collision rate in the form $(U)^{1/2}$; doubling the internal energy increases the collision rate by a factor of $2^{1/2}$.

3. The argon atoms are very few in number, so as soon as equilibrium sets in, they will be characterized by the same temperature as the helium atoms. Thus they have the same average kinetic energy as the helium atoms. Since the kinetic energy is of the form $m\langle v^2\rangle/2$, and since argon atoms are much more massive than helium atoms, their rms speed will be smaller.

4. The b values measure the space occupied by a mole of molecules, and as the calculation

above shows, the molecular radii of these substances must therefore be within a factor of $2^{1/3} = 1.3$ of each other. Positive a values decrease the pressure that the gas exerts on the surface of the containing vessel. This comes about because there is a force that slows down the molecules as they approach the container walls, so to speak, and therefore reduces the momentum transfer per wall collision and thus the pressure. This suggests that molecules exert an attractive force on each other.

6. The answer is "obviously" 1.65 m. If we were asked to justify this, our answer would be based on the symmetry of the U shape. An algebraic demonstration of this would be tedious but quite straightforward.

8. The dependence of the mean free path on the number density, and in particular $\lambda \propto 1/n = V/N$, is the relevant point here. The compression reduces the volume (the number of molecules does not change) and therefore the mean free path is reduced. Just how much the volume is reduced depends on whether the compression is adiabatic or not, but that is not our concern here. It makes sense that the mean free path is reduced: It is harder to get through a dense crowd than a dispersed one.

CHAPTER 20

1. We can count without writing out each case by saying that there are three ways to assign the first number, then two ways to assign the second, and only one choice for third number, making a total of 6. The traditional way to approach this is to think of three boxes and three integers, and count the ways in which they can be filled. For the first box: there are three integers, and any one of them can fill that box. When that is done there are two boxes left and two integers. There are two ways of filling the second box, and finally the third integer goes uniquely into the third box, so that the number of ways is $3 \times 2 \times 1 = 6$. This way of doing things would prove superior if you had to do this problem for four dice.

2. To increase the efficiency, decrease the ratio T_c/T_h. For the second part, probably the most sensible thing would be to scale the heat flow for both reservoirs. There are practical limits to how high we can make T_h, and to get to T_c below the temperature of available coolants, such as river water for power plants, is costly.

6. It is clear from Eq. (20–12) that for a small temperature difference the coefficient of performance of the refrigerator is large, and this means, according to the definition in Eq. (20–10), that little work needs to be done. In the limiting case, when your kitchen is at 40° F, you can just unplug the refrigerator!

7. There is no need for a complicated calculation. We need only recall that the entropy is a state function, and therefore the change in entropy from an initial state to a final one is *independent of the path taken*. The result is unchanged as long as the initial and final states are the same.

10. The process is irreversible, since the gases, once mixed, will not spontaneously unmix. This means that $\Delta S > 0$.

11. A look at the expression for the entropy suggests that since the new volume, 3.0 L, is smaller than the original one, the entropy change would be negative, forbidden by the second law. But that assumes that all of each gas goes into the small container. In fact, such a process would not take place spontaneously. Some of the argon and some of the neon would pass into the common 3.0 L container, but much of the gas would stay where it was. The argon would increase its volume from 5.0 L to 8.0 L, and this would increase the entropy. The neon would be increasing its volume from 12.5 L to 15.5 L, and its entropy would also increase.

CHAPTER 21

1. The missing mass will be (number of electrons) × (mass of an electron) = $(6.9 \times 10^{11}$ electrons$)(9.11 \times 10^{-31}$ kg/electron$) \cong 10^{-18}$ kg. There is no instrument we can use to measure such a small mass, let alone a mass difference of that size.

2. (a) The charge left behind would have the same magnitude as the total electron charge, 1.1×10^6 C, because the coin was initially neutral. (b) If one of the 79 electrons in each gold atom were removed, the total charge would be only 1/79 of the charge just found, or 1.4×10^4 C, which is a huge electric charge.

4. No, just the opposite: Charge opposite to that of the smaller piece would move closer to that smaller piece, because it is attracted, while charge the same as that of the smaller piece would move farther because it would be repelled. The net effect would be an even stronger attraction. This phenomenon, charge induction, is what lies behind the separation of the electroscope leaves in Conceptual Example 21–3.

5. Most objects have little or no net electrical charge, and there is no Coulomb law force between such objects. The Earth is practically neutral, so that there is little or no Coulomb force between us and Earth, as we are also electrically neutral. But Earth is extremely massive, and the gravitational force between us and Earth is adequate to hold us at the surface.

6. The electric force between the two cork balls would be unchanged. The lower ball's mass is irrelevant—it sits on a surface. The force of gravity on the upper ball would now be twice as large as above and would match precisely the Coulomb force acting on it. It would now be in equilibrium and would not move farther.

7. Charges q_1 and q_2 are identical. If we place q_3 precisely on the x-axis between the other two charges, q_3 will be equally attracted to the other two charges. If q_3 is displaced slightly toward either q_1 or q_2, its attraction to the nearer charge will be larger than its attraction to the farther one, because the Coulomb force increases as $1/r^2$ when r decreases. Thus q_3 will not return to equilibrium—the equilibrium is unstable.

9. When $L = 0$, the charge is at the middle of the ring, and, by symmetry, the net force should be zero, as in Conceptual Example 21–9. This is indeed a property of our result, and a second check of the calculation.

10. The right side of the rod is positively charged, so we expect on physical grounds that the repulsion on the point charge will become very strong. This is verified with a numerical evaluation of the force. We can also see it in the analytic expression: Our limit is $R \rightarrow L/2$, and the dominant term in the force in this limit is the term $1/(R - L/2)$, which is indeed positive. The force on the point charge is large and to the right.

CHAPTER 22

2. There would be no change in the electric field due to q. However, the force on a q' of opposite sign would be a force with the same magnitude but reversed direction. The force would be repulsive, not attractive.

3. Remembering that the electric field produced by a charge points away from the charge if the charge is positive and toward the charge if the charge is negative, we see that the fields from all three charges are to the right in the region between q_2 and q_3. Thus the net field also points to the right.

4. Very close to one of the charges the net field is to a good approximation the field of the close charge, and this does not depend on L in any way. It is also possible to show that the field depends on p alone at distances $r \gg L$, although this requires a detailed analysis.

6. Although the lines will initially bend toward $-q$, very far away they will be pointing radially outward from a net charge $+q$ $(+2q - q = +q)$; at great distances we see a net charge of $+q$, and the field will be indistinguishable from the field of a point charge $+q$. The fact that 12 lines remain is consistent with our original choice of 24 lines for the line density (Fig. 22–13c).

7. To a point charge very close to the rod, the rod appears to have infinite length, and there is an infinite amount of charge in an infinite rod with a finite charge density. The summation over all the fields from charges in the rod, including the ones that are very distant from the point at which the field is measured, builds up a net field that decreases more slowly than the field of a finite charge distribution.

8. (b)

10. (c). The surface charge density would be larger because the area of the Moon is smaller than that of Earth, so the Moon's surface electric field would be correspondingly larger. If you calculate the (repulsive) Coulomb force between Earth and the Moon you would find about 10^{-5} N, a completely negligible effect.

11. The electron would not move, because it would be attracted to the positively charged plane.

12. (b) Our expression for y is proportional to E. This is the feature that makes the tube we have described here so useful.

CHAPTER 23

3. Gauss' law is now applied to a total charge of $q + 2q - 7q + 4q = 0$. There will be no *net* flux through the surface. Again we stress *net* flux, because there will certainly be flux going out of, and coming into, the surface, as could be seen by putting a cube around the two equal and opposite charges in Fig. 23–12b.

4. We would now use the principle of superposition of electric fields. Each face would get no contribution from the four charges at its edges, but would get an equal contribution from each of the four charges around the opposite face. Thus the flux through each face is $4 \times (q/24\varepsilon_0) = q/6\varepsilon_0$.

5. The symmetry is the same as in the example. If we take a Gaussian surface that is cylindrical with the same axis as the charged cylinder with a radius larger than that of the charged cylinder, exactly the same argument holds, and we obtain the same result. On the other hand, if we draw our Gaussian cylinder *inside* the charged cylinder, then the symmetries are exactly the same, but the enclosed charge is zero. This is what we would expect, as the electric field inside the cylinder is zero.

6. The Gaussian surfaces will again be concentric spheres. In each case we end up with the result $E = \dfrac{Q_{\text{enclosed}}}{4\pi\varepsilon_0 r^2}$. When r is larger than the radius of

the outer shell, then the total enclosed charge is zero, so that $E = 0$. When r lies between the shells, then the total charge enclosed is Q and that is to be inserted in the above equation. When r is inside the inner shell, then no charge is enclosed and $E = 0$ again. There is a non-zero field only between the shells.

7. The motion is determined by the force, and the force on the charge is directed toward the center, with magnitude

$$F = -qE = -\frac{qQ}{4\pi\varepsilon_0}\frac{r}{R^3}$$

This is a "restoring" force proportional to the displacement from the origin. The motion is therefore simple harmonic motion, and the charge will oscillate about that point.

8. We know that at a great distance from the charge distribution the electric field lines from any localized charge, such as found on a finite plane, are spread in a spherically symmetric pattern, as if the charge were a point charge. This means that the field lines will ultimately bend and not point straight away from the charged surface. In a region close to the charged surface, where the distance to the surface is small compared with the distance to the nearest edge, we may make the approximation that the field lines are perpendicular to the charged surface. If we take for a Gaussian surface a very shallow squat cylinder half into the surface, the argument that led to Eq. (23–11) goes through as before, and the result applies here too.

CHAPTER 24

3. False. The sign of this result makes sense. The electric potential at point b is negative. The new charge is positive and will be attracted to the negative potential. Franklin would have to do positive work to bring the same charge back out to infinity. It is better to understand what is happening physically than to rely on your ability to avoid algebraic error.

4. The energy of the at-rest electron-proton system once the electron has been moved far away is zero. Therefore you must add positive energy to the system to make the separation.

5. If we could freeze the charges in position, then there would indeed be a dipole field. However, the two charges form a kind of planetary system, revolving around each other; from a given point P the angle θ that appears in Eq. (24–24) varies uniformly with time. Thus the average dipole potential involves the average of $\cos\theta$. But $\cos\theta$ varies between -1 and 1, and its average value is zero.

8. Yes. The electric field points from the positively charged plate to the negatively charged plate (see for example Fig. 22–19). We also know that the electric field points from the higher to the lower potential surface. This then implies that it is the lower potential surface—the left side plate—that carries the negative charge.

9. The solution is obtained by setting $x = 0$. It is $V = \dfrac{Q}{4\pi\varepsilon_0 R}$. The result follows very simply from superposition. The fact that all the charges whose potentials add up lie on a circle is irrelevant, because the potential is a *scalar* quantity that does not involve directions. The only thing that matters here is that the center is equidistant from all the elements of charge.

10. (d). This is evident from the fact that at a great distance the disk is indistinguishable from a point charge. If we want to take a mathematical limit, we cannot just drop the R^2 term in the square root, because we then get zero. We instead need to work out the term in parentheses by making use of the fact that

$$\frac{x}{\sqrt{x^2 + R^2}} - 1 = \frac{x}{x\sqrt{1 - (R^2/x^2)}} - 1$$

$$= \frac{1}{\sqrt{1 - R^2/x^2}} - 1,$$

then making an expansion of 1 divided by the square root for small R/x.

11. Writing the potential as

$$V = \int_{-\infty}^{\infty} \frac{\lambda\, dz}{4\pi\varepsilon_0\sqrt{R^2 + z^2}}$$ is based on choosing the potential due to an element of charge as vanishing at infinity. As argued in the solution, this is not legitimate here. In fact, the integral written above is independent of R (easily seen by changing variables to $u = z/R$), and therefore gives a zero electric field, an incorrect result.

12. The relevant fact is that the potential is *constant*. This means that its derivatives are zero, consistent with zero electric field. The particular constant value of the potential ensures that the potential is *continuous*. If the potential were not continuous at $r = R$, then the motion of a point charge in that potential would not be physical; a jump in the potential energy would require a discontinuous jump in the kinetic energy, that is, in the velocity of a point charge.

CHAPTER 25

2. The potential difference doubles when Q doubles, but C is unchanged. C depends only on factors such as geometry, and is independent of the amount of charge on the capacitor.

4. The permittivity, ε_0, has units F/m and so must be multiplied by a length to give an acceptable capacitance. The only length in this problem is the radius of the sphere, so $C \propto \varepsilon_0 R$.

5. The energy stored in a battery is local and is held chemically, molecule by molecule. In a capacitor, each time we transfer another charge, it requires more work, because there is an increasing amount of charge already placed on the capacitor. We are fighting an uphill battle.

7. In regions outside the sphere itself, the sphere behaves as if all its charge is concentrated at the center. Thus it requires more work to bring charge from infinity and place it on the smaller conducting sphere because in effect you are closer to the center when you are charging a smaller sphere. Therefore the energy of the system also becomes large.

9. Consider the extreme case where we make this capacitance very small. From Eq. (25–17) we see that a small capacitor has a large effect when it is placed in series with other capacitors; indeed a capacitor with a very small capacitance C_{small} will dominate all the terms, giving as a good approximation $C_{\text{eq}} = C_{\text{small}}$. Thus decreasing the capacitance of the 2 μF capacitor will decrease the equivalent capacitance.

10. Yes, work was done because the electrical energy changed. The sign of the work done by the capacitor is positive, because the capacitor's energy decreases as the Teflon was inserted.

11. Bakelite has a larger value of the dielectric constant κ, so that for a given charge, the field within the Bakelite would be smaller, the voltage drop across the entire space would be smaller, and hence the capacitance larger.

12. The *change* in energy, which is what determines the force, depends only on how much *additional* length of plug is inserted. For example, the energy change is the same whether the plug is first inserted 1 mm in as it is when the plug is already 1 cm in and is then inserted an additional 1 mm.

CHAPTER 26

1. In a proton beam the charge carriers are positively charged, whereas in a wire the charge carriers are electrons, which have negative charge. Moreover, a wire is electrically neutral, because there is a background of positive ions that match the current-carrying electrons, whereas a proton beam in space is not neutral.

2. The question is, Is the rate at which charge goes into the annihilation region the same as the rate of charge that goes out? If we go to the right of the annihilation region, we only have a flux of antiprotons, and the entering rate of charge from the right is $N'e = Ne$. On the left of the annihilation region we have only a flux of incoming protons, and the rate at which charge enters is $N(-e)$. When we add these two terms together, we see that the net rate at which charge enters is zero, the same as the rate at which it leaves. Current conservation is a necessary consequence of charge conservation.

3. For a fixed current density, a quadrupling of the current implies a quadrupling of the area, and since the area is proportional to the radius squared, the radius of the wire will have to be doubled.

4. Table 26–2 shows that the resistivity of iron is about six times larger than that of copper. This means that for fixed E, the current density will be about six times smaller, and for a wire of the same cross section the current will also be a factor of six times smaller. Copper is used widely in the wires of circuits, and appliances, as it is a good conductor and has good mechanical properties.

5. A crucial requirement for a filament is that it should not melt! The other is that it is best to have a higher resistance, since it is the resistance that is responsible for the dissipation of energy, and this dissipation manifests itself in the heating of the coil, and ultimately in the radiation of the coil. Our result above tells us that at a temperature a bit below the copper melting point, the resistance per unit length of our platinum wire is $53/20 = 2.65\ \Omega/\text{m}$. The coefficient α for platinum is the same, but ρ_0 is a factor of 6.2 larger, so that even at the same temperature, the resistance of the platinum filament is that much larger. In addition, the platinum filament can be heated to a higher temperature, increasing the resistance still further. For these reasons the platinum filament is to be preferred.

6. With this exchange, the resistances on both sides would be equal (10 Ω each). With two equal resistances in parallel, the currents would be divided equally. This can be calculated but is also evident from symmetry—two identical paths will carry the same current. This means that the current in each branch is 1.5 A, and the potential difference overall is the same on both sides, i.e. $(1.5\ \text{A}) \times (10\ \Omega) = 15\ \text{V}$. The potential difference across the 4 Ω resistor is $(4\ \Omega) \times (1.5\ \text{A}) = 6\ \text{V}$.

9. With $P = V^2/R$, we can immediately tell that a doubling of the voltage implies an increase of the power by a factor of 4.

10. For a fixed voltage, the power is given by V^2/R. Whatever the resistance R of the bulb is,

the power will be halved in case (a), since the resistance is doubled. The power will be doubled in case (b), since the reciprocal of the resistance is doubled. If the purpose of the lighting is to generate heat to keep the paint from freezing, the first alternative may be inadequate and the second too expensive.

11. The current is given by $(P/R)^{1/2}$. The radiated power is proportional to the overall area of the (cylindrical) wire, hence proportional to d; the resistance is inversely proportional to the cross section of the wire, hence proportional to d^{-2}. Thus, for a given $I \propto (d/d^{-2})^{1/2} = d^{3/2}$. You should therefore reduce the diameter of the wire to decrease the current. That means that the power will be reduced, so the wire will not be quite as effective at heating its surroundings.

CHAPTER 27

2. If we start from the expressions for $\mathscr{E}$ and r, we see that in the formula for $\mathscr{E}$, R_1 must be taken to be zero to the accuracy that the resistances are measured. Similarly, in the numerator of the expression for r, the second term I_1R_1 must also be taken to be zero to the accuracy under consideration. This then implies that $r = \mathscr{E}/I_1$. This can be calculated to two significant figures.

3. For a given battery, with characteristic emf and internal resistance, the expression $P = \mathscr{E}I$ shows that P is largest when I is largest. This is achieved in our circuit by reducing the external resistance as much as possible. Setting $R = 0$ gives $P_{\max} = \mathscr{E}^2/r$.

4. As stated in "Setting It Up," the solution to the problem decides the current direction. If we had initially chosen the opposite current direction our algebraic solution would have been positive. Because the emf $\mathscr{E}_2$ is larger than the emf $\mathscr{E}_1$, we could have anticipated that the current will run counterclockwise.

5. If R_2 is large, there is so much resistance in the leg that contains it that the current I_2 should drop to zero. In effect, the segment containing R_2 would be eliminated from the circuit. In this limit our expressions give $I_1,\ I_2 \rightarrow (\mathscr{E}_1 + \mathscr{E}_2)/(R_1 + R_3)$, and $I_2 \rightarrow 0$, just as we expect.

6. As long as the loop equations are independent, the Kirchhoff rules will always give the correct answers. In this case it is particularly easy to see that this applies: All you have to do is flip the segment (d–battery–a) to the other side of the diamond. In that case the new loop is just the mirror image of the old loop.

7. (a) The resistance can never be negative, whatever the signs of the emf or the current direction. (b) The sign of the potential difference between the two plates shows that the potential increases when we go from plate 1 to plate 2, meaning that plate 2 is at a higher potential than plate 1. This is because positive charges have accumulated on plate 2.

9. Qualitatively the corrections to V are of the general form R/R_V, where R is the generic resistance in the circuit (e.g., combinations of R_1 and R_2 in this example). When the denominator is a factor 100 times larger, the error, instead of being in the 3% range, is in the 0.03% range.

10. A look at Fig. 27–20b shows that we are dealing with the very flat part of the curve on the extreme right. To answer this quantitatively we need to know something about exponential functions, or equivalently about natural logs. As we saw in the example, the time is determined by $e^{-t/\tau} = 1 - p$, where p is the desired percentage. In the flat part of the curve we are dealing with p very close to 1 (0.999, and now 0.9999), so that if we write $p = 1 - x$ (with x very small), we get $-t/\tau = \ln x$ or $t/\tau = \ln(1/x)$. If we look up $\ln(10) = 2.30$, we see that each factor of 10 in the percentage accuracy increases the time (in units of RC) by an additional 2.30 units. In this case we would increase 6.91 ms to 9.21 ms.

CHAPTER 28

2. When a rock is thrown, the gravity force perpendicular to its initial motion is constant, and it always points in the same direction. In the case of a magnetic field, the force changes direction as the velocity changes direction. Furthermore the velocity is constant in magnitude. The path of the electron is therefore quite different from the familiar motion of a thrown rock.

3. For a given charge (and the deuteron and the proton have equal charges), the radius of curvature is proportional to the momentum, the product mv. The deuteron mass is double the proton mass, so it would have the same momentum as the proton if the speed were halved.

4. Let us assume that the charged particle comes out of the opening hole traveling in the $+z$-direction. If the magnetic field is used to define the $+x$-direction, then the magnetic force points in the $+y$-direction, and the electric field must therefore point in the $-y$-direction. Suppose the particle is positive and has an excess velocity that is originally in the $+z$-direction. The magnetic force will now initially be in the $+y$-direction. The particle will acquire a small component of velocity in that direction and will start a circular motion (with angular frequency qB/m) in a clockwise direction as seen by somebody looking along the x-axis. The path will be similar to that of a point on the rim of a wheel whose center is moving with a uniform speed while the wheel is rotating in a direction opposite to what its rolling rotation would be like. A negative particle would have motion like a spot on the rim of a rolling wheel.

9. The wire and field form a plane, and the force is perpendicular to the plane. Whether it goes into or out of the plane depends on using the right-hand rule in accordance with Eq. (28–19).

11. We have already mentioned that bar magnets are influenced by magnetic fields in just the same way as are current loops. This suggests, correctly, that the compass needle, which is a small bar magnet, behaves much like the loop in this example, oscillating about the stable equilibrium position in the absence of damping.

12. The drift velocity does not depend on the width of the strip. The electric field will be of magnitude vB, so that it does not depend on the width of the strip. Therefore the potential $V = Ed$ will double if the width of the strip doubles.

CHAPTER 29

2. The magnitude would be unchanged. We didn't specify the direction of the current in the first place, so there is no real information on direction. But if the current is reversed, the direction of the magnetic field would be reversed. The direction of the field is determined by the right-hand rule: If the thumb of the right hand is in the direction of current, the fingers indicate the direction of the magnetic field.

3. The flux will be a maximum when $\cos\theta = 1$, so that $\theta = 0$. This corresponds to the loop perpendicular to the field.

4. With another row of wire, the number of turns per unit length n would double, and the magnetic field would also double.

6. We work directly from Eq. (29–21), which for $L \gg D$ becomes $B \cong \dfrac{\mu_0 I}{4\pi}\dfrac{L}{D(L/2)} = \dfrac{\mu_0 I}{2\pi D}$, which is the same result as given by Ampère's law for the infinitely long wire.

7. Yes. We curl the fingers of the right hand along the current, and the thumb indicates the direction of the field. This orientation rule is the same one that we found for the magnetic field of a solenoid; indeed, the loop is nothing more than a compressed solenoid.

8. An electric dipole; see Eq. (22–14).

9. Remember that the electric field between the plates depends only on the charge density and is independent of d as long as $R \gg d$. The displacement current and magnetic field between the plates will not change.

CHAPTER 30

2. (c) The induced current will always be in the direction to oppose the change in magnetic field through the loop. As the loop goes back into the region of field, the induced current will be opposite to what it was as the loop left the field. The magnetic field that the induced current creates will oppose what is now an increasing magnetic flux.

4. The motion of the loop toward the straight wire would produce the same change in magnetic flux through the loop as the motion of the straight wire toward the loop. The effect would be exactly the same.

5. (b) The induced emf is the same, but the resistance increases; hence the induced current will be less.

7. The Lorentz force is $q(\vec{v} \times \vec{B})$, and its direction on a positive charge is indeed radially outward, in agreement with the result we found using Faraday's law.

9. Because the kinetic energy doesn't change, the change in total energy (dissipated in Joule heating) comes from the change in gravitational potential energy.

10. We can imagine a large circle, radius R, well outside the pole faces but centered at the center of the faces. The magnetic flux through this circle is to a good approximation $\Phi_B = B\pi r_{\text{face}}^2$, where r_{face} is the radius of the magnet. The same symmetry argument gives the electric field lines forming circles centered at the center of the pole face. As in the example, the magnitude of the field is now determined by $E \times 2\pi R = \pi r_{\text{face}}^2 \alpha$, or $E = r_{\text{face}}^2\alpha/(2R)$; the field falls off as $1/R$. If R is larger than the whole magnet then $E = 0$.

CHAPTER 31

1. (b) Far smaller. The susceptibility of copper is much less than 1, so the expression for B includes $(1 + \chi_m) \cong 1$ instead of the very large value of the χ_m for iron. This means that B inside will be practically unchanged from its vacuum value.

3. The expression for the magnetic moment is proportional to vr which can be rewritten in the form ωr^2. When the nucleus and the electron rotate about their center of mass, the angular velocity ω is the same for both of them. However, the center of mass is very close to the massive nucleus, so

that to good approximation $r_N = (m_e/M_N)r_e$. Thus the contribution of the nucleus to the orbital magnetic moment is negligible.

4. The terrestrial environment, in particular terrestrial temperatures, are such that the thermal energy of the tiny magnets (of order kT) dominates the energy of their interaction with any magnetic field B. In particular, the difference in the energies between alignment and anti-alignment ($2m_BB$) is tiny compared with kT. Thermal effects destroy order, and in this case, with $kT \gg m_BB$, they dominate the ordering that the field attempts to impose. Only at ultra-low temperatures, say below 10K for realistic fields, would you expect the alignment to be almost perfect.

6. Our calculation was based on perfect alignment of all unpaired electrons. But the assumption of a single domain is not realistic for everyday situations. This does not mean that near-perfect alignment is impossible: A nearly perfect alignment in ferromagnetic materials occurs with the application of external fields of several Tesla.

CHAPTER 32

1. (d) Doubling the number of turns without changing anything else doubles the turn density, which appears squared in the expression for the inductance of a solenoid. This will increase the induced emf by the greatest amount.

3. (a) The area of solenoid 1 increases by a factor of 4 and so does the value of L_1. There is no change in M, which does not involve A_1. (b) There is no change in either L_1 or M. Even though R_2 increases, the overlap with R_1 does not if, as here, the areas started out with the same value, so that M does not change.

4. a. The permeability is larger, indeed much larger as the material in question is ferromagnetic.

6. We must change something in the inductor, and since the geometry is fixed, that leaves the number of turns, which increases the stored energy as N^2.

7. It is limits on the current that can be carried by wires that has the most effect on our ability to make large magnetic fields. The appropriate use of ferromagnetic cores does enable these fields to attain many Tesla.

8. This is incorrect and is a matter of understanding the limits. No matter how large L is, if it is fixed there will always be a time much greater than R/L for which V_L will drop to zero.

9. The voltage doesn't depend on the value of the inductor at all. It is solely determined by the original voltage across the capacitor that in turn depends on Q_0 and C. Even though V_L in the example has an L dependence, it will cancel out if we insert the value $\omega^2 = 1/LC$.

10. The decay constant α is ten times larger, while it remains much less than ω. The reasoning that allows us to approximate the period is the same, and since $t_{1/2}$ is ten times smaller, there are ten times fewer oscillations in that time span.

CHAPTER 33

2. No; the only conceivable effect would be on the direction in which the current is induced, and in AC that is obviously unimportant.

3. For the higher frequency, 6 MHz, the capacitive reactance is small and the circuit has a small resistance to current flow. This is a manifestation of a capacitor's transparence to rapidly changing currents.

4. The resistance to current flow in the inductive circuit increases dramatically for higher frequencies—the opposite behavior from that of the capacitive circuit. The inductor acts as an open switch in the limit of very high frequencies.

7. The time dependence of V_L is proportional to $-\cos(\omega t + \phi)$, and this takes its most negative value when $\cos(\omega t + \phi) = +1$, or $\omega t + \phi = 0, 0, 2\pi, \ldots$, or $\omega t = -\phi, -\phi + 2\pi, \ldots$. If we recall that $\omega t_1 = \pi/2$, we see for $\omega t = -\phi \cong +60°$, $t < t_1$. Thus we take the next occurrence, $\omega t = -\phi + 2\pi$.

8. In the calculation of the example, R is proportional to the square root of the discrimination requirement, i.e. $(0.01)^{1/2} = 0.1$. Thus by choosing R a factor of 10 smaller we can improve the discrimination requirement by a factor of 100.

9. Examination of the equation for the ratio of potentials indicates that for $\omega \rightarrow \infty$, the left-hand side reduces to $V_1/(V_0 + V_1)$. For high frequencies, the circuit acts as though the capacitor is not present, and voltage V_1 is dropped across the resistor.

CHAPTER 34

2. Recall that the motion of the electron in the presence of fields is determined by the equation $\vec{F} = -e(\vec{E} + \vec{v} \times \vec{B})$. With the magnitude of B given by E/c, we see that the second term is of order v/c compared with the first one. Electrons in metals move with nonrelativistic velocities so that the first term is by far the more important one.

3. The electric and magnetic fields in a wave are intriniscally coupled through Maxwell's equations, and as Eq. (34–6), for example, indicates, the coupling is *local*, that is, at every point in space. This means that elimination of the electric field will also eliminate the magnetic field. Don't invest.

6. The pressure is the weight of a film of water of height h acting on an area of 1 m^2, namely $(10^3\ \text{kg/m}^3)hg$. If we set this equal to the radiation pressure and solve for h we find $h \cong 2.4 \times 10^{-8}$ m, a height only about 50 atoms deep! Radiation pressure is in most circumstances a small effect.

9. The light emitted by a lightbulb consists of the (incoherent) superposition of radiation by a huge number of oscillating charges. Each such oscillator emits dipole radiation, but because all these oscillators act incoherently, all the angular dependences average out and the distribution is spherically symmetric. Is this an "antenna"? It is as long as we agree that by this word we mean any system that radiates. If we insist upon *coherent* radiation, a lightbulb is not an antenna.

10. With the assumption that all of the power lost in the Polaroid sheets goes into heating, the ratio of acquisition of thermal energy is the ratio of intensity *lost* in the two sheets. In the first sheet, half the intensity is lost. In the second sheet, the intensity lost is the fraction $1 - \cos^2\theta = 3/4$. Thus the ratio is $(1/2)/(3/4) = 2/3$.

11. The classical answer (i.e. when there are *many* photons) is that the ratio of momentum to energy is $1/c$. This must also be valid for individual photons, and we therefore expect that the momentum of a single photon of frequency f will be hf/c.

CHAPTER 35

2. Figure 35–14 shows that if θ' is to be decreased, then ψ must decrease (Snell's law). This, however, means that ϕ will increase, and this can only happen if θ increases.

6. In this case we are talking about rays that go from air to water. Every such ray is bent to the vertical, meaning every such ray can enter the water and there is no analog to total internal reflection. The fish sees the entire upper hemisphere concentrated within a cone whose opening angle is the critical angle. That includes the fisherman's eyes at water's edge. Given that this is the case, the fisherman might be better off standing up—by being sufficiently above the surface, the fish can be visible to the fisherman at every depth.

CHAPTER 36

2. Attach a plane mirror to the object that rotates and then reflect a ray from the mirror onto a screen a distance L away during the rotation. The image on the screen will move across an arc length $2L\alpha$, and if L is large, this will be measurable. In effect, the distance magnifies the rotation.

5. It is easiest to see from rays 2 and 3 in Fig. 36–15 that the image will become smaller and move away from the mirror toward the focal point. Only ray 3 changes.

8. The magnification is less, as you can most easily see from the rays in Fig. 36–26 (the rays are refracted less).

9. Down. This is most easily seen if you used rays 2 and 3; ray 2 wouldn't change, but ray 3 would.

CHAPTER 37

2. Yes, if we measure y, R, and d, we can solve Eq. (37–4) for λ.

4. Changing the length of the feeding cables by different amounts will introduce a phase difference for the signals at the antennas, corresponding to the new path-length difference. However, the signals remain coherent, and there will be interference at your house. Whether this is destructive or constructive is a matter of the numerical value of the new phase difference.

5. We see from the solution that Δx is proportional to λ. Red light has a larger wavelength than blue, so that Δx will be larger for red light, and there will be fewer bands for red light than for blue.

6. While our list of wavelengths in the solution shows that the spacing in wavelengths between successive values for constructive interference is not equal, it will certainly be a good approximation to put a minimum (destructive interference) equidistant between 700 and 420 nm, namely $\lambda \cong 560$ nm. How would you find it exactly?

CHAPTER 38

1. Higher orders do indeed help, because as Eq. (38–7) shows the resolution increases with order, and it would be easier to resolve two closely spaced peaks.

2. The starting point will be the laser beam shining perpendicular to the CD. You could then either tilt the CD or move to the side so that you are observing the CD at an angle, and at an angle corresponding to the first- or higher-order maxima for the laser light, you will see a bright reflection.

3. The blue light has shorter wavelength, making the angles of the minima smaller, and the spacing between them on the screen is less than for red light.

4. In order to find the exact positions of the maxima, we must take the derivative of the intensity with respect to α (or θ) and set that equal to zero (see Problem 38–31).

5. If the two objects are arbitrarily far away—think of two stars—they may be arbitrarily far apart and still make an angle as small as that specified by the Rayleigh criterion. For very distant objects, it is in fact only the angular resolution—the minimum angular separation that can be resolved—that matters, and separation distance is not a quantity that is relevant here.

7. The overall deflection is $2\theta = 50°$.

CHAPTER 39

3. The Earth-based observer if situated at the end of the galaxy, would read 300 yrs on the clock, just like the spaceship pilot.

5. No, the equation in the solution shows that $u/c < 1$ no matter how large $(\lambda_1/\lambda_0)^2$ is.

6. The image is moving away from the light source, and therefore its light will be redshifted. The Alternate Solution describes this redshift, which corresponds to a shift with a velocity V that is given by adding the two velocities u according to the relativistic velocity addition formula.

7. The detailed mechanism of the clock is irrelevant to the time dilation. The effect is a consequence of the relation between space and time. In any case, the amplitude of a harmonic oscillator does not enter into the frequency. Only the mass and the spring constant do, and their transformation properties under Lorentz transformations must be such that the result of our calculation is intact.

9. The Lorentz transformation gives $t' = \gamma t$, and in view of our answer for t, we get $t' = 2L/u$. This is certainly a reasonable result. All the clocks read alike in the rest frame of spaceship B, by definition. The nose cone of A travels with speed u and traverses the length of B (in its rest frame), so that the time elapsed is $2L/u$.

10. Yes, since our nonrelativistic world deals with velocities $v \ll c$. In the limit that we may treat c as infinite, $\gamma = 1$. The events are simultaneous, the train fits into the tunnel for both observers, and all is well.

11. Once we know the connection between energy and momentum, the answer is yes. Momentum conservation still means that the two particles must have equal and opposite momenta. Then with a relativistic connection between energy and momentum [Eq. (39–36)], the conservation of energy becomes an equation for a single unknown, which can always be solved.

12. There are two huge technological difficulties. (1) There is no antimatter lying around. If there had ever been any, it would long since have annihilated with matter. Antimatter can be made in accelerators, but that costs a lot of energy, and having a large laboratory on a spaceship is at present hard to imagine. Perhaps there will be a future technology that will make accelerators very compact. (2) Antimatter is hard to keep around. It will annihilate with the matter of the walls of any container, and again give rise to huge explosions. There may one day be a technology that uses electromagnetism to hold antimatter away from container walls that are made of matter.

CHAPTER 40

2. All of the power is emitted in the form of radiation, but most of it is in the form of waves whose wavelengths do not lie in the visible range. A lightbulb generates a great deal of radiation with wavelengths in the infrared range, what we perceive as heat. In fact, incandescent bulbs are highly inefficient ways of delivering light, and in our society a great deal of money is spent to cool the spaces that they heat.

3. The reduction in the number of photons is by a factor of $(0.9 \times 10^5)/15 = 6 \times 10^4$. Since the intensity falls as the inverse of the square of the distance, the star could be seen if it were a factor $\sqrt{6 \times 10^4} \cong 250$ times farther away.

4. With a shorter wavelength, and therefore higher frequency, the photoelectrons would be emitted with a non-zero kinetic energy. With a longer wavelength, no photoelectrons would be emitted. Radiation could still be absorbed and/or reflected.

5. We know from kinetic theory that T is proportional to the root mean square velocity v in the gas, so that v scales as $\sqrt{T}$. This means that the momentum scales in the same way, while the wavelength scales as $1/\sqrt{T}$.

6. The wavelength scales with the mass m of the (nonrelativistic) particle as $1/\sqrt{m}$, so that it is much smaller for neutrons than it is for electrons. The maximum value of $\sin\theta$ is 1, and this means that the value of n can be much larger for a smaller λ, that is, many more diffraction peaks will fit in the 90° range of possible θ-values.

8. Yes. In dimensional analysis you ask what constants of the problem can enter and then combine them to make a quantity with the desired dimensions, which here is energy. That m and L could play a role as parameters is clear; what is new is that Planck's constant can also appear. The numerical factor is not defined, just as in the case of the use of the uncertainty relation.

CHAPTER 41

1. The energy of the photon is proportional to the frequency and therefore inversely proportional to the wavelength. In the two-step loss of energy, the energy is smaller in each step, and therefore the wavelength is larger in both steps.

2. Twice-ionized lithium is like hydrogen, with $Z = 3$ instead of 1. This means that the energies, which are proportional to $(Ze^2)^2$ [a factor of e is the electron charge and a factor of Ze is the nuclear charge], are 9 times larger than those of hydrogen. This changes the ionization energy to 122 eV and the estimated temperature to 4×10^5 K.

3. Because the level spacings are equal, the transitions between neighboring levels all have the same frequency and therefore the same wavelength. There would thus be only one spectral line corresponding to a change of energy $\hbar\omega_0$.

6. With a field of magnitude 10^8 T, the energy difference between the two spin states is of the order of 10^4 eV, huge on the atomic scale. All of the spins would be pointing "down," because spin-down has a lower energy than spin-up.

7. As you can see from the chart, 36 electrons make a closed shell. The thirty-seventh electron starts a new shell, and the atom with $Z = 37$ is therefore an alkali.

CHAPTER 42

1. The change is visible in Eq. (42–2). We now have a square two-dimensional "box," so that this equation will read $N_{ie} = (L/d)^2$. As a consequence, E_F is proportional to $n_v^{1/2}$ rather than $n_v^{1/3}$.

2. The calculation would not apply to the Sun, whose mass is the same but whose radius is 1.4 million km rather than 7000 km. The electron energy will be nonrelativistic. At this stage of its existence the Sun maintains its equilibrium not by internal degeneracy pressure, but by the pressure associated with the energy released in nuclear reactions.

3. We see from the expression for R that $R \propto n^{5/3-2} = (1/n)^{1/3}$. Taken alone, this result suggests that the pressure balance could be maintained at smaller and smaller values of R as n increased. But as noted above, the energy-momentum relation for the fermions changes when n increases significantly, and the balance of pressures is not sustainable.

4. The de Broglie wavelength is

$$\lambda = \frac{2\pi\hbar}{p} = \frac{2\pi\hbar}{mv_{\text{rms}}} = \sqrt{\frac{4\pi^2\hbar^2}{3mkT}}$$

so that the expression indicates $n\lambda^3 = \text{const}$, which implies that the interparticle separation and the de Broglie wavelength are of the same order of magnitude.

CHAPTER 43

1. The Fermi energy is some 7 eV, and that is very much smaller than the energy equivalent of the rest mass of an electron, namely about 0.5 MeV. All energies that arise in this example are much less than this value. That guarantees nonrelativistic behavior throughout.

4. In intrinsic semiconductors the density of n- and p-carriers is the *same*.

CHAPTER 44

2. The de Broglie wavelength is much smaller than the closest distance to the nucleus, so this criterion alone might not suggest that quantum-mechanical effects would play an important role. But remember the atom is a highly quantum-mechanical entity, and the α particle penetrates to a distance well within the innermost Bohr radius. In fact, quantum mechanics does play an important role in the effect of the α on the electrons.

4. Nuclei and neutron stars consist only of nucleons (protons and neutrons), and in both cases they are packed closely—in one instance by the attractive nuclear forces, in the other by the pressure of gravity. This close packing automatically implies that the densities are of the same order of magnitude. The force of gravity caused by the huge mass squeezes the neutrons a bit more than the nuclear forces do. In fact, if the mass of the neutron star is large enough, it will collapse enough to end up as a black hole.

6. $S_n(^{56}\text{Fe}) = [M(n) + M(^{55}\text{Fe}) - M(^{56}\text{Fe})]c^2$. While there is no particular odd-even effect in this case, we might expect ^{55}Mn to be more stable than ^{55}Fe because of its smaller nuclear charge and smaller mutual Coulomb repulsion.

The neutron separation energy is 11.2 MeV rather than the 10.2 MeV for the proton separation energy, so our conjecture is correct; it does take more energy to remove a neutron than a proton.

7. The nuclide ^{209}Pb gives up its neutron rather easily in order to reach the special double magic number of $Z = 82$ and $N = 126$. The liquid-drop model does not take into account the existence of magic numbers, which are, however, a feature of the shell model.

8. With a density of 19,000 kg/m^3, we have a volume of $1.6\,\text{kg}/(1.9 \times 10^4\,\text{kg/m}^3) = 0.8 \times 10^{-4}\,\text{m}^3$. This is about 80 cm^3, or a cube of about 2 in on a side. The mass of a basketball would be almost 1000 kg, far too much to lift without machinery.

9. The answer is (b). The ^{237}Np nucleus is so much more massive than the α particle that it must move very slowly in order to conserve linear momentum. But kinetic energy contains a v^2 factor, so the α particle carries off most of the kinetic energy.

11. The 2 protons can be used again for another proton cycle. The gamma rays contribute to the star's internal energy and can either leave the star as radiant energy or result in another reaction. The neutrinos interact weakly and are likely to leave the star.

12. Very roughly, atomic energies are a million times smaller than nuclear energies. For a given power output, 10^6 times more chemical reactions must take place, and this means that whatever burns in the Sun must be used up in 10^{-6} the time estimated for the Sun's burnout time from nuclear reactions. Since that naïve estimate was 10^{11} yr, we obtain 100,000 years, much shorter than geological times.

CHAPTER 45

1. The electron is about 2000 times lighter than a proton. A collision of the alpha particle with an electron corresponds to a collision between a car and a pigeon. Such a collision could not deflect a car by 90°, and an electron cannot be responsible for the deflection of α particles.

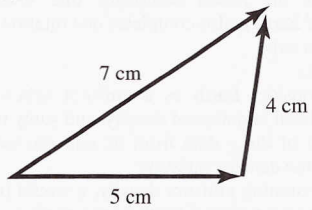
2. In the center-of-mass frame, the proton has equal and opposite momentum to the electron, corresponding to a value of pc that is also 5 GeV. The proton rest mass is 0.94 GeV, and thus its motion, too, is relativistic.

5. The experiment is never carried out exactly at the threshold energy. At any energy above the threshold energy, the protons and antiprotons move away from each other, and the annihilation does not occur.

7. When we go from particle to antiparticle, Q and B change signs. Thus the first two particles cannot be their own antiparticles. The third one has $Q = B = 0$, so it can be its own antiparticle, just like the photon. This is evident from the quark assignment—just change the c-quark to its antiparticle and vice versa.

8. This is not entirely a fair question, because it requires some knowledge about the quantum numbers involved and their conservation. The conservation of quark-type in the strong interactions means that in a reaction that has no t quark in the initial state, the t quark in the final state must be accompanied by a $\bar{t}$. This means that the initial energy of each of the incoming particles is equal to that of the rest energy of the top quark rather than half that value.

9. The mass of a single hydrogen atom is M. Thus the number of atoms per cubic meter is

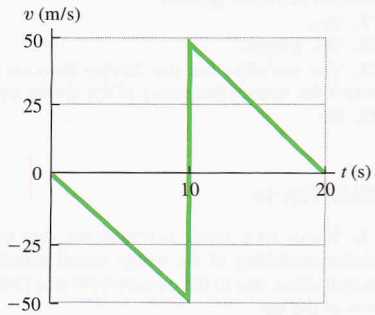


$$\frac{\text{atoms}}{\text{m}^3} = \frac{\text{kg}}{\text{m}^3} \times \frac{\text{atoms}}{\text{kg}} = \frac{\text{kg}}{\text{m}^3} \times \left(\frac{\text{kg}}{\text{atom}}\right)^{-1} = \frac{\rho}{M}.$$

With $M = 1.67 \times 10^{-27}$ kg, this turns out to be about 0.6 atoms per cubic meter.

Answers to Odd-Numbered Understanding the Concepts Questions

CHAPTER 1



1. Yes; a vector $\vec{V}$ will have 4 components: $\vec{V} = (V_x, V_y, V_z, V_w)$.
3. Mine is 180 cm, or 1.80 m.
5. They are dimensionless.
7. Define $c = 299{,}792{,}458$ m/s, then $1\text{ m} = c(1/299{,}792{,}458\text{ s})$.
9. Yes.

11. No; if the angle between the two unit vectors are 60°.
13. About 99.6% accurate.
15. About 0.3% (assuming a weight of 150 lb and an uncertainty of about 0.5 lb).
17. The surface area of a mouse is large relative to its body size, and the energy radiated through the skin needs to be compensated with sufficient food intake.
19. No.
21. Three; infinite number of sets.

CHAPTER 2

1. In case the car in front of you suddenly stops, your car would travel further before you react, and it would take longer for it to stop after you apply the brake.
3. t is proportional to $g_x^{-1/2}$, and v is proportional to $g_x^{1/2}$.
5. No.
7. $h_{\text{Moon}}/h_{\text{Earth}} = g_{\text{Earth}}/g_{\text{Moon}}$, $h_{\text{Moon}} \approx 5$ m.
9. True.
11. 0; yes.
13. a = constant and $v_0 = 0$.
15. False.
17. 3rd, 2nd, 1st; $v_1 = v_3 > v_2$.
19. Need to measure the diameter d of each wheel; number of rotations per unit time $= v/\pi d$.
21. A box sliding up or down a straight ramp, two unequal masses connected by a string hanging over a fixed pulley, a vehicle accelerating uniformly down a straight road, etc.
23.

CHAPTER 3

1. A little higher.
3. A strong wind can alter the result significantly.
5. No.
7. R is proportional to v_0^2.
9. The ball will land ahead of the car.
11. No.
13. Tilt the umbrella forward at an angle θ, with $\tan\theta$ = running speed/raindrop speed.
15. (a) Outside the edge of the merry-go-round, (b) on yourself or next to you.
17. There is an initial eastward velocity.
19. Only (a) does.
21. No.

CHAPTER 4

1. A projectile motion with horizontal initial velocity.
3. Use a spring scale.
5. The reading is first greater than your weight, then becomes equal to it before getting less than it, and eventually becomes equal to it again.
7. False.
9. The tableware does not accelerate as fast as the tablecloth.
11. The direct cause is the normal force exerted by the person on the table.
13. Everything except gravitational and magnetic forces.
15. Gravity is balanced by the drag force of the air.
17. For example, pull the mass with a spring scale with a constant force F and measure the acceleration a.
19. The greater cross-sectional area of the rubber ball results in greater air resistance.
21. The friction force exerted by the road on the tires accelerates the vehicle; the engine forces the tires to turn, initiating the friction from the road.
23. She will land at a point further than half the radius away from the center of the merry-go-round.
25. Centrifugal force, the upward force that enables an astronaut to "float" inside a space shuttle, the backward force that keeps you at rest on the driver's seat as you accelerate your car forward.
27. Gravity speeds up the marble on its way down and slows it down on its way up, the bowl's contact force keeps it in a circular path, friction slows it down and eventually stops it.
29. It exceeds your weight.
31. Yes; the downward force from the branch.
33. Balance an object and check to see if $\Sigma\vec{F} = 0$.
35. The engine forces the driving tires to turn, which cause the road to exert a forward force of friction on the tires.
37. No.
39. Forces may not necessarily initiate motion.

CHAPTER 5

1. The tension in the wire must have a vertical component to balance the weight of the walker.
3. The mass of the string is not negligible, and/or the observer is in a non-inertial frame of reference.
5. The tension in the rope would vary; friction increases the tension necessary to move the load.
7. To increase the static friction from the road that serves as centripetal force.
9. No; yes.
11. Both help keep the boat from moving sideways; the keel also helps prevent the boat from overturning, while the centerboard is much lighter.
13. Yes in principle; friction reduces efficiency.
15. The weight of additional people causes the scull to sit lower in water, increasing the drag force of the water.
17. All of the statements are true.
19. Gravity serves as the centripetal force; no.
21. Yes.
23. No; the net force is never zero; tension in the string and the weight of the bob.
25. No.
27. Less static friction is available from the ground.
29. The lowest point, where the tension in the vine is the greatest.
31. The die will curve away sideways while descending the bowl's wall.
33. The first term dominates at low speeds ($v \ll b/c$), the second one dominates at high speeds ($v \gg b/c$).

CHAPTER 6

1. Use $(\vec{F}_{\text{drag}} + \vec{F}_g)\cdot d\vec{r} = dK = d(mv^2/2)$ and integrate to find the speed of the baseball.
3. Yes; the force opposes the motion and reduces the kinetic energy of the object.
5. The centripetal force does zero work and does not change the speed (and the kinetic energy) of the object.
7. No.
9. The energy for the work done on the smokestack comes from the engine, not the man; the work done on the man by the deck equals the work he does on the smokestack.
11. No (if terminal speed has been reached).
13. Yes. For example, the friction of the road that accelerates a car from rest.
15. An amount equal in magnitude to the (negative) work of the drag forces attributed to your weight.
17. Friction from the wall does positive work on the participants while their speeds increase; no net work is done on them once they reach constant speed.
19. Measure the maximum height attained by the first acrobat and hence the kinetic energy imparted to him.
21. The one chopping the bone.
23. To the moving observer $\vec{F}$ and $\vec{v}$ are opposite in direction, so $\Delta K = W < 0$.

25. The mass m of the parachutist and the height h of the jump.
27. The net work done by the drag force is negative, rather than zero, for one complete round trip.

CHAPTER 7

1. No.
3. It means that U of the person at the bottom of the well is lower than that at sea level.
5. Loss of mechanical energy due to air friction as well as during the collision with the floor; a ball thrown down with a large initial speed has a significant amount of initial kinetic energy.
7. Yes; energy released from sugar and oxygen may be converted into the mechanical energy of motion, the heating of muscles and bones, and that in the chemical products that the body produces, etc.
9. No; if yes the spring would be able to oscillate forever (inside a vacuum tube).
11. Measure the final speed v of a falling object from height h (in a vacuum tube) to see if $mgh = mv^2/2$; observe the motion of satellites and planets.
13. Yes; air friction and the collision force from the floor.
15. The normal force is always perpendicular to the direction of motion (which is tangential) so it does no work; this can be verified from $E_i = E_f$.
17. Not necessarily.
19. If they were, then as the ball comes back to where it started its kinetic energy (and speed) would return to the same value as before.
21. None, although the energy of Earth as a whole is fairly constant, at least over time intervals that's much shorter than geological scales.
23. Back to the height reached after the first bounce.

CHAPTER 8

1. Yes (for the Sun-comet system).
3. Yes, the center of mass does stop; no, since $\vec{v}_{cm}$ can be zero before the collision.
5. No. It follows a parabolic path.
7. The body is curved like a horseshoe "draped" over the bar, so only part of the body is above the bar.
9. Yes; $x_{cm} = m_{point}\,R/(m_{circle} + m_{point})$.
11. Yes.
13. Yes; yes (albeit imperceptibly).
15. Short enough so that our ordinary senses cannot detect a finite time interval.
17. Assuming elastic collisions, the smaller ball can reach 9 times the initial height of the larger one.
19. Conservation of momentum of the gun-ammunition system.
21. It moves slightly forward.
23. As the parachute moves faster it collides with more air molecules (per unit time) moving at higher speeds towards it.
25. 45° (with no energy loss); less than 45° from the table (with energy loss).

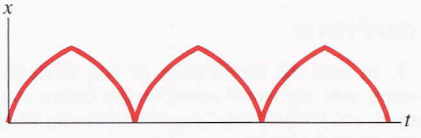
CHAPTER 9

1. Down (with right-hand rule); up (with left-hand rule); yes, but one has to be consistent.
3. The angular momentum of the rotation stabilizes the motion.
5. The wheel moves downstream to an observer on the shore and backward relative to the boat.
7. Lower.
9. The one filled with water.
11. Shorten r by a factor of $1/\sqrt{2}$.
13. The force of the water against the side of the canoe can tip it over.
15. The angular speed, which cannot exceed a certain amount or the wheel will disintegrate.
17. To increase the torque applied by increasing the lever arm.
19. The longer wrench allows you to exert a greater torque by providing a longer lever arm.
21. The spring will be further stretched.
23. Two.
25. 1:1.
27. Not enough centripetal force available to support the circular motion.

CHAPTER 10

1. Yes.
3. The wheels have angular momentum so they tend to maintain their orientation.
5. To keep the center of mass as low as possible to increase stability.
7. Considerable torque is required to change the direction of the large spin angular momentum of the fan.
9. Little torque is exerted on the person using the bent leg technique; lifting weight with bent back requires you to counter the torque of the weight.
11. Acquire an initial rotation by using the contact force from the diving board to provide a torque about his/her center of mass.
13. The angular velocity is in the same direction as that of the torque from the cue about the center of mass; the spin angular momentum acquired equals the angular impulse delivered by the cue.
15. No. The friction from the ground exerts a torque on you.
17. Zero.
19. Yes.
21. The pilot must arrange his ailerons and rudder to introduce a force that will push the nose up.
23. The student will also turn, but by only half as much.
25. Slow down.
27. It is absorbed by Earth.
29. (b).

CHAPTER 11



1. Pushing against the slope results in a reactionary force from the slope that tends to push the climber away from it.
3. The force of gravity on the mass would produce a net torque about the point of suspension if the rope is not vertically aligned.
5. Stable equilibrium.
7. No; an object is approximately rigid if its deformation is considerably smaller than its dimensions.
9. True.
11. $\Sigma F_x = ma_x$, $\Sigma F_y = ma_y$, $\Sigma \tau_A = I_A\alpha$ (A is the contact point between the motorcycle and the curb); possible only if the curb extends below the center of the wheels.
13. Yes.
15. The one which makes an angle of 60° with the horizontal.
17. No.
19. No.
21. Unstable equilibrium.
23. It increases the tensile strength of bricks.
25. By heating up the diamond.
27. A structure (e.g., graphite) featuring layers of planes is more vulnerable to shear forces applied along the planes; yes.

CHAPTER 12

1. Drag forces in fluids, the tension in ropes or rods, the normal force between two objects in contact, etc.
3. Yes.
5. Launch the satellite near the equator, in the direction of Earth's rotation; launch it in the direction of the orbital motion of Earth around the Sun.
7. No.
9. A straight line passing through the Sun.
11. Yes.
13. As the Moon completes one revolution around Earth it also completes one rotation about its own axis.
15. Yes.
17. Consider Earth as a uniform sphere plus some local variation of density, and study the deviation of the g data from its uniform value to probe the density variation.
19. Assuming uniform density, g would be uniform on its surface if Earth were a perfect sphere.
21. (b) is correct.
23. The surface of Jupiter is not as rigid as that of Earth,
25. Zero.
27. Yes.
29. $g = 0$ inside a hollow Earth.

CHAPTER 13

1.

3. K_{max} increases by a factor of 4.
5. The thinner air on the mountain top provides less drag on the pendulum, while the g value there is lower—these two factors affect T in opposite directions.
7. Yes; the positive work done by the external driving force.
9. It should be shortened.
11. Increase.
13. T is decreased by a factor of $(3/2)^{1/2} \approx 1.22$; A is decreased by a factor of $(3/2)^{1/4} \approx 1.11$.
15. (a): Driven harmonic motion while wind is blowing; (b): driven harmonic motion; (c) driven harmonic motion while the child is pumping and damped while he or she is not; (d) and (e): damped harmonic motion.
17. Yes.
19. Yes; longer.
21. You are adjusting the driving frequency to match the natural frequency of the diving board.
23. No.

CHAPTER 14

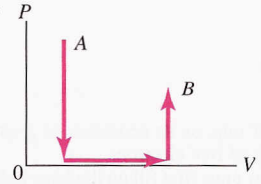
1. Waves on a string is transverse, due to the elastic stretching of the string; sound waves are longitudinal, due to the compression and rarefaction of the air.

3. For more time, as no energy is transferred to the air to produce the sound wave.
5. (a) is correct.
7. For the same wavelength, the frequency of sound is higher in helium, as the speed of sound in helium is higher due to its lower density.
9. Sound waves cannot propagate in vacuum.
11. $h(x, t) = h_0 \sin(kx - \omega t + \phi_0)$.
13. Yes.
15. The wavelength must be decreasing, causing the frequency to increase.
17. Increase the tension in the wire.
19. No; v is more than doubled.

CHAPTER 15

1. Yes.
3. The pulses approach each other and superimpose as they meet, reinforcing each other if they are on the same side, canceling if they are on opposite sides, and forming a tilted pulse if they are perpendicular to each other. After passing through each other they move on, maintaining their integrity.
5. Stick the gum on one fork and listen to the beat again. If the beat frequency gets lower then this fork oscillates at a higher frequency than the other one.
7. f is unchanged, while λ decreases.
9. A single pulse is the superposition of many harmonic waves of different wavelengths, which travel at different speeds and cause the wave to spread into many ripples.
11. The energy of the wave on the string takes kinetic form rather than elastic potential form at the moment the two pulses cancel each other out, very much like the moment the string is flat in a standing wave.

CHAPTER 16



1. Hot air is less dense than cold air and the buoyant force of the surrounding cold air lifts the balloon.
3. The weight in water is less than that in air by that of the water displaced, from which we know the volume, and hence density, of the body. Fat content is then deduced from the density data.
5. It weighs more as the buoyant force is less than the weight of the compressed air inside.
7. Yes.
9. Its high density allows for a relatively short column to balance air pressure.
11. The head would implode if $p < 0$. The value of $\rho v^2/2$ is always positive;
ρgh can be both positive or negative; p is usually positive but it can be assigned any value as long as $\Delta p = p_1 - p_2$ is unaffected.
13. $h_{max} = P_{air}/\rho_{water} g \approx 10.3$ m.
15. Yes if the sails are curved, which is not absolutely necessary but works better.
17. Styrofoam has greater volume and weighs less in air; estimate the volume and find the density from m/V.
19. The sides of the can are pushing in on the liquid.
21. The oil is closer to the center of the centrifuge—think of the centrifugal force as an effective gravity pointing away from the center of rotation.
23. The water pressure on one's chest and lungs prevents air from entering a long tube deep under the water surface.
25. It remains the same.

CHAPTER 17

1. $\approx 4 \times 10^{23}$ molecules.
3. The pressure increases as depth increases, and more air molecules are present in a given volume at a higher pressure.
5. An equilibrium is reached among all the three phases at the triple point, much like how ice and liquid water can coexist at 0°C.
7. Stand in front of a radiant heater and compare the heat it generates before and after it is turned on.
9. A very cold tire may have exceptionally low pressure, and boosting it to the nominal value while it is so cold could cause the pressure to be dangerously high when the tire is heated up by driving.
11. No.
13. The ball expands upon being heated so it cannot pass through the ring; heating the ring will work.
15. Measure the temperature of each substance to see if it has reached a common value.
17. As vast numbers of tiny molecules collide randomly with the wall of the container, there is no perceptible net force on the wall.
19. Nothing, except for the possible confusion it might cause.
21. Icebergs would sink to the bottom of the ocean. As enough ice builds up below the water surface, it could largely deplete the space occupied by liquid water, and that would be devastating to sea life.

CHAPTER 18

1. Work done on the air as it undergoes adiabatic compression causes its temperature to increase.
3. Yes.
5. (a) and (c) .
7.

9. To improve thermal insulation with the air trapped in between the layers.
11. An incredible amount of shaking would be required for any significant temperature increase, even if the container is thermally insulated.
13. Fluids with very large specific heat: as thermal reservoir to store and transfer heat and to limit temperature variation; fluids with very small specific heat: as lubricant in machinery.
15. $\Delta Q_{net} = c_1 m_1 \Delta T_1 - c_2 m_2 \Delta T_2 = 0$,
so $\Delta T_1/\Delta T_2 = -c_2 m_2/c_1 m_1$.
If $c_1 = c_2 = c_{water}$ then $\Delta T_1/\Delta T_2 = -m_2/m_1$;
and $\Delta T_{Hg}/\Delta T_{water} = -c_{water}\, m_{water}/c_{Hg}\, m_{Hg} = -m_{water}/[c_{Hg} m_{Hg}/c_{water}] = -m_{water}/m_{eff}$, i.e., 100 g of mercury behaves effectively like water of mass $c_{Hg}(100\text{ g})/c_{water} = 3.3$ g.
17. It takes far more energy to completely separate water molecules from each other than to slightly "loosen them up".
19. $W_{net,2} = 2W_{net,1}$.
21. Not if $c(T)$ is known.
23. Friction turns 100% of the mechanical energy into heat, and a rapid process prevents thermal equilibrium from being established.
25. Yes. $c_{Hg} \ll c_{water}$ so $\Delta T_{Hg} \gg \Delta T_{water}$.
27. Keeping the engine idling greatly limits the airflow across the radiator surface that can help cool the engine, and winter air is typically drier and has lower specific heat.

CHAPTER 19

1. T increases; the gas molecules on average speed up due to the extra momentum imparted upon them by the inward movement of the piston.
3. It is the probability per a range of one meter.
5. The intermolecular collisions are largely elastic and leave the average molecular kinetic energy unchanged.
7. Thermal equilibrium can still be established between the wall and the gas molecules, yet relatively large fluctuations from the average value of molecular kinetic energy would make T less well defined.
9. Not quite meaningful as an indicator of average molecular kinetic energy, which is a statistical quantity involving a large number of molecules.
11. The intermolecular collisions are largely elastic which conserve momentum, so the same total momentum is carried by the molecules to the wall after the collisions.
13. The miniscule size of the molecules makes it harder for them to hit each other.
15. Air.
17. The inward moving piston collide with gas molecules to increase their average speed (and hence energy).
19. The pane of glass is bombarded on both sides with equal pressure.
21. The airflow helps more energetic water molecules to escape from the water surface
23. Measure the heights of a large group of people and divide the heights into small and equal-sized increments, then check the number of people whose heights fall within each increment. No absolute certainty.
25. The average molecular rotational kinetic energy is a function of temperature.

CHAPTER 20

1. Yes if the ocean temperature is higher than that of the air, as in winter times.
3. Only in the sense that it is associated with the "randomization" in spontaneous physical processes.
5. No.
7. In warm climates.
9. Gas X will permeate the bottle and diffuse throughout the room.
11. Cream poured into a cup of coffee diffuses and mixes up with the coffee, for example. Entropy is increased.
13. They can convert essentially 100% of the electrical energy into heat, but not to work.
15. Only part of the heat released from the chemical energy is converted into mechanical work.
17. No, the room would get even warmer.
19. Extensive.

CHAPTER 21

1. The midpoint of the line joining the two charges.
3. The charges acquired by the balloon through rubbing attracts the opposite charges induced in the wall.

5. The force on each charge and its mass; if $m_1 = 5m_2$ then $d_1 = (1/5)d_2$.
7. The ones farther form the nucleus.
9. The "peanuts" are charged through rubbing and attract the opposite charges induced in your hand.
11. The equilibrium at the center of the ring is unstable.
13. Take the charged cork ball and touch one of the three uncharged ones, then simultaneously touch it with the two remaining balls.
15. The hand becomes charged after rubbing.
17. No.
19. Yes if each contains an equal number of electrons and protons, but that would probably not be the case.
21. The forces $\vec{F}_{21}$ and $\vec{F}_{23}$ both double, so $\vec{F}_1$ and $\vec{F}_2$ will both increase in magnitude and rotate counterclockwise.

CHAPTER 22

1. To prevent a dangerous charge buildup in the gasoline-carrying vehicle by channeling the excess charge to the ground.
3. For the same reasons for introducing the electric field; the gravitational field lines can only end at (not start from) matter.
5. $Q_1 : Q_2 = -5 : 1$.
7. Two locations, one at $-2\text{ cm} < x < +4\text{ cm}$ and the other at $x > 10\text{ cm}$.
9. The electric field lines above the surface of Earth point down.
11. The charges on the comb cause the molecules in the paper to polarize, resulting in a net attraction.
13. The charge distribution is that of two dipoles touching at one end, resulting in a net dipole field.
15. The density of the field lines a distance r from the charge is proportional to $1/r^2$, which would be inconsistent with the electric field if it goes like $1/r^{2+\delta}$.
17. A sphere uniformly charged to some negative net charge would do.
19. Yes; the field is not zero since the two dipoles are not at the same location.
21. If $F_E > F_g$ it will accelerate upward, otherwise downward. The initial height is irrelevant.
23. Just find the field due to q_1 and neglect those due to q_1 and q_2.

CHAPTER 23

1. No.
3. The net charge enclosed by the surface is zero, but the electric field on the surface may not be.
5. For a spherical Gaussian surface of radius r centered at the location of a point charge, Φ would be $4\pi cr$, which depends on r of the Gaussian surface, rather than just the charge enclosed.
7. Zero.
9. Zero.
11. The electric field in between the two plates doubles while that elsewhere vanishes. The net flux over a Gaussian surface remains the same.
13. Only that it is invariant under a rotation about the axis of symmetry of the wire.
15. No net charge is present in the region.
17. The electric field is not uniform over the Gaussian cylinder for a charged line of finite length.
19. The charge density is independent of z.
21. No.

CHAPTER 24

1. 1 Joule.
3. Insert a uniformly charged plane within the sphere.
5. The electrostatic potential energy; the work that was done in assembling the charges together.
7. At $\theta = 0$.
9. It is always an equipotential except during the brief time interval when equilibrium is being established as charges redistribute themselves on its surface.
11. The person is charged and the hair (with like charges) repel each other; to prevent a dangerous current from running through the person.
13. No; $E_x = \Delta V/\Delta x$.
15. Yes.
17. The work done by the electrostatic force along any enclosed loop is zero.
19. Yes.
21. Yes.

CHAPTER 25

1. No.
3. If the field drops abruptly to zero outside the plates then the voltage drop around a closed path consisting of one segment leading from one plate to another and another segment that closes the path from outside would be non-zero.
5. The potential difference becomes infinitely large, as it takes an infinite amount of work to concentrate a charge on an infinitely thin wire.
7. The charge on one plate is Q and that on the other is $-Q$.
9. V decreases, C increases, and U decreases.
11. Parallel plates.
13. It reduces C.
15. Yes.
17. Not in classical physics.

CHAPTER 26

1. Yes.
3. The thinner one, as its resistance is greater.
5. The density of free electrons.
7. While water must first fill up the hose before streaming out, a piece of metal is already loaded with free electrons.
9. Yes, but it is a very small effect.
11. No.
13. Eq. (26–25) gives $\rho \approx 10^{-7}\ \Omega\cdot\text{m}$ with $\tau \approx 10^{-14}$ s and $n_e \approx 10^{29}\text{m}^{-3}$.
15. It melts as too much heat is generated to be entirely dissipated in time.
17. $R_{\text{eq}} = R_1 + R_2$.
19. Bulb 2 is brighter when the switch is open; bulb 1 is brighter when the switch is closed.
21. Increase.
23. To increase its length (and hence resistance) without taking up too much space.

CHAPTER 27

1. A large current can flow through the body as tap water is a good conductor.
3. The equation representing the loop rule is unchanged.
5. No.
7. $C \approx 1000\ \mu\text{F}$, $R \approx 10\ \Omega$, $RC \approx 0.01$ s.
9. If I reverses Q would become $-Q$.
11. Put the two emf's in series to drive the two lightbulbs in parallel.
13. I increases to $3I$.
15. R_2 and R_3 are in series (branch 1), as are R_5 and R_6 (branch 2). Combine these with R_4 (branch 3), with the three branches in parallel, to obtain a single equivalent resistance, R_{eq}, which forms a one-loop circuit along with R_1 and the emf. Impossible for Fig. 27–8(b).
17. The steady-state I_1 decreases.

CHAPTER 28

1. The positive charges (ions) have no collective velocity but the free electrons do.
3. By an electric field; $\vec{v}$ must change direction if the force is magnetic.
5. No.
7. No.
9. Incoming charged particles are concentrated in the polar region where the magnetic field is the strongest.
11. A single circular loop.
13. Repel; attract if one of the current is reversed.
15. Attract.
17. No; yes.
19. No.
21. (d).

CHAPTER 29

1. The needle will maintain an orientation that follows the circular path of the compass itself.
3. The direction of the magnetic force depends on that of the current flow.
5. No.
7. An extended wire is made of many segments, each producing a magnetic field of its own magnitude and direction.
9. It is much easier to measure force accurately.
11. Replace ε_0 with ε.
13. The field doubles for two loops with currents flowing in the same sense, and is zero if they flow in opposite sense.
15. The magnets attract when adjacent poles are opposite and repel when they are the same. The fields add up when unlike poles are adjacent and cancel when like poles are adjacent.

CHAPTER 30

1. No.
3. (e).
5. Yes; the magnetic field may increase in one part of the region and decrease in another part.
7. (a) No, (b) yes, (c) no, (d) no.
9. No.
11. Yes; to compensate for the thermal energy dissipated by the induced current in the metal plate.
13. No change.
15. The falling water gives up its gravitational potential energy and drive the rotary turbine blades in a magnetic field to generate induced current.
17. It falls with $a < g$ as it is above the tube and is entering it, and with $a = g$ when completely inside the tube.
19. An induced current in the ring antiparallel to that in the coil is induced; the ring will not jump.

21. An induced current in the ring antiparallel to that in the coil is induced; the size of the ring must allow the magnetic force on it to cancel with its weight.
23. The residual magnetic field in the iron frames of the moving car induced a current in the wire loop.

CHAPTER 31

1. The nucleus is much more massive than the electrons.
3. Make the core of a solenoid out of the material and check to see if the magnetic field increases or decreases due to the presence of the core.
5. Yes.
7. Yes; very difficult to measure due to ferromagnetism, try search for it at high temperature.
9. Magnetically hard material.
11. The alignment of magnetic moments causing paramagnetism becomes less effective as temperature increases.
13. Pulled into the region.
15. The orbital angular momentum of the electron does not change if $\vec{B}$ is perpendicular to its plane of motion, and changes if $\vec{B}$ is parallel to the plane.
17. 0.
19. The field of a bar magnet is non-uniform.

CHAPTER 32

1. Not necessarily.
3. (b), (a), (c).
5. Yes.
7. (b).
9. Construct an *RL* circuit and measure its time constant to find *L*.
11. Due to the current flow.
13. It depends on the total electromagnetic energy U in the circuit, or I_{max}, or V_{max} across the capacitor.
15. Yes.
17. There is no dissipation mechanism to lower the magnetic energy, so I does not drop.
19. $\frac{1}{2}mv^2$ and $\frac{1}{2}kx^2$.
21. The regions in between two wires carrying the same current has lower magnetic pressure than the region outside both wires, resulting in a net attraction between the wires.

CHAPTER 33

1. It must amplify and confine the magnetic field and have sufficient mechanical strength.
3. $X_C = 1/\omega C$ approaches zero as ω is very high.
5. The time average of the current is zero but that of the power is not.
7. The time average of the current is zero so one must use I_{rms}.
9. They can be reversed in principle; step-up becomes step-down, and vice versa.
11. (c).
13. An inductor.
15. No, unless they are of the same kind (say, both are capacitive).
17. The impedances are not infinite for any finite frequency.
19. To prevent signal loss due to abrupt changes in impedance.
21. When $\omega = (1/LC)^{1/2}$.
23. No; transformers can be used.

CHAPTER 34

1. No.
3. The ionosphere has an abundance of free charges, like a metal.
5. Yes.
7. No.
9. They must have very large area, lower density, and high reflectivity; it's difficult to sail into the solar wind.
11. Rotate a polarizer to see if you can get a near-zero transmission.
13. It goes out.
15. All of it.
17. The angular momentum is zero for a linearly polarized electromagnetic wave, and non-zero if it's circularly polarized.
19. Reflective.
21. $F_B \ll F_E$ since $v/c \ll 1$.

CHAPTER 35

1. Through reflection.
3. Extremely difficult; having three mutually perpendicular mirrors ensures that the incident beam is reflected straight back.
5. The bodyguard appears taller.
7. It appears to be shorter and closer to the surface of the water.
9. (d).
11. Not if you tilt your head toward the direction of the coin.
13. A distant house appears as two images, one of which inverted.
15. No air is present in space to scatter the sunlight.
17. As you scan downward from the vertical line you first see his upper body (which appears to be stretched), then you see the reflection of his lower body (upside-down), followed by a direct view of his lower body.
19. No.
21. Light reflected from the Moon has relatively little red component.

CHAPTER 36

1. The sign reads "AMBULANCE" for drivers who see a vehicle arrive from behind in the rear-view mirror.
3. No, but the image is dimmer.
5. $(x, y, z) \rightarrow (-x, -y, z)$.
7. Convex.
9. It is a convex mirror in which images are smaller than the objects, allowing a wider field of view.
11. Yes.
13. Yes.
15. Not very, except the one originated from the focal point.
17. It accentuates any imperfection of the eye by exposing the edge of the lens.
19. Not very plausible.

CHAPTER 37

1. There is no reduction in intensity due to the slits.
3. The fringes are in principle visible without a screen, but they are usually so close together in the field of view since the eye is a converging lens. A screen makes it much easier.
5. Adjacent wavelengths resulting in destructive interferences differ by a factor of 3 but $\lambda_{max} < 3\lambda_{min}$ for visible light.
7. Light rays are parallel when viewed from afar, simplifying the analysis.
9. The total energy over the entire space remains conserved.
11. No.
13. To minimize the reflection $n_{coat} = (n_{air}n_{glass})^{1/2}$.
15. Energy is intensified in other locations.
17. A tiny change in λ can result in a measurable shift in the interference pattern.
19. Total destructive interference requires identical amplitudes of two waves.
21. The slit spacing is much greater than λ.

CHAPTER 38

1. The diffraction pattern spreads out and gets dimmer overall.
3. No image distortion due to the atmosphere.
5. Short wavelength.
7. No.
9. The spreading of the diffraction pattern is proportional to λ, which is longer for red light.
11. When in place it blocks all the light except the two beams at the edges of the single slit.
13. A continuous spectrum (rainbow bands).
15. It interacts with the atoms.
17. One sees "around" the object as one changes the viewing angle of a holographic image.

CHAPTER 39

1. No.
3. [energy/speed^2] = [mass].
5. No.
7. It would indicate that there is no relative motion between Earth and ether during the measurement.
9. No.
11. No.
13. Yes.
15. No; the wire is not charge-neutral in the moving frame and produces both an electric and a magnetic field.
17. An entire pattern of wavelengths signifying a certain element (e.g., hydrogen) has been redshifted.
19. No, light falls only in an accelerated frame or in the presence of gravity.
21. No.

CHAPTER 40

1. Wave-like behaviors are prominent only when a photon interacts with objects comparable in size with its wavelength.
3. rate $\approx (P/hf)(r/2R)^2$, where P = power emitted by the cigarette, f = photon frequency, r = radius of the retina, R = 500 m.
5. The momentum (and hence wavelength) of an electron is different in different reference frames.
7. Yes; W increases with e.
9. T.
11. They don't; τ is longer according to an observer moving relative to the particles.
13. Yes, $L = \frac{1}{2}\lambda$.
15. Yes, but the probability is negligibly small.
17. No.
19. ΔE can be very large during a very short time interval Δt, but not for long.
21. No.

CHAPTER 41

1. $n = 0$ would lead to $\Delta p = 0$, in violation of the uncertainty principle.
3. λ_{min} occurs as the electron jumps from $n = \infty$ to $n = 1$. λ_{max} can be infinity.
5. No.
7. The different isotopes of hydrogen have different reduced mass and hence slightly different spectral lines.
9. The exclusion principle does not apply to two identical atoms so far apart that their electron clouds do not overlap.
11. The effective Z for neutral He is about twice as much as that for He^+, and ΔE is proportional to Z^2.
13. When the potential energy is minimum, the force vanishes.
15. Antiparallel.
17. No.
19. $T = 1.7 \times 10^6$ K; the actual fraction of atoms in the first excited state is much lower than 50% at room temperatures.

CHAPTER 42

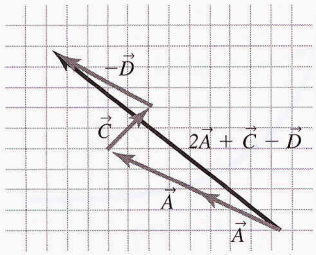
1. Most of the electrons would be in the ground state at room temperature, and many chemical reactions would not be possible.
3. The decay of an excited atom with the emission of a photon has a rate that is enhanced by a factor of N^2 in the presence of N other photons of the same momentum and polarization.
5. If $E_F \gg kT$ then only those electrons with energies near E_F can be thermally excited. If $E_F \ll kT$ then all the electrons can participate in thermal excitation, and quantum statistical effects are negligible.
7. Yes; $P_F \sim m_n c$.
9. No.
11. In the absence of the exclusion principle, the atoms in distant galaxies would have their electrons mostly in the ground state, and there would be no resemblance between their spectra and spectra on Earth.
13. The sequence of transitions is much more likely.
15. The pumping mechanism must involve large energy input; the cavity in which the X-rays are to be reflected back and forth is difficult to make; de-excitation may occur for electrons from various states other than the desired excited state; the decay time from a highly excited state is very short.
17. No.

CHAPTER 43

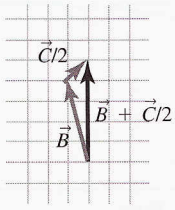
1. No, they are identical.
3. To a good approximation, yes.
5. Holes can be spontaneously filled by stray electrons or by directing a beam of low-energy electrons to the surface.
7. It makes a transition from the top of the valence band to the bottom of the conduction band.
9. Each acceptor atom in a p-type extrinsic semiconductor provides an empty space for an electron from the top of the valence band to jump up to, requiring very little excitation energy. The vacancies left by these electrons form holes.
11. The energy always comes from the voltage source. The variation in the current that flows into the base amplifies the current into the collector by acting as a "gatekeeper" for the current that is generated by the biasing voltage, but does not itself provide energy.
13. The electronic excitation energy in a typical insulator is greater than that of a visible-light photon; the energy gap in a semiconductor is higher than that of an infrared photon but lower than that of a visible-light photon; and the electrons in a partially filled conduction band in a metal can absorb both infrared and visible-light photons.

CHAPTER 44

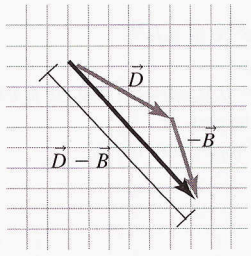
1. Measure the deflection of the alpha particles in an electric and magnetic field to determine the charge-to-mass ratio (Q/M), then combine with the Rutherford scattering data to determine Q and M.
3. The total A is conserved.
5. Strip an atom of one or more electrons and we get a positively charged ion. To get a negatively charged one we must either give the atom an extra electron, making it very unstable, or take a proton away from its nucleus, requiring a relatively large amount of energy.
7. The study of the inner structure of a nucleus requires high-energy alpha particles, which could disintegrate upon collision; nuclear forces between the alpha particles and the nuclei are not known as precisely as electromagnetic forces.
9. ^{16}O.
11. Radiation adversely affects blood cells. A radioactive material in the bone marrow affects the place where these cells are created, and there the effect is particularly strong.
13. It would take a minimum energy of about 1 MeV for neutrons to cause ^{238}U to fission.
15. In fission a number of divisions of (A, Z) into (A_1, Z_1) and (A_2, Z_2) are possible, as long as $M(A, Z) > M(A_1, Z_1) + M(A_2, Z_2)$. It is very unlikely that both combinations (A_1, Z_1) and (A_2, Z_2) will be stable.



CHAPTER 45

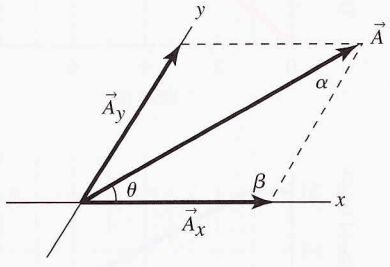


1. Sum of the interior angles in the triangle $= 2\pi + \alpha > 2\pi$, where α is the angle at which the two meridians cross each other at the North Pole.
3. Reactions such as $n \rightarrow p + e^- + \bar{\nu}$ are possible if the total baryon number is conserved and other applicable conservation laws are also observed.
5. (a) Electromagnetic and gravitational force, (b) electromagnetic force, (c) gravitational and electromagnetic force, (d) strong nuclear force and electromagnetic force, (e) electromagnetic force, (f) gravitational and strong nuclear force.
7. No; no.
9. Advantage: energies not accessible in the laboratory can be attained; disadvantages: particles cannot be controlled, and the rate at which they arrive decreases very rapidly with their energy.
11. The conservation laws do not apply to a virtual process.
13. There would be about one proton decay per year in one cubic meter of water.
15. Absorption due to intergalactic dust, the Hubble constant could be smaller for larger u.
17. A boson, (a) no, (b) no.

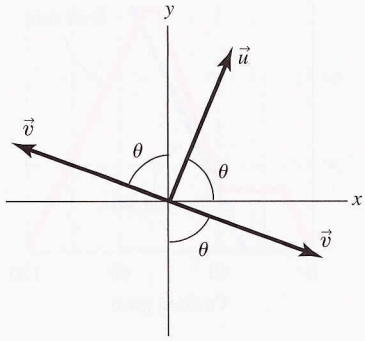


Answers to Odd-Numbered Problems

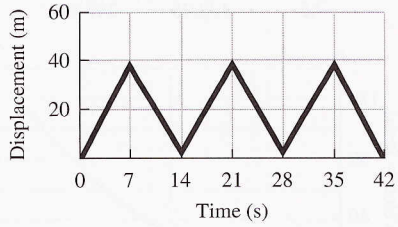
CHAPTER 1



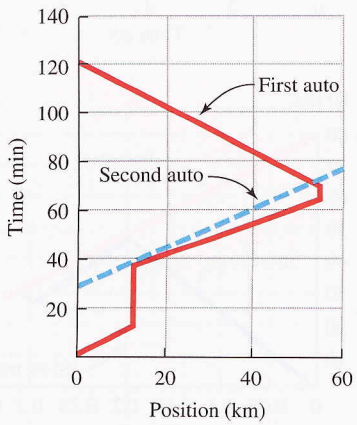
1. 3.0×10^3 green jelly beans.
3. 3.5600×10^4 cents
5. 10^7; 10^{14}.
7. 1.8×10^{10} atoms.
9. \$1.18/kg.
11. 32.2 ft/s^2.
13. 3.33 g/cm^3.
15. 34 mi/gal; 10 mi/gal.
17. 0.0402%; 8.49×10^{-6}%.
19. $0.2(1 \pm 30\%)$ m^3.
21. 5%.
23. $[MLT^{-1}]$.
25. $[ML^2T^{-1}]$.
27. No.
29. (a) $[L^{-1}]$, (b) $[L^5T^{-2}]$.
31. (a) $[M^{1/2}L^{3/2}T^{-1}]$, (b) $[ML^2T^{-2}]$.
33. 2 tons.
35. 3.5×10^{-6} cm^2.
37. (a) 10^6 mechanics, (b) 10^6 mechanics, (c) 10^6 mechanics.
39. 1×10^{21} droplets.
41. 1×10^{-19}.
43. 9×10^6 automobiles.
45. 30 cm.
47. 1.2×10^{57} hydrogen atoms; 8.2×10^{56} hydrogen atoms;
49. ≈100 m.
51. Her position can be described by the clockwise angle ϕ from the north-south line drawn from the center to the starting point (south end of the lake). Her direction of travel will be tangent to the circle with a constant speed of 3 m/s at an angle ϕ clockwise to the south direction.
53. $(1.2\hat{i} + 8.2\hat{j})$ paces (8.3 paces, 82° north of east).
55. Take the origin where the catch was made, with the x-axis to the right and the y-axis upfield. Catch: $0\hat{i} + 0\hat{j}$; first turn: $0\hat{i} + 0\hat{j} + 15\hat{j} = 15\hat{j}$; second turn: $0\hat{i} + 15\hat{j} - 15\hat{i} = -15\hat{i} + 15\hat{j}$; third turn: $-15\hat{i} + 15\hat{j} + 10\hat{j} = -15\hat{i} + 25\hat{j}$; fourth turn: $-15\hat{i} + 25\hat{j} + 20\hat{i} = 5\hat{i} + 25\hat{j}$; fifth turn: $5\hat{i} + 25\hat{j} - 5\hat{i} = 25\hat{j}$; touchdown: $25\hat{j} + 65\hat{j} = 90\hat{j}$.
57. $V_x = +V\cos\alpha$.
59. $\overrightarrow{AB} = (7, 0) = 7$ at an angle of 0°; $\overrightarrow{BC} = (-7, 7) = 7\sqrt{2}$ at an angle of 135°; $\overrightarrow{CA} = (0, -7) = 7$ at an angle of 270°.
61. (a) $\vec{A} = -4\hat{i} + 2\hat{j}$, $\vec{B} = -\hat{i} + 4\hat{j}$, $\vec{C} = 2\hat{i} + 2\hat{j}$, $\vec{D} = 5\hat{i} - 3\hat{j}$, (b) $-11\hat{i} + 9\hat{j}$, 9.2



63. $A_x = A\sin(60° - \theta)/\sin 120°$; $A_y = A\sin\theta/\sin 120°$;



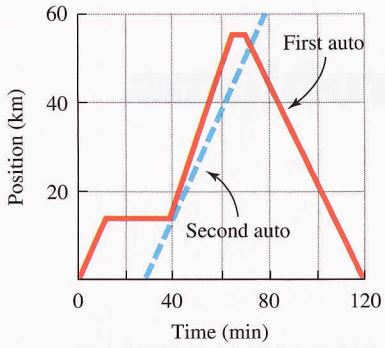
65. (a) 10^{-6} metric tons/g, (b) 10^{-6} m^3/cm^3.
67. 13 min.
69. 2×10^{27} molecules.
71. 3×10^{-8} cm.
73. 2×10^{41} kg/galaxy; 1.2×10^{68} H atoms.
77. 10^3 trucks/day; 2×10^3 trucks/day.
79. 1.1×10^8 km; 29 yr.
81. 10^{44} molecules.
83. (a) $\vec{v} = -v\sin\theta\,\hat{i} + v\cos\theta\,\hat{j}$, or $\vec{v} = +v\sin\theta\,\hat{i} - v\cos\theta\,\hat{j}$.

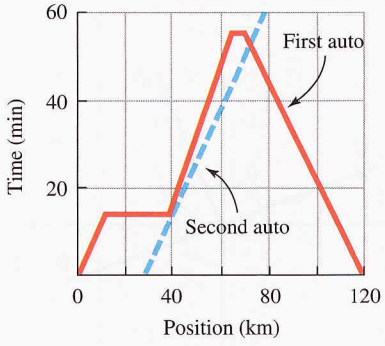


85. (a) $r\sin\theta\cos\phi$, (b) $r\cos\theta$, (c) $r\sin\theta\sin\phi$.
87. $t_0 = (\text{a constant})\ell(\lambda/t)^{1/2}$.

CHAPTER 2

1. +21 cm; 21 cm from the origin in the positive direction.
3. 252 m; 0;

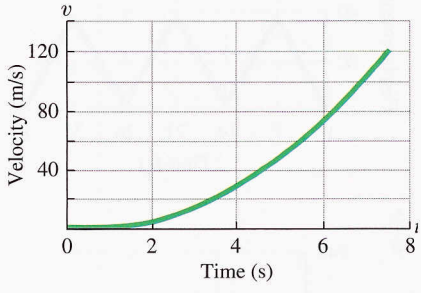


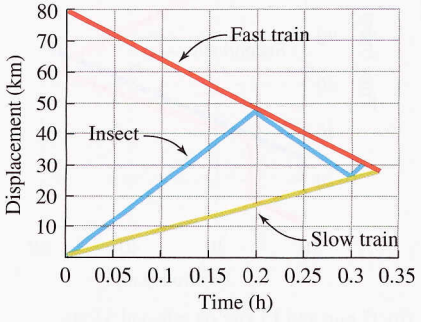


5.
(a)

(b) 37 min and 15 km; 68 min and 53 km.

7.





9. (a) $4.3\hat{j}$ mi; (b) $0.56\hat{j}$ mi/min.

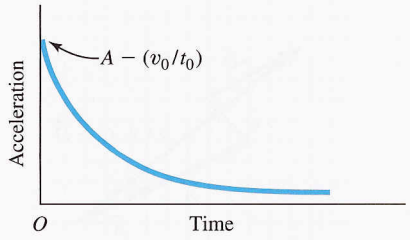
11.

t (s)	v (m/s)	x (m)
0.0	0.00	0.00
0.5	0.75	0.19
1.5	1.75	1.44
2.5	8.75	6.69
3.5	21.75	21.94
4.5	39.75	52.69
5.5	62.75	103.94
6.5	90.75	180.69
7.5	122.75	287.44

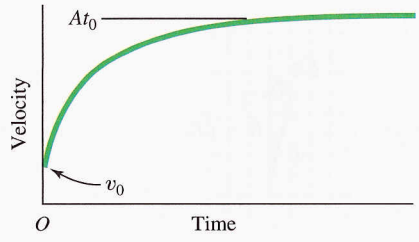
13. 80 km.

15. $1.4\hat{i}$ cm/s; $1.8\hat{i}$ cm/s; $3.5\hat{i}$ cm/s; $2.0\hat{i}$ cm/s.

17. 39 s.



19. $0.30g$.



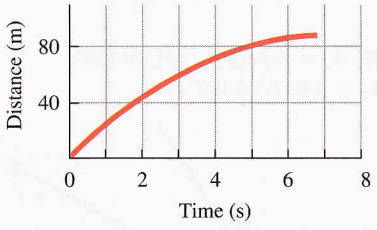
21. 1.6 m/s^2.

23. $A\omega\cos(\omega t)$; $-A\omega^2\sin(\omega t)$.

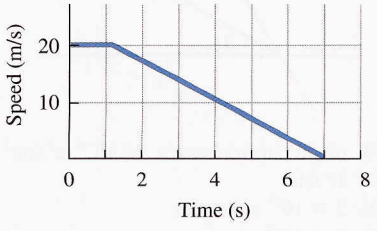
25. The particle never gets farther from the origin than A; it oscillates back and forth through the origin. The magnitude of the velocity is maximum at the origin and zero at $x = \pm A$. The magnitude of the acceleration is maximum at $x = \pm A$ and zero at the origin.

27.

29. 2.02 ft/s^2 (0.61 m/s^2).



31. 0.75 m/s.

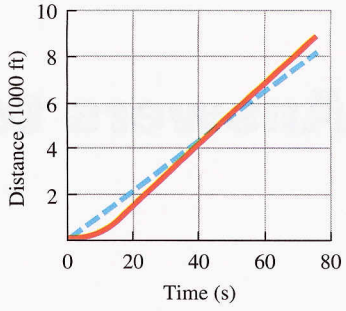


33. (a) $8.0 - 0.5t$, easterly with t in s, v in m/s, (b) 34 m to the east.

35. 1×10^4 m/s^2; 7×10^{-4} s.

37.

(a)



(b) -3.6 m/s^2.

39. 1.92 s.

41. (a) 2.96 m/s^2, (b) 97.2 s.

43. (a)

(b) 5940 ft (1.13 mi); (c) 54 s.

45. 3.65 s.

47. (a) 8.0×10^{-9} s; (b) 6.3×10^{14} m/s^2.

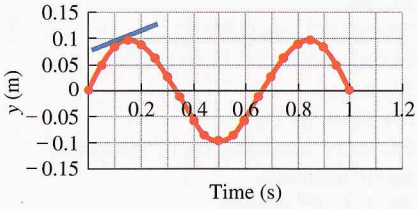
49. 4.0 m/s^2; 18 m.

51. 54 m.

53. 9.0×10^5 m/s^2; 6.7×10^{-4} s.

55. Not much time to say anything!

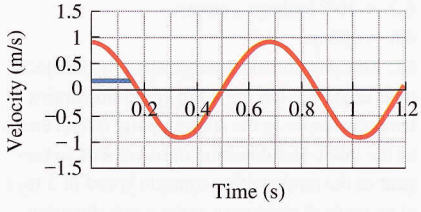
57. 1.1 s.



59. 3.5 s.

61. -22 m/s; 25 m; 20 m/s.

63. 28.4 m.



65. $-4e^{-0.5t}$; $(2 - v/2)$, with t in s, v in m/s, and a in m/s^2.

67. (a)

(b) 0.15 m/s, (c) 0.94 m/s^2,

(d)

69. $(3v_f/\alpha)^{1/3}$.

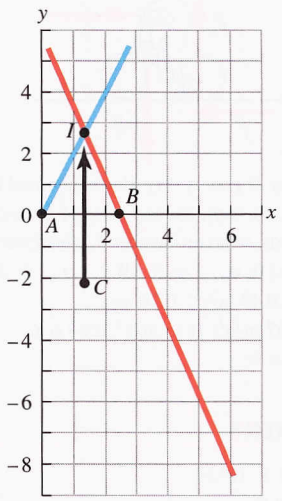
71. 0.7 m; 3 m.

73. 12 m.

75. 1.6 m/s^2; 15 m.

77. $x_0 + v_0t + (1/2)a_0t^2 + (1/6)Jt^3$.

79. (a) $-(14\text{ m/s})\hat{j}$, (b) $(13\text{ m/s})\hat{j}$, (c) $(1.4 \times 10^4\text{ m/s}^2)\hat{j}$



81. 1.6 m; 0.08 s.

CHAPTER 3

1. $(15\hat{i} + 15\hat{j})$ km; $(30\hat{i} + 15\hat{j})$ km; $(30\hat{i} + 43\hat{j})$ km; 52 km, 55° N of E.

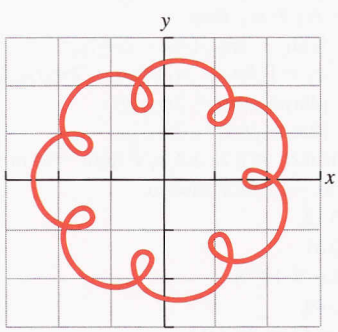
3. $\vec{r}_A = 0$; $\vec{r}_B = 25\hat{i}$ m; $\vec{r}_C = (5\hat{i} + 35\hat{j})$ m; $\vec{r}_D = 35\hat{j}$ m.

5. $(1.3\hat{i} + 2.7\hat{j})$ km; $(0.1\hat{i} + 4.9\hat{j})$ km.

7. $(3.60 \text{ m/s})t\hat{i} + (6.00 \text{ m/s})t\hat{j}$, $0 \le t \le 41.6$ s; $[-(141 \text{ m}) + (7.00 \text{ m/s})t]\hat{i} + (250 \text{ m})\hat{j}$, 41.6 s $\le t \le$ 77.3 s.

9. $(2.0\hat{i} - 3.5\hat{j})$ m; 4.0 m; $-4.0\hat{j}$ m; $d = 4.0$ m; $4.0\hat{i}$ m; $d = 4.0$ m; $\theta(t) = -\pi t/T$.

11. 4.0 m/s^2, opposite to the direction of the velocities.



13. $(3.7 \text{ m/s}^2)\hat{j} - (2.4 \text{ m/s}^2)t\hat{k}$.

15. 30 km/h, 31.6° north of west, $(-4.3\hat{i} + 2.7\hat{j})$ km.

17. (a) $[(0.000225 \text{ m}^2/\text{s}) - (0.0009 \text{ m}^2/\text{s}^2)t]\hat{j}/[(0.0169 \text{ m}^2) + (0.00045 \text{ m}^2/\text{s})t - (0.0009 \text{ m}^2/\text{s}^2)t^2]^{1/2}$, (b) $0.017\hat{j}$ m/s; 0.

19. $\vec{v} = [-(4\pi/T)\sin(\pi t/T)\hat{i} - (4\pi/T)\cos(\pi t/T)\hat{j}]$ m/s; $\phi = \pi/2 - \pi t/T$.

21.

23. $[T^{-1}]$; $v_0 = 0$; $v \to -u$; $a_0 = -Bu$; $a \to 0$.

25. 12 m/s (horizontal); $h = 7.4$ m.

27. (a) 3.64 s, (b) 11.5 m, (c) − 14.7 m/s (down); + 14.7 m/s (up).

29. (a) 0.43 s, (b) 5.4 ft/s^2, to the left.

31. 5.2 m/s.

33. 187 m/s.

35. 25° below the horizontal.

39. 76°; 14°.

41. (a) 34 m/s, (b) 30 m, (c) 60 m.

43. 329 m.

45. (a) 1.4 s, (b) successful; 8.6 m above the bar.

47. 15° and 75°; 0° and 90°.

49. (a) 7.8×10^3 m/s, (b) 9.1 m/s^2 toward Earth's center.

51. 2.5 m/s^2.

53. 9.5 s.

55. 0.86 km.

57. (a) (0.15 m, −0.32 m), (b) $(-9.3 \times 10^2 \text{ m/s}^2)\hat{i}$, (c) $(-9.3 \times 10^2 \text{ m/s}^2)\hat{j}$.

59. 1.21R.

61. 15.8 km/h, 18° south of east.

63. 50 km/h.

65. (a) 15 ft/s, (b) 6.7 ft/s.

67. (a) 843 km/h, (b) 781 km/h, 26° W of S, (c) 3900 km, 26° W of S.

69. (a) 29.5 km/s, (b) 30.5 km/s, (c) 30.0 km/s.

71. (a) 45 m/s at 65°, (b) 84 m.

73. $(10\cos\theta + 6)t\hat{i} + (10\sin\theta)t\hat{j}$, with r in km and t in hr; 127°; 68 s.

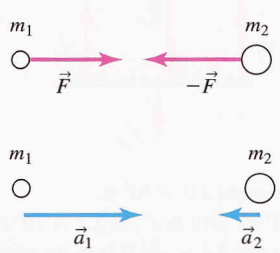
75. The hammer will hit the deck.

77. (a) 4.4 m/s, (b) 0.88 m going up; 0.88 m coming down; 0, (c) 1.8 m.

79. $\vec{r} = [(5.0 \text{ m/s})t - (0.36 \text{ m})\sin\theta]\hat{i} + [(0.36 \text{ m})(1 - \cos\theta)]\hat{j}$; $\vec{v} = (5.0 \text{ m/s})[(1 - \cos\theta)\hat{i} + \sin\theta\,\hat{j}]$; $\vec{a} = (69 \text{ m/s}^2)(\sin\theta\,\hat{i} + \cos\theta\,\hat{j})$.

CHAPTER 4

1. (a) Force of gravity (toward Earth), (b) force of gravity (down), normal force from the ice (up); and a small friction force from the ice (opposite to the motion), (c) essentially none.



3. 600 N in the $-y$-direction.

5. Yes.

7. (a) 3.0×10^{-4} N, (b) 3.0×10^{-4} N.

9. (a) The acceleration opposite to the motion is due to a retarding force. (b) The observer sees the car (initially at rest) move backward with increasing speed until it reaches $\vec{v}_0$. She would say that this is due to a backward force from the wind, etc.

11.

13. -5.7×10^5 m/s^2; -1.1×10^3 N.

15. $(F/m)\hat{j}$; no change.

17. $(0.91 \text{ N})\hat{i} + (2.3 \text{ N})\hat{j}$.

19. 6.5×10^2 N.

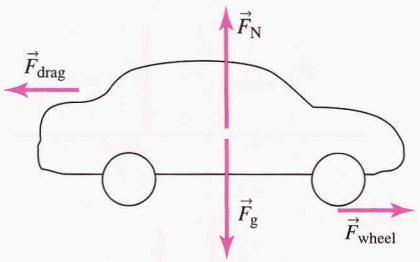
21. $T = F$; $0.433F$.

23. 78 N.

25. 1.6×10^{-21} m/s^2.

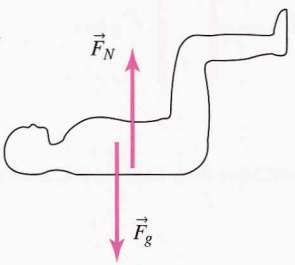
27. (a) Earth, (b) the ice and Earth, (c) none.

29. (a) half, (b) twice.



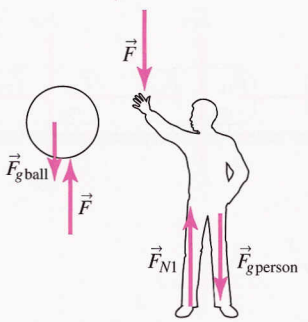
31. (a) 0.14 m/s^2, (c) 1.2×10^4 N backward.

33. $(\hat{i} + \hat{j} + 2\hat{k})$ N.

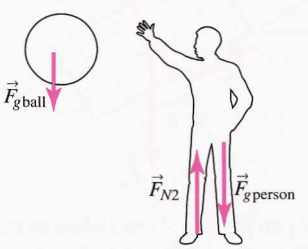


35. Yes; yes; yes; 0.70 m/s^2; not real.

37. (a) Parallel to the window edge, (b) at an angle given by $\tan\theta = a'/g$, (c) parallel to the window edge.

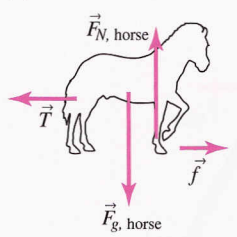


39.

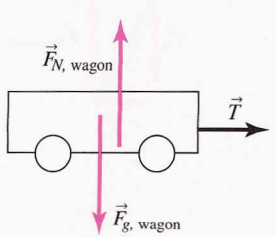


41.

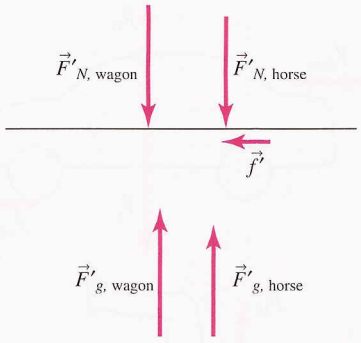
43.



(a)

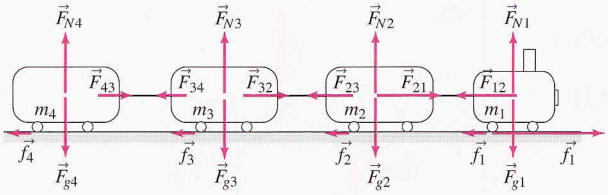


(b)

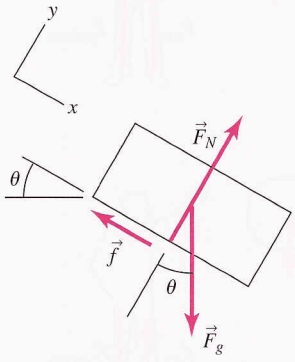


45.

(a)



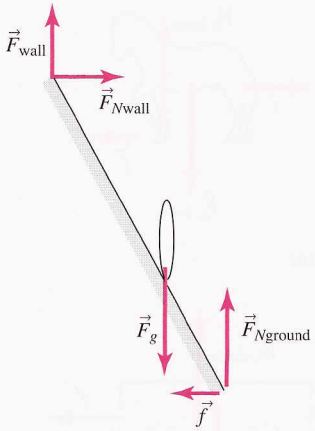
(b)



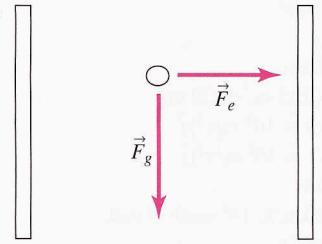
(c)

(d) a forward force from Earth on the horse's hooves.

47.



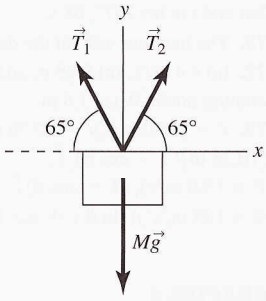
49.



$\Sigma F_x = F_g \sin 21° - f = ma$ (x-direction);
$\Sigma F_y = F_N - F_g \cos 21° = 0$ (y-direction).

51. There is a net horizontal force from the wall.

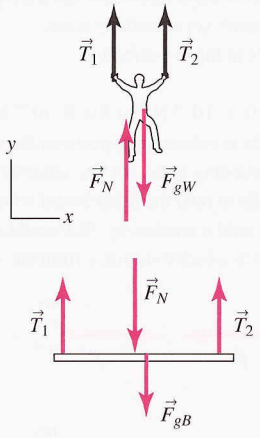
53.



55. (a) $F_g = mg$ down; $F_N = F_g = mg$ up, (b) mg down and $2mg$ up, (c) mg down.

57. $(1/M)(F_1^2 + F_2^2)^{1/2}$; $\tan^{-1}(F_2/F_1)$.

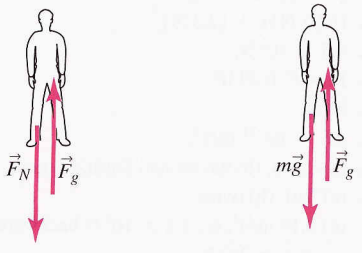
59. $(-1.1 \times 10^{-2} t^{-5/4})$ N, t in seconds.



61. (a) $c = (k/m)^{1/2}$,
(b) $A = 0$; $B = +v_0(m/k)^{1/2}$.

63. (a)

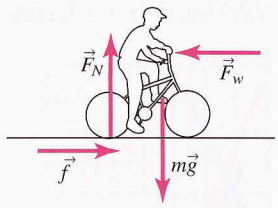
(b) 82.2 N up, (c) 1.55 m/s^2 up.



65. $T = (m_W g + m_B g)/4$;
$a = [4T - (m_W g + m_B g)]/(m_W + m_B)$.

67. (a) Backwards; 3.0×10^4 N,
(b) 1.6×10^4 N; 0.18 m/s^2, (c) 1.1×10^4 N from the first car; 5.2×10^3 N from the third; 0.18 m/s^2.

69.



(a)

(b) same forces, but the upward force would be fictitious.

71. (a) $[A] = [ML^{-1}]$ with units of kg/m,
(b) $(Av^2 - mg)/m = (Av^2/m) - g$,
(c) $v_t = (mg/A)^{1/2}$.

73.

(a) force of gravity: mg (down); normal force of ground: F_N (up); friction force of ground: f (forward); wind resistance: F_w (backward),
(b) 0, (c) 0; $v_w + v$; 0, (d) $v + v_w$; 0; 0.

75. (a) 0.40 m/s^2; 0.20 m/s^2,
(b) 0.067 m/s^2; 0.13 m/s^2, (c) 8.6 g.

77. $\phi = \theta$.

CHAPTER 5

1. 1.4×10^4 N.

3. 980 N.

5. 0.095 s.

7. (a) 24 N, (b) 7.8 N.

9. (a) 66 N, (b) 5.1 m/s^2 up.

11. (a) 2.5 m/s^2 forward,
(b) 3.5×10^3 N forward.

13. $M_{\max} = 9.2$ kg; $M_{\min} = 4.5$ kg; 0.

15. 9.8 mm/s^2; 2.5 mm/s^2.

17. $a_1 = [(m_1m_2 + m_1m_3 - 4m_2m_3)/(m_1m_2 + m_1m_3 + 4m_2m_3)]g$;
$a_2 = [(m_1m_2 - 3m_1m_3 + 4m_2m_3)/(m_1m_2 + m_1m_3 + 4m_2m_3)]g$;
$a_3 = [(-3m_1m_2 + m_1m_3 + 4m_2m_3)/(m_1m_2 + m_1m_3 + 4m_2m_3)]g$;
$T_1 = [8m_1m_2m_3/(m_1m_2 + m_1m_3 + 4m_2m_3)]g$;
$T_2 = [4m_1m_2m_3/T_2 = [4m_1m_2m_3/(m_1m_2 + m_1m_3 + 4m_2m_3)]g$. If $m_2 = m_3 \neq m_1$, then
$a_1 = [(m_1 - 2m_2)/(m_1 + 2m_2)]g$;
$a_2 = a_3 = [(2m_2 - m_1)/(m_1 + 2m_2)]g$;
$T_1 = [4m_1m_2/(m_1 + 2m_2)]g$;
$T_2 = [2m_1m_2/(m_1 + 2m_2)]g$.

19. 48.0 N; 96.0 N; 2.2 m/s^2 (up); -0.2 m/s^2 (down); -1.8 m/s^2 (down).

21. 0.12.

23. 0.61.

25. 3.6×10^2 N.

27. 0.40.

29. (a) 52 m, (b) 3.9 s.

31. (a) 1.8 s, (b) 2.6 N, (c) 0.65.

33. (a) $370/(\cos\theta + 0.75 \sin\theta)$ N,
(b) 37°; 2.9×10^2 N.

35. 0.077.

37. 9.5×10^2 N.

39. 0.060 m^2.

41. 0.57 m/s.

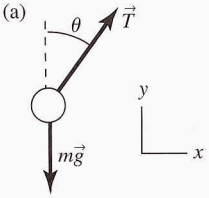
43. 0.67.

45. 5 m/s.

47. 1.3 m/s^2 toward the center.

49. 1.4×10^2 N toward the center.

51. $v_{\max} = 32$ m/s, $v_{\min} = 5.8$ m/s.



53. 9.5 cm.

55. 0.26.

57. 1.0×10^3 m/s tangent to the orbit.

59. 4.43 m/s.

61. (a)

(b) 0.4 m/s.

63. 4.5 m.

65. 0.72 m.

67. 55 m/s.

69. (a) 21 N, (b) 18 N.

71. 1.6×10^{-12} kg/m^3.

73. 1.2×10^2 N.

75. (a) 0.5 N, (b) 1.2 N.

77. (a) $\Delta x_2 = -\Delta x_1/2$, (b) $a_1 = -1.78$ m/s^2 (down); $a_2 = +0.89$ m/s^2 (up), (c) 9.6 N.

79. -0.3 m/s^2, towards mass-1.

81. $\omega = (g/\mu_s R)^{1/2}$.

83. $\omega = [g/(\ell \cos\theta)]^{1/2}$.

85. 26 m.

87. 11 m/s.

89. 2.3 m.

CHAPTER 6

1. (a) 39 J, (b) 1.0 m/s; 89 m/s, (c) 0.40 m/s.

3. (a) The force of gravity = 98 N (down); the upward pull = 98 N; $F_{net} = 0$, (b) 0, (c) 98 J.

5. 1.0×10^4 J.

7. (a) 2.4×10^2 J, (b) friction force, (c) 0.

9. 730 J; -730 J.

11. -3.73 J.

13. 1.8×10^3 J.

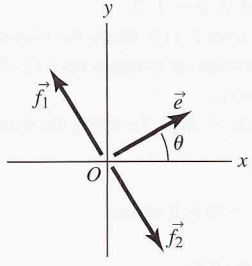
15. 2.8×10^{11} J.

17. 2.5 m; $(0.916)^n(3.00\text{ m})$.

19. 0.127 J; 0.159 J; 0.175 J.

21. $-mgR(1 - \cos\theta)$.

23. +3.



25. 0.89 m/s.

27. 2.53.

29. 3.9×10^3 J.

31. 6.1×10^3 J.

33.

$-\sin\theta\,\hat{i} + \cos\theta\,\hat{j}$; $\sin\theta\,\hat{i} - \cos\theta\,\hat{j}$.

35. 3.4.

37. -24 J.

39. $F_x L$.

41. 0.067 J.

43. $2g_1 - 4g_2$.

45. 8.6 m/s.

47. 8.1×10^{-2} J.

49. 14 J.

51. 2.1×10^3 J.

53. -15 J, -5 J; conservative.

55. (a) 6.3×10^{-2} J, (b) 0, (c) 5.9×10^{-2} J, (d) -5.9×10^{-2} J.

57. (a) 4 J; 6 J; 6 J; 4 J, (b) +5 m, (c) conservative.

59. Constant forces are included; not a function of position only.

61. (a) $0.16C$ J; 0, (b) $0.32C$ J.

63. 22 bulbs.

65. 0.7 kW.

67. 52 kW.

69. 5.0 m/s; 1.3 m/s.

71. 4.7×10^7 W.

73. (a) 16 m/s, (b) 0.5 s, (c) 12 s.

75. 5.8×10^{-12} J; 5.8×10^{-9} J.

77. 0.62; 0.31.

79. -0.2 J.

81. 0.034.

83. (a) 2.2×10^7 J, (b) -2.2×10^{-7} J.

85. (a) $mg = 26$ N down; $F_N = 22$ N perpendicular to plane (up); $f_k = 5.4$ N parallel to plane (down), (b) -18 J; 0; -7.0 J, (c) 4.4 m/s.

87. 5.3 J.

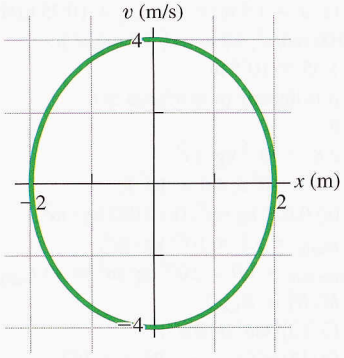
89. (a) 0, (b) -0.20 J, (c) 9.8 J.

91. $mgH(1 + \mu_k \cot\theta)$.

93. $W_g = mgL(\cos\theta_f - \cos\theta_i)$; $v = [2gL(1 - \cos\theta_i)]^{1/2}$; $W_T = 0$.

95. $0.01mK/x$.

CHAPTER 7



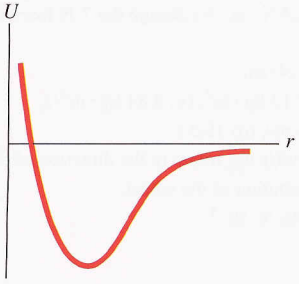
1. (a) 0.20 kJ, (b) 29 J; 2.3 kJ.

3. 25 m.

5. 1.2×10^{-2} J.

7. (a) $-8x$ J, with x in m, (b) +18 J, (c) 4.1 m/s.

9.

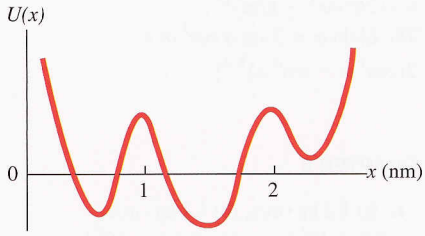


11. 0.541 m; 0.468 m.

13. 0.43 m; 0.48 m.

15. (a) 7.1 m/s, (b) -0.25 J, (c) 0.73.

17. $mg_0 y - (1/2)mg' y^2$.



19.

21. $E/(0.8\text{ N})$, $-E/(2.5\text{ N})$.

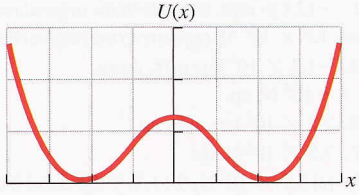
23. (a) To the right, (b) $(k/m)^{1/2}x$, (c) to the left; $-(k/m)^{1/2}x$.

25.

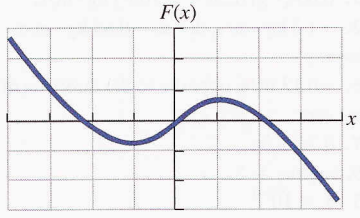
27. $x = 0$ is unstable and $x = \pm 0.24$ m is stable.

29. 503 m/s.

31. 130 m/s; same.



33. (b) $(2gH)^{1/2}$, (c) $2(gH)^{1/2}$.



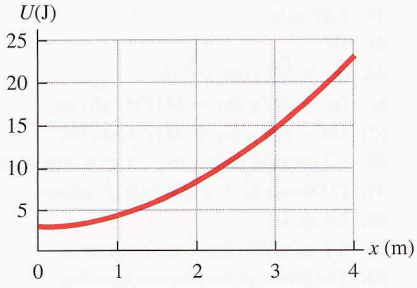
37. -5.0×10^4 J.

39. (a) 1.4 m/s, (b) 1.1 m/s, (c) 8 cm from point a.

41. (a) $U(x) = \frac{1}{2}k\left(\sqrt{h^2 + x^2} - L\right)^2$.

(b) $U(x) = -\dfrac{k\left(\sqrt{h^2 + x^2} - L\right)x}{\sqrt{h^2 + x^2}}$.

43. (a) GMm/r^2 toward M, (b) $GMm/2r$, (c) $-GMm/2r$.



47. -6.2×10^4 J.

49. $\approx$ 20 cents.

51. 5.9×10^2 J.

53. (a) $(3 + 3x^2/2 - 0.2x^3/3)$ J, with x in m.

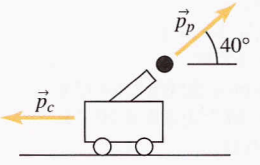
(b)

55. (a) Conservative, (b) not conservative.

57. $-A/3$; no.

59. -2 J; -2 J; +2 J.

61. (a) 7.7 m/s; 14.7 m/s (b) the skier leaves the surface.



63. (a) 4.4 m/s, (b) 3.7 m/s, (c) 5.9 N; 4.2 N.

65. (a) Conservative force, (b) $-C/r$, (c) 2.1×10^7 m/s.

67. (a) +1.13 J, (b) −0.083 J, (c) −0.30 J, (d) 0.70 m/s, (e) 8.8 cm, (f) 5.0 cm.
69. 1.1 m/s.
73. (a) $(1/2)mv^2 + (1/2)kr^2$, (b) $R(k/m)^{1/2}$, (c) $(2E/mr^2 - k/m)^{1/2}$.
75. $L[\sin\alpha + 2\sin\alpha\cos^2\alpha + 2(\cos^3\alpha - \cos^6\alpha)^{1/2}]$.

CHAPTER 8

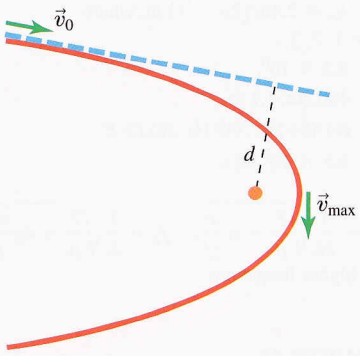
1. (a) 1.2 kg · m/s, (b) 5.1 kg · m/s, (c) 7.0×10^2 kg · m/s, (d) 7.6×10^2 kg · m/s.
3. (a) 4.2×10^2 kg · m/s, (b) 6.0×10^6 kg · m/s, (c) 1.2×10^4 kg · m/s, (d) 3.3×10^{-22} kg · m/s, (e) 1.4×10^{-2} kg · m/s.
5. (a) −1.0 m/s, (b) 3.5 J.
7. (a) $(-1.9\hat{i} - 10.8\hat{j})$ kg · m/s, (b) $(-4.9\hat{i} - 6.8\hat{j})$ m/s, (c) $(-0.90\hat{i} - 2.9\hat{j} - 1.2\hat{k})$ m/s, (d) 24 J; 64 J; 19 J.
9. 40 m/s.
11. −12 kg · m/s, opposite to the original motion; 1.7×10^4 N, opposite to the original motion.
13. -1.2×10^3 kg · m/s, down; 1.3×10^4 N, up.
15. 2.2×10^2 kg · m/s, up.
17. 7.5×10^2 N, up.
19. (a) 5.7×10^2 N, (b) 1.4×10^2 J, (c) 0.011 s.
21. $0.60\sqrt{g(0.20 + 0.10N)}$ kg · m/s.
23. −1.3 kg · m/s, down; −0.65 kg · m/s, down.
25. −0.13 m/s, opposite to the direction of the first cart.
27. 0.74 m/s.
29. $m_1/m_2 = 3$.
31. 4×10^{-9}.
33. (a) $M/(m + M)$, (b) $[(m + M)/m]\sqrt{2gh}$.
35. (a) $v[m_2^2 + M(m_1 + m_2)]/M(m_2 + M)$ forward, (b) $v[m_1^2 + M(m_1 + m_2)]/M(m_1 + M)$ forward, (c) $v(m_1 + m_2)/M$ forward.
37. (a) −0.20 m/s, (b) inelastic; 64%.
39. 2.59 m/s.
41. 15°.
43. (a) $\sqrt{2gh}$, (b) $\sqrt{2gh}$, (c) $[(m - 3M)/(m + M)]\sqrt{2gh}$, up, (d) $[(m - 3M)/(m + M)]^2h$, (e) $9h$.
45. 1.2 m/s 60° below the $-x$-axis, not elastic.
47. $(2.00 \text{ m/s})\hat{i} + (1.00 \text{ m/s})\hat{j}$; elastic.
49. 2.6 m/s.
51. 8.7 m/s, 20° above the horizontal.
53. The driver of the car was speeding!
55. 0.78 m from the heavier sphere.
57. $X = 0.38$ m; $Y = -0.66$ m.
59. 0.
61. $X = 0$; $Y = 1.0$ m from the bottom of the handle.
65. $4R/3\pi$ from the center of the arc, along the bisector.
67. $X = Y = 0.6$ m; $X = Y = 0.5$ m.
71. -3.3×10^3 kg/s.
73. 1% of mass must be discarded.
75. 2.5×10^3 m/s.
77. 5.0 m.
79. (a) Spit out seeds one at a time, (b) 6×10^{-3} m/s.
81. (a) 7.9 m/s (to the right), (b) 7.9 m/s (to the right), (c) −1.9 m/s (to the left); +1.1 m/s (to the right), (d) 2.1×10^4 N (to the right).
83. (a)

(b) 4.1 m/s recoil, (c) upward impulse provided by the ground.
85. (a) $[8M(M - m)/(M + m)^2]h$, (b) $-[4mM/(M + m)^2]h$.
87. 26 km/h.
89. $R/6$ from the center of the styrofoam sphere.
91. (a) 0.11 m/s, (b) 0, (c) −0.074 m, (d) 0.

CHAPTER 9

1. 0.68 rad/s^2.
3. −17 rad/s^2.
5. 7.3×10^{-5} rad/s from the South Pole to the North Pole; 2.0×10^{-7} rad/s perpendicular to the orbital plane.
7. (a) -2.62×10^2 rad/s^2, (b) 1.67×10^2 m.
9. (a) 0.10 rad/s^2, (b) 11 rev, (c) 2.1×10^2 m.
11. (a) $a = 1.5$ m/s^2; $x = x_0 + (0.75 \text{ m/s}^2)t^2$, (b) 100 rad/s^2, (c) $\omega = (100 \text{ rad/s}^2)t$.
13. 1.35×10^{-4} m.
15. α is linearly proportional to t.
19. 9.
21. 2.8×10^{-3} kg · m^2.
23. 1.3×10^2 J; 4.0×10^2 J.
25. (a) 0.021 kg · m^2, (b) 0.083 kg · m^2.
27. $I_{\text{Earth}} = 9.8 \times 10^{37}$ kg · m^2; $I_{\text{Neutron star}} = 1.0 \times 10^{39}$ kg · m$^2 \approx 10\ I_{\text{Earth}}$.
29. $M(R_1^2 + R_1^2)/2$.
31. $(3/10)(\tan^2\alpha)MH^2$.
33. $(8/15)\pi[(\rho_1 - \rho_2)R_1^5 + \rho_2 R^5]$.
35. $(16/45)MR^2$.
37. 24 lb.
39. 98 kg.
41. $L(F_{1y} + F_{2y})/2$ perpendicular to the rod.
43. (a) 2.3 N · m, (b) change the 7-N force to 5.4 N.
45. 0.38 N · m.
47. (a) 2.13 kg · m^2, (b) 8.84 kg · m^2/s, (c) 0.886 rev, (d) 18.3 J.
49. 3.8 rad/s up; rotate in the direction of the original rotation of the wheel.
51. -2.46×10^{-5}.
53. 2 s.
55. 0.12.
57. 13.4 m; 17.9 m.
59. 0.95 m.
61. 0.050 m/s^2.
63. 2.3 rev.
65. 5.1×10^6 m.
67. $(3v_0^2/4g)\sin\theta$.
69. m_1R_1/R_2; no.
71. (a) 0.72 kg · m^2/s, (b) 3.8 J, (c) 7.6 J.
73. $3\mu MgR/(R + 2r)$.
75. $MgR^2/(R^2 + 2r^2)$.

CHAPTER 10

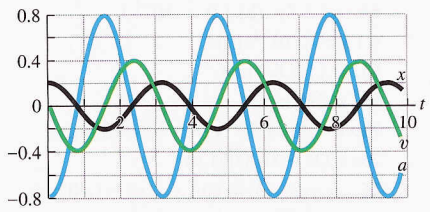


1. (a) 1.1×10^{10} kg · m^2/s down, (b) 7.9×10^9 kg · m^2/s down.
3. (a) 5×10^4 kg · m^2/s down, (b) 5×10^4 kg · m^2/s down.
5. 1.5 kg · m^2/s north.
7. $-7.4t^2\hat{k}$ kg · m^2/s (into the page).
9. $(mt^2/2)(bv\hat{i} - aw\hat{j} - av\hat{k})$.
11. $\vec{r} \times [m_2m_1/(m_1 + m_2)]\,d\vec{r}/dt = \vec{r} \times \mu\, d\vec{r}/dt$.
13. (a) $6.4 \times 10^{-2}\ \hat{k}$ kg · m^2/s (along ω-direction), (b) same.
15. (a) $m\omega d^2$ along the axis of rotation, (b) $3m\omega d^2/4$ along the axis of rotation, (c) $m\omega d^2/2$ along the axis of rotation.
17. $(17\hat{i} - 19\hat{j} + 14\hat{k})$ N · m.
19. $140\hat{k}$ N · m (perpendicular to table).
21. $MgR\sin(\omega t)$.
23. $mvd\sin(2\theta)$ up; 0; impulsive force from the wall.
25. $-7\hat{i} + 9\hat{j} + 10\hat{k}$.
27. 1.1 rad/s.
29. 30 m/s.
31. 0.103 rad (0.016 rev).
33. 0.15 rad/s.
35. 5.3×10^2 N · m along the axis.
37. 409 rad/s.
39. 0.14 J.
41. $r_n = (n^2\hbar^2/mk)^{1/4}$, $n = 1, 2, \ldots$; $v_n = (n^2\hbar^2k/m^3)^{1/4}$, $n = 1, 2, \ldots$; $K_n = \sqrt{k/m}\,n\hbar/2$, $n = 1, 2, \ldots$.
43. No energy level 2.0 eV above the lowest state; possible excitation energies are 10.2 eV, 12.1 eV, 12.75 eV, ...
45. $\omega_p = \Delta\theta/\Delta t = Mg\ell/I\omega$ along the z-axis.
47. 2.8 rad/s.
49. 72 rad/s.
51. 0.62 rad/s; −33 J; friction.
53. 3.3 rad/s.
55. (a) 4 m/s, (b) 0.8 s.
57. h.
59. (a) 19.4 m/s, (b) 0.127, (c) 0.132.
61. 26 kg; 52 rad/s; 12 kg.
63. 4.0×10^3 J.
65. (a) K/L, (b) L^2/MK, (c) $2\pi L^3/MK^2$, (d) MK^3/L^4.
67. $K \approx 1 \times 10^{17}$ J; $L \approx 6 \times 10^{20}$ kg · m^2/s.
69. (a) 2.4 m/s, (b) 2.4×10^2 rad/s.

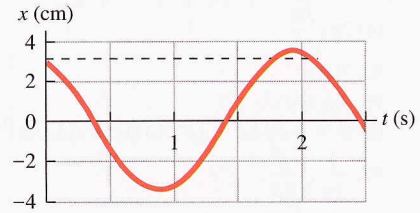
CHAPTER 11

1. 40 kg.
3. 139 N down; 96 N down.
5. (2, 0, 1) m.
7. 1.7 m.
9. 0.8 m.
11. 14.2 N · m in xy-plane 27° from $-x$-axis ($\perp \vec{r}$).
13. (a) $3L/4$; $11L/12$.
15. 0.57 Mg.
17. 1.2×10^2 N; $F_{N_A} = 0$.
19. (a) 2.9 m.
21. (a) 2.9×10^2 N 13.5° above the horizontal, (b) $F_V = 3.5 \times 10^2$ N down; $F_H = 2.8 \times 10^2$ N.
23. (a) $\tan^{-1} \mu_s$, (b) $\tan^{-1}(\Delta/2L)$.
25. 0.58 Mg outward.
27. 1.2 kN.
29. 1.9×10^2 N right; 73 N left; 23 N left.
31. (a) $F_{N_A} = mg\ell_2/2\ell_1$ down; $F_{N_B} = mg(\ell_2 - \ell_1)/2\ell_1$ up, (b) seat will lose contact at B and turn clockwise, (c) 74 N; 25 N.
33. (a) 56 N, (b) $(164\text{ N})\hat{i} + (46\text{ N})\hat{j}$.
35. 353 kg.
37. (a) $F_{N_1} = 0$; $F_{N_3} = F_{N_2} = (M + m)g/2 - mgx/L$; $F_{N_4} = 2mgx/L$, (b) $F_{N_4} = 0$; $F_{N_1} = -2mgx/L$, $F_{N_3} = F_{N_2} = (M + m)g/2 + mgx/L$.
39. $MgR \sin\theta$.
41. 1.33×10^4 N.
43. (a) 0.255 nm.
45. 0.524; 0.740.
47. 2.97 cm.
49. $(\Delta L/L)_c = 0.014$; 14 mm.
51. 2.5×10^2 N/m^2.
53. $\Delta y \approx 10^{-13}$ m.
55. 0.12° below the horizontal.
57. 1.99928 cm.
61. 9.1×10^{-12} m^2/N.
63. 69 N.
65. (a) $(Mg/2)\cot\theta_0$, (b) $(3g\cos\theta_0)/2L$, (c) $\omega = \sqrt{(3g\sin\theta_0)/L}$.
67. 85 N.
69. 1.36×10^3 N.
71. (a) Near legs: $(1 + 2\mu_k)Mg/4$ up; $(1 + 2\mu_k)\mu_k\, Mg/4$ to the left; far legs: $(1 - 2\mu_k)Mg/4$ up; $(1 - 2\mu_k)\mu_k\, Mg/4$ to the left, (b) 0.
75. $\tan(\theta/2)$.
77. 6.88.
79. Top ball: mg, $0.577mg$, $1.155mg$; bottom ball: mg, $1.155mg$, $2.000mg$, $0.577mg$.

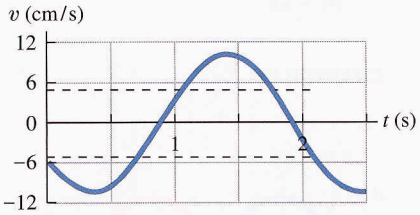
CHAPTER 12



1. 2.975×10^{-19} s^2/m^3.
3. (a) $[ML^4T^{-2}]$, (b) $\sqrt{mh}$, (c) $2\pi\sqrt{m/h}$ = a constant.
5. (a) 1.9×10^{-6} N, (b) must be the same.
7. 4.2×10^{-10} N; $\approx 10^{-7}\, W_{\text{fly}}$.
9. 6.6×10^6 m.
11. 1.51 h.
13. 9.56×10^6 m.
15. 4.9 m.
17. 0.25.
19. 6.18×10^5 m.
21. 26 m/s.
23. 1.6×10^{-3} rad/s.
25. 1.09×10^4 m/s.
27. (a) 1.85×10^8 m, (b) 7.99×10^8 m, (c) impossible.
29. 7.79 km/s tangent to the orbit; 1.52×10^{10} J; 2.56×10^{13} kg · m^2/s perpendicular to the orbit.
31. 1.74 h.
33. 1.49×10^{11} m.
35. 13 km/s.
37. 2.99 km/s.
39.
(a)



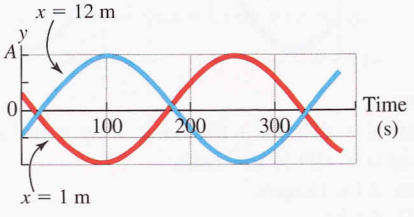
(b) 75.6 km/s perpendicular to the radius, (c) 4.76×10^7 km.
41. (a) 6.91×10^3 m/s, (b) 1.74×10^{13} kg · m^2/s, (c) 8.68×10^{12} kg · m^2/s, (d) the satellite crashes.
43. (a) 7.73×10^3 m/s, (b) 1.03×10^{14} kg · m^2/s, (c) -5.98×10^{10} J, (d) zero, (e) cannot be circular.
45. 0.996860; 0.996868.
47. $(2R^3/GM)^{1/2}$.
49. The tidal force on Jupiter is about 8% that on Earth.
51. 7.9×10^3 m/s.
53. 4.51×10^2 km from the Sun's center.
55. $\theta \approx 3 \times 10^{-10}$ rad; yes.
57. $4\pi(R^3/GM)^{1/2}$.
59. 3.5×10^{-15} m.
61. 0.40 rad/s.
63. (a) 1.66×10^3 m, (b) 2.8 m/s, (c) a speed of 1.76 m/s is needed to orbit the asteroid.
65. (a) Circular orbits are supported, (b) $T^2/r^{n+1} = 4\pi^2(m/k)$ = a constant.
67. $\Delta U \approx -4\pi fr$; $\Delta E = -2\pi fr$; $\Delta K \approx 2\pi fr$.
69. (a) 1.92 m/s relative to himself, which is 1.97 m/s relative to the ship, (b) 1.9 h.
71. (a) 1.68 m/s^2, (b) 1.95 m/s^2.
73. (a) Possible, (b) 1.83×10^7 s, (c) unstable.



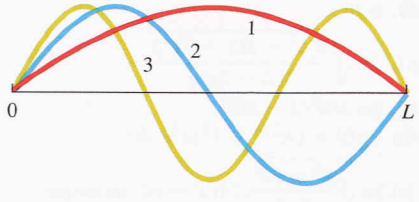
CHAPTER 13

1. $\pi/2$ rad.
3.

5. 4.09 s.
7. −0.038 m.
9. 7.0137×10^{-6} m
11. $x = A\cos[(2.0\text{ rad/s})t - 1.17\text{ rad}]$, t in s.
13. (a) 1.6 rad/s; 4.0 s, (b) 1.3 m.
15. (a) 4.08 cm/s, (b) 6.41 cm/s; 23.6 cm/s^2.
17. (a) $x = (3.4\text{ cm})\sin[(3.0\text{ rad/s})t + 2.1\text{ rad}]$, (b) 1.8 s, (c) 0; 0.71 s; 1.1 s; 1.8 s, (d)



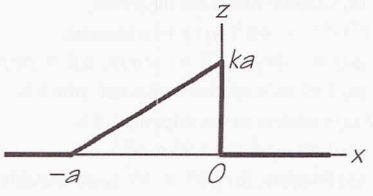
19. R.
21. $x = R\cos(\omega t + \delta)$, with $R = 1.5 \times 10^{11}$ m and $\omega = 1.99 \times 10^{-7}$ rad/s.
25. 2.4 s; 15 cm/s.
27. 5.1 kg.
29. 0.18 N/m.
31. 1.5×10^2 N.
33. 1.2 s.
35. $x = (1.0\text{ cm})\sin[(71\text{ rad/s})t + \pi/2]$.
37. 1.1 s.
39. 0.042 m/s.
41. 6.1 rad/s.
45. 2 m/s; 0.7 m; 0.3 J.
47. (a) $(\ell^3/R_E^3)M_E$, (b) $GM_Em\ell/R_E^3$ toward the center, (c) $-GM_Emx/R_E^3$ toward the center of the tunnel, (d) 1.4 h, (e) 1.4 h.
49. $F_{\text{net}} = -kx^3/2\ell^2$.
51. 9.79 m/s^2.
53. (a) 2.23 m, (b) 430 m.
55. (a) 1.7 s, (b) 0.05 m.
57. $E = mgL(1 - \cos\alpha) \approx mgL\alpha^2/2$ (for $|\alpha| \ll 1$).
59. 0.76 s.
61. $2\pi\sqrt{\dfrac{2(L^2 - 3Ly + 3y^2)}{3(L - 2y)g}}$.
63. (a) $MR^2/2 + M\ell^2$, (b) $-g\ell\theta = (R^2/2 + \ell^2)d^2\theta/dt^2$, (c) $2\pi\sqrt{\dfrac{R^2 + 3\ell^2}{2g\ell}}$, (d) $T \to \infty$; no torque.



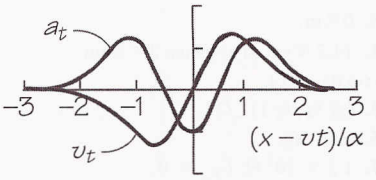
65. (a) 2.7 s, (b) 1.0×10^{-4} J, (c) 3.6×10^{-2} m/s.
67. 0.113; 8.4 min.
69. 0.095 kg/s.
71. $k \approx 6 \times 10^4$ kg/s^2; $b \approx 10^3$ kg/s.
73. (2.0 + 0.00051)s.
75. $x_{3.0} = -5.40$ cm; $x_{4.8} = -1.48$ cm; $x_0 = -6.65$ cm.
79. 1.8 Hz.
81. (a) 2.2 N · s/m, (b) 0.25 s, (c) $\Delta\omega = 8.0$ rad/s; $Q = 3.1$.
83. 0.36 m.
85. $\sqrt{2}\,\omega$.
87. 2.5 s.
89. (a) $0.553H$, (b) $0.347H$.
91. (a) 1.2 s, (b) $\pi\sqrt{\frac{2m}{k}}$, (c) $\pi\sqrt{\frac{2m}{k}}$, (d) $2\pi\sqrt{\frac{m}{k}}$.
93. 9.0 s.
95. (a) $2A/e^2$, (b) $U = -e^4/4A + (e^4/4A)x^2$; $e^4/(4A^3m)^{1/2}$.
97. $\frac{1}{2\pi}\sqrt{\frac{g}{2R}}$.
99. $\frac{1}{2\pi}\sqrt{\frac{2k}{3m}}$.

CHAPTER 14

1.

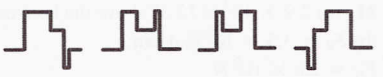


3. 200 m/s.
5. 23 m^{-1}; 48 Hz.
7. 5.1×10^3 m/s; 3.5×10^3 m/s.
9. 7.0×10^4 MN/m^2.
11. 8.03×10^{11} dyne/cm^2.
17. Yes.
19. $Y = 3.2 \times 10^5$ MN/m^2; $G = 8 \times 10^4$ MN/m^2; $L = 1.3 \times 10^4$ km.
21. $\mu\omega^2R^2$.
23. 25 km/h.
25. $\ell(k/m)^{1/2}$.
27. 2.1×10^3 W; 5.3×10^2 W.
29. 8.9×10^{-10} m.
31. $\mu v\omega^2 z_0^2 \cos^2(kx + \omega t)$.
33. $P = \mu v\left(\frac{\omega}{k}\right)^2\left[\frac{df}{d(x - vt)}\right]^2$.
35. 1.08 m; 0.54 m; 0.36 m;



37. 13 N.
39. $m_2/m_1 = 1/9$.
41. 1.
43. 3.5 Hz, 22 rad/s, 0.28 s; 7.1 Hz, 44 rad/s, 0.14 s; 11 Hz, 67 rad/s, 0.094 s.
45. 8.49×10^2 N.
47. 1.28 kg/m^3; 0.085 kg/m^3.
49. 89 dB; 65 dB; 39 dB.
51. 6.3×10^{-2} W.
53. 1.97×10^9 N/m^2.
55. 343 m/s.
57. 147 Hz.
59. (a) 0.874 m; 378 Hz, (b) 372 Hz.
61. 1.5×10^7 m/s.
63. 1.88×10^3 Hz.
65. 440 Hz/$(1 + 0.060t)^{1/2}$.
67. 965 m/s (3.5 × 10^3 km/h).
69. 1.3 kHz.
71. $\lambda_n = 2.40/(2n - 1)$ m, where $n = 1, 2, 3, \ldots$.
73. 3.2×10^6.
75. 400 Hz; 1.1 m.
77. (a) 484 Hz; 543 Hz, (b) *D*; *B*.
79. 3.5×10^2 m/s.
81. $f_1 = \frac{1}{2L}\sqrt{\frac{T}{\mu} + \alpha\frac{\pi^2}{L^2}}$; $f_2 = \frac{1}{L}\sqrt{\frac{T}{\mu} + 4\alpha\frac{\pi^2}{L^2}}$; the higher frequency.

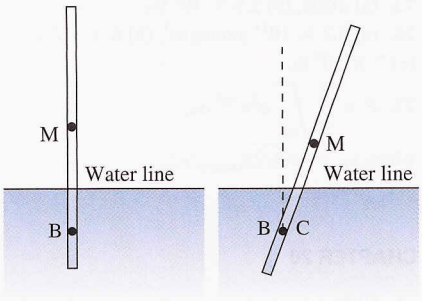
CHAPTER 15



1. $A = \sqrt{2}$; $\tan\phi = 1$, or $\phi = \pi/4$.
3. $1.41z_0 \sin[kx - \omega t + (\pi/4)]$.
5. 3.6 cm.
7. $\delta = 2\pi/3$ and $-2\pi/3$.
9. $2z_0 \sin[kx + (\pi/4)]\cos[\omega t + (\pi/4)]$, which represents a standing wave; x(nodes) = $[n - (1/4)](\pi/k)$, where $n = 0, \pm1, \pm2, \ldots$.
11. (a) 11 Hz; 7.3 m/s; (b) $z_\ell = 3\sin(kx + \omega t)$; $z_r = 3\sin(kx - \omega t)$.
15. 6 m.
17. 506 Hz.
19. 422 Hz.
21. −1.6%.
23. $z = 2A\cos(\omega t - kL)$.
25. 0.59 cm.
27. (a) 37°; (b) 17.5°; (c) 37°.
31. (a) −1 cm, 0, +1 cm; (b) (6 cm) $\sin(\pi r - \pi vt)$, where $r = (y^2 + 4)^{1/2}$.
33. (d) Total energy is conserved.
35.

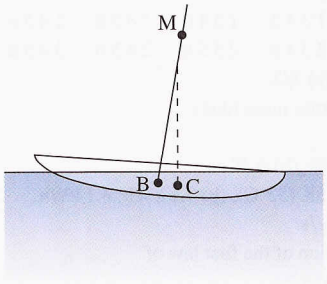
$z(x, t) = 0$ for $x < (vt - a)$ and $x > vt$; $z(x, t) = k(x - vt + a)$ for $(vt - a) < x < vt$.
37. $v_t = z_0\left[2(x - vt)\left(\frac{v}{\alpha^2}\right)\right]e^{-(x-vt)^2/\alpha^2}$;
$a_t = z_0\left[-\frac{2v^2}{\alpha^2} + 4(x - vt)^2\left(\frac{v^2}{\alpha^4}\right)\right]e^{-(x-vt)^2/\alpha^2}$;

39.



41. −0.069*A*; 1.07*A*.
43. 6.6×10^{-3}.
45. $\frac{B}{A} = \frac{k_2 - k_1}{k_2 + k_1} = \frac{\sqrt{\mu_2} - \sqrt{\mu_1}}{\sqrt{\mu_2} + \sqrt{\mu_1}}$; $\frac{C}{A} = \frac{2k_2}{k_2 + k_1} = \frac{2\sqrt{\mu_1}}{\sqrt{\mu_2} + \sqrt{\mu_1}}$;
$z_i = A\cos(k_1x - \omega t)$;
$z_r = B\cos(k_1x + \omega t + \pi)$;
$z_t = C\cos(k_2x - \omega t)$.
47. 1 MHz.
49. (a) 400 Hz; 0.4 m; 160 m/s; (b) 7.7 cm.
51. $\Delta T/T = 9.1 \times 10^{-3}$.
53. $69\cos(4\pi t)$ Hz.
55. 90 Hz; 101 Hz; 111 Hz.
57. 6.0×10^{-7} m; 3.9×10^{-7} m.
59. (a) and (b) are linear.
61. z(envelope) $\simeq \sin[\Delta k(x/2) - \Delta\omega(t/2) + (\pi/4)]$; $f = (\omega_1 - \omega_2)/2\pi$; $\lambda = 2\pi/(k_1 - k_2)$.

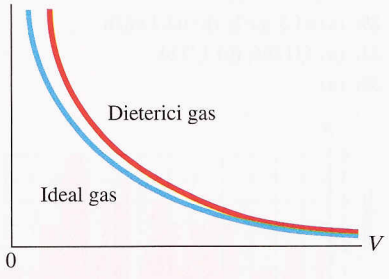
CHAPTER 16



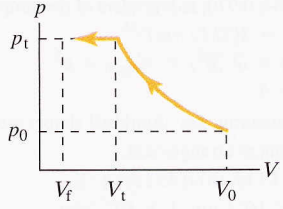
1. 1.15×10^3 kg/m^3.
3. 50 L.
5. $\Delta d_1 = af/\sqrt{2}$; $\Delta d_2 = -af/\sqrt{2}$;
7. 2.1×10^5 N/m^2.
9. (a) 5.1×10^4 N, (b) 1.3×10^2 N (equivalent to lifting 13 kg).
11. 7.8×10^2 N/m^2; p will decrease.
13. 1.11×10^5 Pa; 2.02×10^5 Pa; 1.11×10^6 Pa; 1.01×10^8 Pa.
15. 1.02×10^5 Pa; 1.05×10^5 Pa.
17. $h_{\text{Venus}} = 0.838$ m; $h_{\text{Neptune}} = 0.619$ m.
19. 52 N; 2.2 mm.
21. Sink.
23. 8.4×10^2 kg/m^3.
25. 9.3 m.
27. 0.71 m^3.
29. 13 m^2.
31. 0.96×10^3 kg/m^3.
33. $\rho_1 < \rho_3 < \rho_2$; $D/H = (\rho_3 - \rho_1)/(\rho_2 - \rho_1)$.
35. 8.1×10^2.

37.

(a)



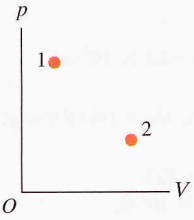
(b)



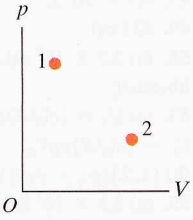
39. 2.9 m/s; 0.23 kg/s.
41. 57 mi/h.
43. 0.81 cm.
45. 1.6×10^2 W (0.22 hp).
47. -4.7×10^2 Pa (gauge); 4.7×10^2 Pa.
49. 9×10^{-2} N; rise.
51. (a) 7.7 m/s; (b) 4.3 h.
53. (a) 2 m/s; (b) 2.2×10^5 Pa (2.2 atm).
55. $p_0 + (1/2)\rho v_0^2 + \rho g h_0 = p_1 + (1/2)\rho v_1^2 + \rho g h_0$; $p_0 + (1/2)\rho v_0^2 + \rho g h_0 = p_2 + (1/2)\rho v_2^2 + \rho g h_0$; $v_0 D^2 = v_1 d_1^2 + v_2 d_2^2$.
57. $y = y_0 + (\omega^2/2g)r^2$ (which describes a parabola).
59. $a = 1, b = 1$.
61. 5.4 cm.
63. 3.9 atm; less air.
65. (a) 27 m/s; (b) ≈200 times the rate of flow of the hose; (c) 1.9×10^{-3} m^2; (d) 3.65×10^5 Pa (gauge).
67. Yes.
69. (a) 6.0×10^2 kg/m^3, (b) $-0.39 \times 10^3\ \Delta$ N (up), (c) $0.39 \times 10^3 \Delta$ N (down), (d) 1.44 Hz.
71. (a) 1.8×10^5 Pa, (b) 4.8×10^5 Pa, (c) 7.0×10^{-4} m/s, (d) 13 m/s; (e) 0.37 L/s.
73. $[2g(h_1 - h_0)]^{1/2}$.
75. 8.6 min.

CHAPTER 17

1. (b), (e), (f) are in thermal equilibrium.
3. The extensive variable are (a) and (d), and the intensive variable are (b) and (c).
5. (a) $t_F = -40°F$; $t_C = -40°C$, (b) none, (c) $t_F = +575°F$, $T = +575K$.
7. 95.9°F to 108.5°F.
9. $\Delta p = 0.29$ Pa.
11. (a) 457°C; 854°F, (b) −196°C; −321°F, (c) 297K; 24°C, (d) 2.2°C; 276K.
13. $T = 1.25t_R + 273$; $t_F = 2.25t_R + 32$.
15. 672°R; 7.6°R; 10,800°R; 492°R; 430°R; 447°R.
17. 52°C (126°F).
19. 0.5 mm.
21. 8.0×10^{-4} K^{-1}.
23. 7.0 cm^3.
25. (a) $\Delta T = 104°C$, (b) 57×10^{-6} K^{-1}, (c) 5.9×10^{-3}.
27. 1.3×10^{-4} cm^2.
29. (a) steel, (b) 0.99971 Hz ≤ f_{aluminum} ≤ 1.00029 Hz; 0.99979 Hz ≤ f_{copper} ≤ 1.00021 Hz; 0.99987 Hz ≤ f_{steel} ≤ 1.00013 Hz.
31. 2.1%.
33. 1.4×10^3 cm^3.
35. 7.4×10^4 m^3.
37. 0.47 kg/m^3.
39. $p_2/p_1 = 0.562$.
41. 1.30×10^5 Pa; 0.28×10^5 Pa; 1.58×10^5 Pa.
43. 3.1×10^{-10} m.
45. (a) 6.1×10^4 Pa; 308K, (b) 3.5×10^{-3} m^3, (c) 0.77 atm.
47. (a) $pV = NKT$, (b) $P(V - bN) = N(kT - aN/V)$, (c)

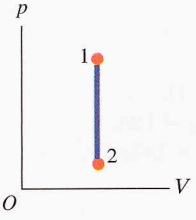


49. 22.4×10^{-3} m^3; 1.29 kg/m^3.
51. 6 kg/m^3.
53. 2.42×10^9 molecules.
55. (a) 71 atm, (b) 71 atm.
57. 40.5 cm^3; 142 cm^3;

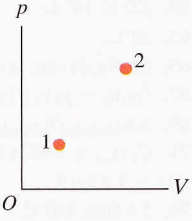


59. 1.4 kg/m^3; 0.74 m^3/kg.
61. (a) $p_2 = 10^5$ Pa; $V_2 = 600$ cm^3; $T_2 = 568K$, (b) $p_3 = 1.30 \times 10^5$ Pa; $V_3 = 600$ cm^3; $T_3 = 762K$, (c) $p_4 = 1.30 \times 10^5$ Pa; $V_4 = 300$ cm^3; $T_4 = 381K$.
63. 4.0×10^{-2} m^3.
65. 2.56×10^3 J; 2.15×10^3 J; the energy of the gas is ≈10^4 the energy of the ball.
67. 373.15K.
69. (b) 421K (148°C).
71. $E_{3200°C} = 1.84 \times 10^4\ E_{25°C}$.
73. (a) 6.25×10^{10} Hz, (b) 5.83×10^{12} Hz, (c) 1.67×10^{13} Hz, (d) 6.25×10^{13} Hz.
75. 9.4×10^{-6} m.
77. 4.47×10^{26} W.
79. 2.05×10^{17} W; almost the same.
81. 5.67×10^{-8} W/m$^2 \cdot$K^4.
83. 37 kg.
85. $a = (T_1Z_2 - T_2Z_1)/(Z_1 - Z_2)$; $b = (T_1 - T_2)/(Z_1 - Z_2)$; not necessarily.
87. 0.1 m^3.
89. 26 m/s.
91. 0.754×10^{-23} J/K′.

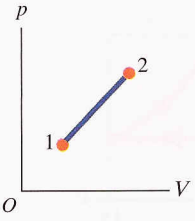
CHAPTER 18



1. Reversible transformations: (c), (e) and (h); irreversible transformations: (a), (b), (d), (f), and (g).

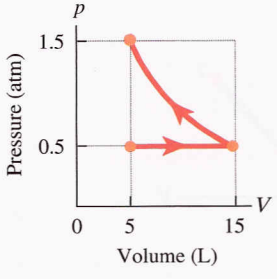


(a)



(b)

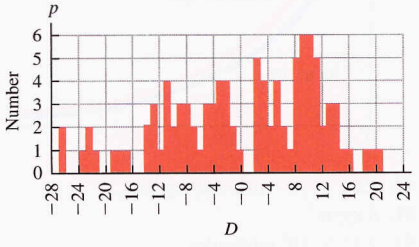
(c)



(d)

(e)

3. 5×10^2 cal/s.
5. $c'_p pV/R$.
7. (a) 262.8 g of water and 37.2 g of ice at 0°C, (c) 300 g of water at 7.6°C.
9. (a) 0.22 cal/g · K; 5.9 cal/mol · K, (b) 0.103 cal/g · K; 5.8 cal/mol · K, (c) 0.04 cal/g · K; 8 cal/mol · K.
11. 308K.
13. 167K.

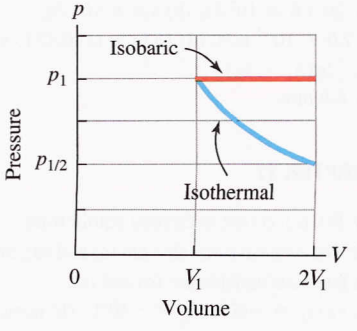


15. 7.6%.
17. 287K (14°C).
19. 7.4 kW.
21. Pine: 144 Btu/h; Fiberglas: 62 Btu/h; $R_{\text{eff}} = 16\ \text{ft}^2 \cdot \text{h} \cdot {}^\circ\text{F/Btu}$.
23. (a) $\kappa_{\text{eff}} = \kappa_1\kappa_2(L_1 + L_2)/(\kappa_2 L_1 + \kappa_1 L_2)$, (b) $(\kappa_1 L_2 T_1 + \kappa_2 L_1 T_2)/(\kappa_1 L_2 + \kappa_2 L_1)$.
29. $\dfrac{1}{L}\dfrac{dQ}{dt} = \dfrac{2\pi\kappa(T_2 - T_1)}{\ln(1 + \alpha/R_1)}$.
31. 6.7°C.
33. 33 times.
35. 1 cal = 4.14 J.
37. (a) 11.9°C, (b) 10.1°C, (c) ΔT of the water is less than in part (a), (d) net negative temperature change.
39. 1.0×10^6 J.
41. 3.0×10^5 J.
43. 0.012 m^3; 0.0034 m^3; -1.6×10^3 J.
45. (a) $[ML^{-4}T^{-2}]$, (b) $(V_2 - V_1)[p_0 - (V_2 + V_1)\beta/2]$, (c) same as part (b).
47. 4.1×10^3 J.
49. 633 cal.
51. (a) 2.7×10^4 cal, (b) -3.5×10^4 cal; liberated.
53. (a) $U_A = (c'_V/R)p_A V_A$; $U_B = (c'_V/R)p_B V_B$; $U_C = (c'_V/R)p_B V_A$, (b) $(1/2)(p_A - p_B)(V_B - V_A)$.
55. (a) 2.8×10^2 K; 6.1×10^2 K, (b) 1.2×10^3 J, (c) 2.3×10^2 J, (d) 1.4×10^3 J (into the gas).
57. −0.72K (cooled).
59. 5.0×10^4 J.
63. 20°C.
65. (a) No, (b) no, (c) no.
67. $(p_0 V_0 - p_1 V_1)/(\gamma - 1)$.
69. $\Delta p_{\text{adiabatic}}/\Delta p_{\text{isothermal}} = 1.24$.
71. $C_V/C_p = 0.683$; $W_{\text{on}} = 1.43 p_1 V_1$; $\Delta U = 1.43 p_1 V_1$.
73. 5.4 atm; 210°C.
75. 61.7 cm^3; 151 cm^3.
79. (a)

(b) 1.5 atm, (c) -3.2×10^2 J.
81. (a) $+7.1 \times 10^3$ J, (b) $+2.5 \times 10^3$ J.
83. $\text{slope}_{\text{adiabatic}}/\text{slope}_{\text{isothermal}} = \gamma$.
85. 255K.
87. 3.85×10^3 J.
89. $dm/dt = 20 \times 10^3$ kg/s.
91. (a) 10 atm, (b) -5.7×10^3 J, (c) -5.7×10^3 J (from the gas).
93. (a) $C_p = 3R/2 + RV(pV^2 - a)/(pV^3 - aV + 2ab)$, (b) $C_V = 3R/2$, (c) $\gamma = 1 + 2V(pV^2 - a)/[3(pV^3 - aV + 2ab)]$.
95. 32°F.
97. $+2.48 \times 10^3$ J.
99. (a) 7.18×10^5 Pa (7.1 atm), (b) 5.9×10^{-2} m^3, (c) 2.0×10^4 J, (d) 137K, (e) $+2.0 \times 10^4$ J, (f) $+1.2 \times 10^4$ J.
101. 0.90 W.

CHAPTER 19

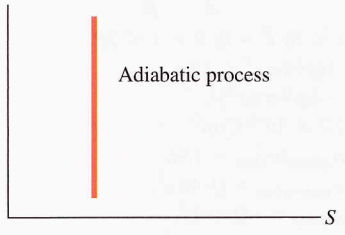
1. (a) 1.0×10^{-4}; 5.8×10^{-2}, (b) 6.1×10^{-3}; 0.23, (c) 1.0×10^{-12}; 1.2×10^{-4}, (d) 6.1×10^{-11}; 4.9×10^{-4}.
3. 4×10^{24} components; 4×10^5 m^2.
5. 6 Pa.
7. (a) 3.8×10^3 J, (b) 304K, (c) 3.8×10^5 m^2/s^2, (d) 6.1×10^2 m/s.
9. $PA = U$.
11. 11 m/s.
13. 4×10^{-17} Pa.
15. (a) 290K, (b) 2.90×10^5 K, (c) 3.6 J.
17. (a) 6.1×10^{-21} J, (b) 3.5×10^{-10} m/s.
19. 7.0×10^5 m/s.
21. 484 m/s; 517 m/s; 412 m/s; 1934 m/s.
23. (a) 1.2×10^4 m/s, (b) 1.9×10^3 m/s.
25. 4.9×10^{-3} m/s.
27. 7.2×10^{73} K.
29. (a) 61.8 mi/h, (b) 62.4 mi/h.
31. (a) 1/1296, (b) 1/324.
33. (a)



(b) 124.
35. (a) +6.4, (b) 474, (c) +20.
39. 0.984; 0.970; independent of the temperature.
41. $v_{\text{av}} = 2(2kT/\pi m)^{1/2}$.
43. $\langle\vec{v}\rangle = \vec{u}$; $\langle\vec{v}^2\rangle = v_{\text{rms},0}^2 + u^2$.
45. $s = 5$.
47. monatomic gas; dumbbell shape; atoms not linear; linear arrangement.
49. (a) 17 kJ, (b) 0.45 kJ/kg · K.
55. 1×10^{-3} atm; 1×10^{-7} atm.
57. ≈100 m.
59. 6×10^{19} atoms; 6×10^{16} atoms; 30 Pa.
61. 0.63; no change.
63. (a) $v_{\text{esc}} = 4.1 \times 10^3$ m/s, (b) 1350 K; v_{rms} and T both decrease, (c) similar effect, (d) lighter component will make up a smaller fraction of the atmosphere.
65. (a) Yes, (b) $x/(1 - x)$, (c) $x^{-1/2}$; no.
67. (a) 7.0×10^5 m, (b) The mean free path decreases by a factor of 1000 to 7.0×10^2 m.
69. 2×10^{-3} m/s.
71. $p = nE/3$.
73. (a) 285K, (b) 2.8×10^4 Pa.
75. (a) 3.2×10^{11} atoms/m^3, (b) 6×10^4 s, (c) 7×10^7 m.
77. $P = \dfrac{4}{\pi}\displaystyle\int_{u_0}^{\infty} u^2 e^{-u^2}\, du$, where $u_0 = \sqrt{3/2}\, v_{\text{escape}}/v_{\text{rms}}$.

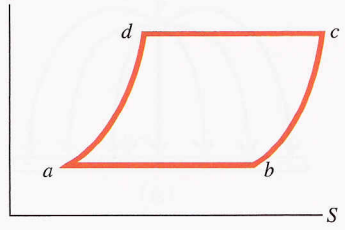
CHAPTER 20

1. 50%.
3. (a) The possible outcomes are



1 2 3 4	1 2 3 5	1 2 3 6	1 2 4 5	1 2 4 6
1 2 5 6	1 3 4 5	1 3 4 6	1 3 5 6	1 4 5 6
2 3 4 5	2 3 4 6	2 3 5 6	2 4 5 6	3 4 5 6

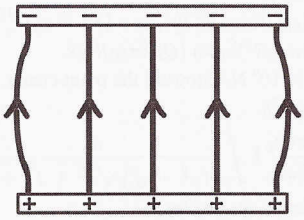
(b) 1/15, (c) 3/5.
5. 252 times more likely.
7. 29%.
9. (a) 38%, (b) 0.38 cal.
11. (a) 325K (52°C), (b) 9.1 kWh; 4.1 kWh.
13. 270 kg/s.
15. Violation of the first law of thermodynamics.
17. 60.
19. Engine A is not reversible.
21. 127 W.
23. 13.7; 9.1.
25. $C_V(T_2 - T_3)$.
27. 5.5 W (0.0074 hp).
29. The statement cannot be trusted.
31. ≈1 cent.
33. (a) $T_3 = p_L V_U/nR$; $T_4 = p_L V_L/nR$, (b) $\Delta U_{\text{IV}} = -C_V p_L(V_U - V_L)/nR$, (c) $Q_{\text{IV}} = +[1 + (C_V/nR)]p_L(V_U - V_L)$, (d) $\eta = nR(p_U - p_L)(V_U - V_L)/[C_V(p_U V_U - p_L V_L) + nRp_U(V_U - V_L)]$.
37. $1 - [(T_3 - T_4)/\gamma(T_2 - T_1)]$.
39. 7.9×10^{-2} J/K · min; irreversible.
41. 31°C; +10 J/K.
43. +0.75 kJ/K.
45. +8 J/K.
47. $\Delta S_{\text{gas}} = +44$ J/K; $\Delta S_{\text{universe}} = +44$ J/K.
49. 20 J/K.
51. The entropy of the gas decreases.
53. $\Delta T = 0$; $\Delta S = +32.5$ J/K.
55. (a)



(b) $W_{\text{isobaric}} = p_1 V_1$; $W_{\text{isothermal}} = 0.693 p_1 V_1$, (c) $\Delta S_{\text{isobaric}} = 0.693 nc'_p$; $\Delta S_{\text{isothermal}} = 0.693 nR$.

57. Process $A \rightarrow B$ (isobaric):
$Q = (nR(T_B - T_A)$, $W = nR(T_B - T_A)$,
$\Delta U = (3/2)nR(T_B - T_A)$, $\Delta T = T_B - T_A$,
$\Delta S = (5/2)nR \ln(T_B/T_A)$;
Process $B \rightarrow C$ (adiabatic): $Q = 0$,
$\Delta U = (3/2)nR(T_C - T_B)$,
$W = (3/2)nR(T_B - T_C)$,
$\Delta T = T_C - T_B$, $\Delta S = 0$;
Process $C \rightarrow D$ (isothermal): $\Delta T = 0$,
$\Delta U = 0$, $W = (3/2nRT_C \ln(T_A^{2/3}T_C/T_B^{5/3})$,
$Q = (3/2)nRT_C \ln(T_A^{2/3}T_C/T_B^{5/3})$,
$\Delta S = (3/2)nR \ln(T_A^{2/3}T_C/T_B^{5/3})$;
Process $D \rightarrow A$ (constant volume):
$Q = (3/2)nR(T_A - T_C)$, $W = 0$,
$\Delta U = (3/2)nR(T_A - T_C)$, $\Delta T = T_A - T_C$,
$\Delta S = (3/2)nR \ln(T_A/T_C)$.
59. $\Delta S_{\text{gas}} = Q/T < 0$ (decreases);
$\Delta S_{\text{reservoir}} = -Q/T > 0$ (increases); no conflict because this is a reversible process.
61. (a) $T = T_0$, (b) $+nR \ln 3$, (c) $+nR \ln 3$, (d) 0.
63. (a) +87 J, (b) 2.7K, (c) +0.38 J/K.
65.
(a) T

(b) T



67. (a) 2.25×10^{-2} m^3, (b) 273K, (c) −11.5 J/K.

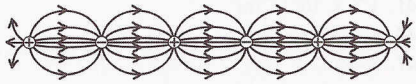
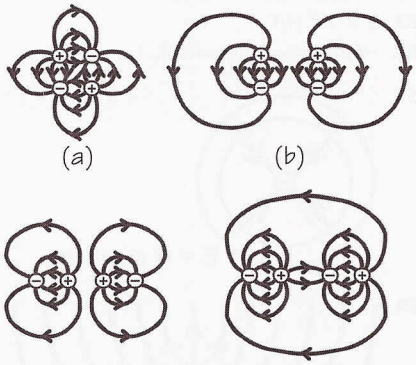
(c) 1.65×10^6 J/kg.

CHAPTER 21

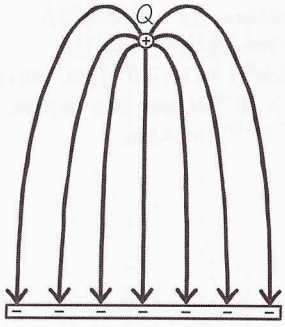


1. 6.2×10^9 fewer electrons.
3. 4.82×10^4 C.
5. 7.9×10^{-12} per atom.
7. -2×10^{-10} C, 1.25×10^9 electrons; -1×10^{-10} C, 6.2×10^8 electrons; -1×10^{-10} C, 6.2×10^8 electrons.
9. 2.2×10^{-10}.
11. (a) 1.8×10^{51} electrons, (b) 3.5×10^{-39}.
13. (a) conserved, (b) not conserved, (c) conserved, (d) not conserved.
15. -8.5×10^{-24} C.
17. 46 N repulsion, 23 N attraction.
19. $q = 1.6 \times 10^{-19}$ C, 1 electron.
21. 3.5×10^{-10}, mass much larger.
23. (a) 3×10^9 esu in 1 C, (b) 4.8×10^{-10} esu.
25. $q_1/q = q_2/q = \frac{1}{2}$.
27. (a) 2.6×10^{-9} N toward the proton (centripetal), (b) 9.2×10^5 m/s, (c) 4.9×10^{14} Hz, (d) 8.6 N/m.
29. 1.4×10^{-8} C.
31. $q_1 = +1.1 \times 10^{-7}$ C, $q_2 = -3.2 \times 10^{-7}$ C, $q_3 = +5.3 \times 10^{-7}$ C.
33. 0.9 m.
35. $x = 44.4$.
37. zero.
39. $\vec{F}_+ = 39$ N 30° above the line joining the two "up" quarks, $\vec{F}_- = 40$ N toward the center of the line joining the two "up" quarks.
41. (a) $\Sigma\vec{F} = 0$, (b) unstable, (c) stable.
43. (a) $\sqrt{3}kq^2/2L^2$, 9.7° above the $-x$-axis, (b) $3.2kqQ/L^2$, 6.3° below the $-x$-axis.
45. $(2kq\lambda/x_0)\hat{i}$.
47. $kqQ/d(L + d)$, away from the rod.
49. Let the radius of each ring be R and the separation between them be $2L$. If $Qq(R^2 - 2L^2) < 0$ then the equilibrium is stable, otherwise unstable.
51. 1.4 N away from the center.
53. 3.0×10^{-7} C.
55. 0.52 N.
57. $3kq^2[3(2.25 + y_0^2)^{-3/2} - (0.25 + y_0^2)^{-3/2}]\hat{i}$, y_0 in cm.
59. 5.7 N/m^2; same.
61. 1.5×10^{-3} C.
63. 6.6°.
65. (a) $v = (e^2/4\pi\varepsilon_0 mR)^{1/2}$,
(b) $L = (e^2mR/4\pi\varepsilon_0)^{1/2}$, (c) $v = e^2/4\pi\varepsilon_0 L$,
(d) $R = 4\pi\varepsilon_0 L^2/me^2$, (e) $\tau = 32\pi^3\varepsilon_0^2 L^3/me^4$,
(f) $v = 2.2 \times 10^6$ m/s; $R = 5.3 \times 10^{-11}$ m; $\tau = 1.5 \times 10^{-16}$ s.
67. (a) $F_{\text{net}} = kq^2[\ell(\ell - 2x)/x^2(\ell - x)^2]$ away from the closer charge; $x = \ell/2$,
(b) $F_{\text{net}} = -2kq^2\ell\,\Delta x/[(\ell/2)^2 - (\Delta x)^2]^2$,
(c) $f = (1/2\pi)(32kq^2/\ell^3 m)^{1/2}$.
71. (a) $\vec{F} = kqQR \sum_{n=-\infty}^{\infty} \left\{ \frac{1}{[(na)^2 + R^2]^{3/2}} \right\} \hat{j}$,
(b) $\vec{F} = \frac{k\lambda Q}{R} \int_{-\infty}^{\infty} \frac{du}{(u^2 + 1)^{3/2}} \hat{j}$.

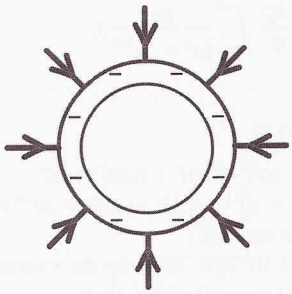
CHAPTER 22



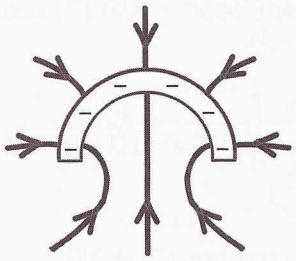
1. $1.8 \times 10^7(-0.60\hat{i} + 0.80\hat{j})$ N/C.
3. $(1.14 \times 10^{11}$ N/C$)\hat{r}$; $-(1.82 \times 10^{-8}$ N$)\hat{r}$ (toward the nucleus).
5. 3.19×10^6 N/C, 78° above the $+x$-axis.
7. (a) $-(1/4\pi\varepsilon_0)(8q/\ell^2)\hat{i}$, (b) 0, (c) $(1/4\pi\varepsilon_0)\{2qd/[d^2 + (\ell/2)^2]^{3/2}\}$ away from the origin.
9.
$$\vec{E} = \frac{2\vec{p}}{4\pi\varepsilon_0 r^3}\left\{\frac{1}{[1 + (L/2r)]^2[1 - (L/2r)]^2}\right\}.$$
$$\vec{E} = \frac{2\vec{p}}{4\pi\varepsilon_0 r^3}.$$
11. Stable; $(1/2\pi)(Qq/\pi\varepsilon_0 a^3 m)^{1/2}$.
13. Tripled.
15.



17.



19.



21. 2.7×10^4 N/C perpendicular to and away from the line.
23.

25.

27.

29. σ/ε_0 perpendicular to the plates and away from them; 0.

31. (a) $(z_0Q/2\pi\varepsilon_0R^2)[1/z_0 - (R^2 + z_0^2)^{-1/2}]\hat{k}$, (b) $(Q/4\pi\varepsilon_0R^2)\hat{k}$, (c) $(Q/2\pi\varepsilon_0R^2)\hat{k}$.

33. 7.3×10^4 N/C toward the point charge.

35. $Q/4\pi r^2h$.

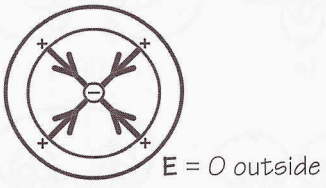
37. (a) $\dfrac{\sigma L z_0}{2\pi\varepsilon_0}\hat{k}\displaystyle\int_{-L}^{L}\frac{dx}{(x^2 + z_0^2)\sqrt{x^2 + L^2 + z_0^2}}$, (b) $(\sigma/2\varepsilon_0)\hat{k}$, (c) $(\sigma/2\varepsilon_0)\hat{k}$.

39. 0.65 μC.

41. 1.7×10^{-7} C/m^2.

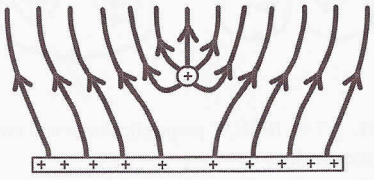
43. $(q\lambda/2\pi\varepsilon_0m)^{1/2}$.

47. 3.4 cm.



49. 5.7 s^{-1}.

51. $-(1.41 \times 10^{-6}\ \text{N}\cdot\text{m})\hat{k}$.

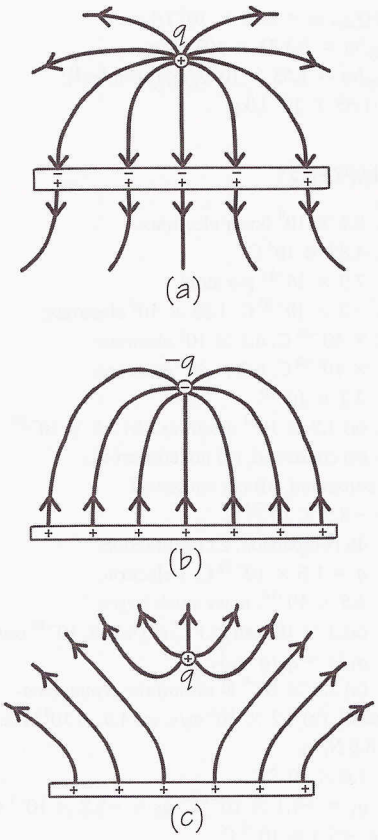


53. 2×10^6 N/C.

55. $-6p^2/4\pi\varepsilon_0r^4$ (attraction).

57.

59.



61. (a) $\{(\lambda R/2\pi\varepsilon_0)/[y^2 - (R/2)^2]\}\hat{j}$, (b) $-\{(\lambda R/2\pi\varepsilon_0)/[x^2 + (R/2)^2]\}\hat{j}$.

63. $[(1 + 8.5t^2)\hat{i} + (1 - 14t^2)\hat{j}]$ m, with t in s.

65. (a) 7.2×10^{-14} N away from the plate, (b) -3.2×10^{-13} J, (c) 4.4 m.

67.

69. 19 kN; 0.

71. $\lambda_0L^2/6$.

CHAPTER 23

1. (a) $\sigma\pi R^2/2\varepsilon_0$, (b) $0.866\ \sigma\pi R^2/2\varepsilon_0$.

3. $\lambda h/\varepsilon_0$.

5. $+6\ \text{N}\cdot\text{m}^2/\text{C}$.

7. $\pi E_0R^2/3$.

9. $(q/\varepsilon_0)(1 + R^2/h^2)^{1/2}$.

13. (a) Zero, (b) $1.13 \times 10^8\ \text{N}\cdot\text{m}^2/\text{C}$.

15. (a) Net flux is zero.

17. (a) -3.54×10^{-9} C, (b) -3.54×10^{-9} C, (c) -3.54×10^{-9} C.

19. $9.4 \times 10^2\ \text{N}\cdot\text{m}^2/\text{C}$ out of the sides parallel to the xy- or yz- planes; $10.6 \times 10^2\ \text{N}\cdot\text{m}^2/\text{C}$ out of the side perpendicular to the $-x$-axis; $8.2 \times 10^2\ \text{N}\cdot\text{m}^2/\text{C}$ out of the side perpendicular to the $+x$-axis.

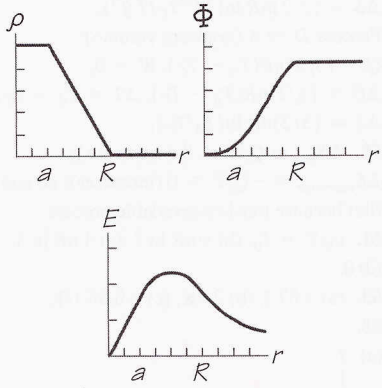
21. $\rho R^2/2\varepsilon_0r$.

23. $E_{\text{rod}}/E_{\text{pt chge}} = 0.02 = 2\%$.

25. -2.3×10^{-4} C.

27. $(1.8 \times 10^4)\hat{r}$ N/C; $(1.8 \times 10^4)\hat{r}$ N/C.

29. $E = 0$ for $r < r_1$; $[\rho(r^2 - r_1^2)/2\varepsilon_0r]\hat{r}$ for $r_1 < r < r_2$; $[\rho(r_2^2 - r_1^2)/2\varepsilon_0r]\hat{r}$ for $r_2 < r$.



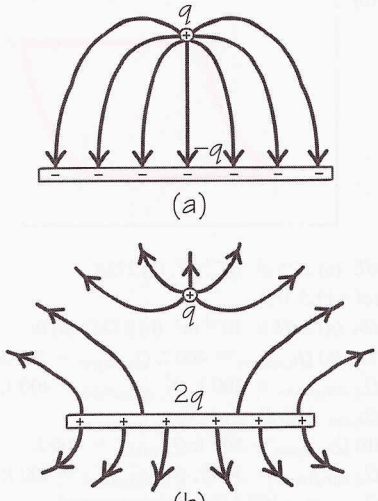
31. $E = 0$ for $r < R_1$; $[Q(r^3 - R_1^3)/4\pi\varepsilon_0(R_2^3 - R_1^3)r^2]\hat{r}$ for $R_1 < r < R_2$; $(Q/4\pi\varepsilon_0r^2)\hat{r}$ for $R_2 < r$.

33. (a) Point the x-axis from plate 1 (where $x = 0$) to plate 2 (where $x = a$), perpendicular to both plates: $\vec{E} = -[(\sigma_1 + \sigma_2)/2\varepsilon_0]\hat{i}$ $(x < 0)$; $\vec{E} = [(\sigma_1 - \sigma_2)/2\varepsilon_0]\hat{i}$ $(0 < x < a)$; $\vec{E} = [(\sigma_1 + \sigma_2)/2\varepsilon_0]\hat{i}$ $(x > a)$, (b) same; must also note that $E = 0$ inside the metallic plate.

35. 1st quadrant: E at $-\theta$; 2nd quadrant: E at $180° + \theta$; 3rd quadrant: E at $180° - \theta$; 4th quadrant: E at θ; $E = 3.3 \times 10^5$ N/C; $\theta = 31°$.

37. $\vec{E} = (-6.7 \times 10^8)\vec{r}$ N/C with r in m, where $r < 3$ cm;
$\vec{E} = [(-1.8 \times 10^4)/r^2]\hat{r}$ N/C with r in m, where 3 cm $< r <$ 8 cm;
$\vec{E} = [(2.7 \times 10^4)/r^2]\hat{r}$ N/C, with r in m, where 8 cm $< r$.

39.



41. $r < R$: $\vec{E} = 0$; $R < r < 2R$: $\vec{E} = (q/4\pi\varepsilon_0r^2)\hat{r}$; $2R < r$: $\vec{E} = -(q/4\pi\varepsilon_0r^2)\hat{r}$.

43. 2.7×10^{-5} C/m^2.

45. $\sigma_{\text{sphere}}/\sigma_{\text{shell}} = 1.96$.

47. $\sigma_{\text{inner sphere}} = Q/4\pi a^2$; $\sigma_{\text{shell, inside}} = -Q/4\pi b^2$; $\sigma_{\text{shell, outside}} = +Q/2\pi R^2$.

49.

51. $\Phi_{x=0} = 0$; $\Phi_{x=a} = ba^4$; $\Phi_{y=0} = \Phi_{y=a} = \Phi_{z=0} = \Phi_{z=a} = 0$; $q = \varepsilon_0ba^4$.

53. (a) $0.067Q/\varepsilon_0$, (b) $Q/4\pi\varepsilon_0R^2$.

57. $0.433EL^2$.

59. $\rho(r) = \varepsilon_0E/r$.

61. $+6000\varepsilon_0$ C/m^3 (constant).

CHAPTER 24

1. 4.6×10^{-14} J.

3. 9.5×10^{-2} J.

5. (a) 0, (b) −1.35 J, (c) +1.35 J.

7. 1.36×10^{-3} J; 0.

41. (a) 5.0 μF, (b) 25 μC.

43. 370 V.

45. 2.1×10^{12} m^2.

47. (a) 10 nF, (b) 1.3, (c) a hyperbola.

49. $C - C_0 = (\kappa - 1)4\pi\varepsilon_0 R$; $\sigma_{\text{ind}}/\sigma = (\kappa - 1)/\kappa$.

51. $q = 2.3q_0$.

53. $\kappa\varepsilon_0 A/[(d + \kappa(D - d))]$.

55. air: 5.3×10^{-10} C; paper: $Q = 2.0 \times 10^{-9}$ C; neoprene: $Q = 3.6 \times 10^{-9}$ C; Bakelite: $Q = 2.6 \times 10^{-9}$ C; strontium titanate: $Q = 1.8 \times 10^{-7}$ C.

57. $(1 - \kappa)Q^2/2C$ (a decrease).

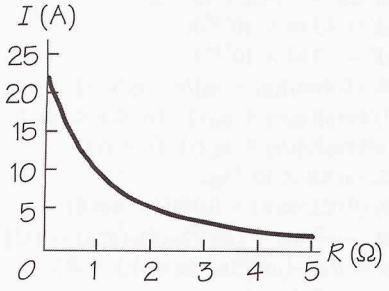
59. 0.32 nF; 0.90 nF.

63. 2.96 μF.

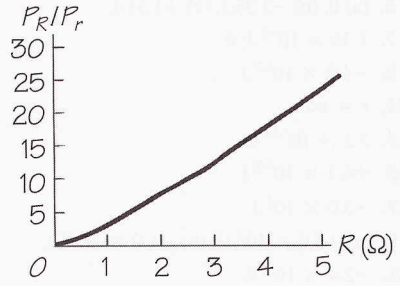
65. (a) $V_1 = C_2V/(C_1 + C_2)$; $V_2 = C_1V/(C_1 + C_2)$, (b) 17 V.

67. $Q \simeq 10^{-6}$ C.

69. (a) $\frac{1}{2}C_1V^2/N$, (b) $\frac{1}{2}NC_1V^2$, (c) $U_{\text{series}} = \frac{1}{2}Q^2N/C_1$; $U_{\text{parallel}} = \frac{1}{2}Q^2/NC_1$.



71. $\frac{1}{2}(\kappa_0 + \kappa_1)(\varepsilon_0 L^2/d)$.
73. $V_A = 8.5 \times 10^2$ V; $V_B = 7.2 \times 10^2$ V; $V_C = 1.43 \times 10^3$ V.
75. 3.4 J; −2.2 J.
77. $(\kappa_1 - \kappa_0)[\varepsilon_0 L^2/D \ln(\kappa_1/\kappa_0)]$.

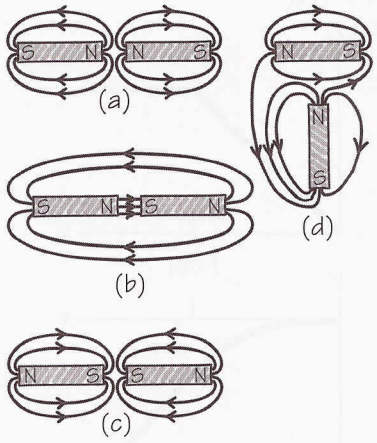


CHAPTER 26

1. 1.2×10^5 A/m^2; 0.46 C.
3. 1.0×10^4 s (2.8 h).
5. 5.8×10^{17} electrons.
7. 8.7×10^{-6} m/s; 2.0×10^{-5} m/s.
9. 4.5×10^{21} electrons; 4.2×10^9 electrons.
11. $\pi J_0 R^2/2$.
13. $v_+ = 1.7 \times 10^{-6}$ m/s, $v_- = -2.5 \times 10^{-6}$ m/s.
15. 3.1×10^{-15} A.
17. 2.8 A; 5.6×10^4 A/m^2; 5.8×10^{-6} m/s.
19. 8.5×10^{-5} m/s; 2.3×10^{-4} m/s.
21. $J_{\text{tube}} = I/2\pi Rd$ along the tube; $J_{\text{plate}} = I/2\pi rd$ radial.
23. $R_2 = 2R_1$.
25. (a) 1.2 Ω, (b) 0.15 cm.
27. 3.27×10^{-2} Ω.
29. 9.6×10^{-4} Ω; 3.0×10^{-4} Ω.
31. 29 m.
33. −0.27.
35. $I_{25} = 19.6$ A; $I_{400} = 17.1$ A.
37. $r_{\text{Cu}}/r_{\text{Al}} = 1.74$.
39. 188 turns.
41. 2.0 Ω; 0.24 kg; 0.48 kg.
43. 33.4 kg.
45. 1.82×10^{-3} Ω; $r = 0.17$ cm; masses are the same.
47. Same brightness for bulbs 1 and 2; bulb 1 is 4 times as bright as bulbs 2 and 3.
49. 5 Ω; 24 V.
51. 90 Ω; 0.18 A; 2.8 W.
53. $R_{\text{eq}} = 100$ Ω.
55. 6 Ω.
57. $I_{2\,\Omega} = 4.7$ A, $V_{2\,\Omega} = 9.3$ V; $I_{4\,\Omega} = 2.3$ A, $V_{4\,\Omega} = 9.3$ V; $I_{6\,\Omega} = 9.7$ A, $V_{6\,\Omega} = 58$ V; $I_{8\,\Omega} = 7.0$ A, $V_{8\,\Omega} = 56$ V; $I_{12\,\Omega} = 10.3$ A, $V_{12\,\Omega} = 124$ V; $I_{24\,\Omega} = 2.7$ A, $V_{24\,\Omega} = 66$ V.
59. (a) 91.3 Ω, (b) 4.38 V, (c) 0.131 A.
61. 6.5×10^{-8} m.
63. $\rho = E/[nev_0(1 - r/R)]$.
65. 2.2 Ω.
67. 1¢.
69. (a) 0.18 A, (b) 35 mA.
71. $(PR)^{1/2}$.
73. 1.9×10^2 J.
75. 84 m.
77. 1.94×10^4 J (5.4 kWh).
79. Change the temperature.
81. 170 V; 43 Ω.
83. The power decreases by 3/4.
85. (a) $\rho L/[\pi r_0(r_0 + \alpha L)]$.
87. $I = [24(4\ \Omega + R_x)/(24\ \Omega + 5R_x)]$ A; $P_4 = [48(4\ \Omega + R_x)/(24\ \Omega + 5R_x)]^2$ W.
89. 0.9 kW; 35 s; 23 min.
91. (a) $R = (\rho_0 L/A)(1 + \alpha k t^2)$, (b) $VI_0/(1 + \alpha k t^2)$, (c) No.
93. $R_2/R_1 = 5.4$.
95. $dT/dt = k/[1 + \alpha(T - T_0)]$, where $k = V^2/mcR_0$; $I(t) = V/R_0\{1 + \alpha[T(t) - T_0]\}$.

CHAPTER 27

1. 0.15 Ω.
3. 0.0075 Ω.
5. 20 A.
7. 0.030 Ω; 300 W.
9. 11.8 V; 0.17 W; 8.7 V; 33 W.
11. $R_2 = R_1$; $R_2 \to \infty$.
13. $V_{gf} = 0$; $V_{ag} = -4.0$ V; $V_{ca} = 5.5$ V.
15. $I_4 = +0.5$ A; $I_5 = +1.0$ A; $I_6 = -1.0$ A.
17. (a) 7.5 Ω, (b) 7.0 Ω.
19. $I_1 = +0.45$ A; $I_2 = +0.38$ A; $I_3 = -0.068$ A.
21. $I_1 = 9.6$ mA; $I_2 = 5.7$ mA; $I_3 = 4.7$ mA.
23. $I_a = \mathscr{E}/[R + (r/N)]$; $I_b = \mathscr{E}/[r + (R/N)]$.
25. 0.38 V; 0.04 V; 0.004 V.
27. One independent junction; $I_1 = 3\mathscr{E}/7R$; $I_2 = I_3 = I_4 = \mathscr{E}/7R$.
29. (a) 60.5 mW; (b) 6.8 mW.
31. (a) 0.075 A, (b) 0.075 A.
33. 2.35 A; 2.52 A; no current.
35. $2V/5R$; $V/5R$.
37. 0.732 V; 0.737 V.
39. 0.010 Ω.
41. (a) 10 Ω, (b) 5×10^4 Ω, (c) 10^5 Ω.
43. 25 V.
47. $R = R_1R_2/R_3$.
49. $R_x = (V/I)/(1 - V/IR_V)(R_V \gg R_x)$.
51. 20 μF.
53. 3.3 Ω.
57. $(\mathscr{E}/R_1)e^{-t/R_1C} + \mathscr{E}/R_2$.
59. 300-Ω resistors in parallel with each other and in series with the 250-Ω resistor and the two capacitors.
61. 6.8×10^3 s (1.9 h).
63. 0.417 A; 0.500 A; 0.167 A.
65. Six 600-Ω resistors in parallel; six 16.7-Ω resistors in series, two series 150-Ω resistors in parallel with two more sets of two series 150-Ω resistors; three series 66.7-Ω resistors in parallel with three series 66.7-Ω resistors.
67. (a) 0.25 kA, (b) 12.7 V, (c) 1.1×10^6 J.
69. $I = \{-(R + \alpha) + [(R + \alpha)^2 + 4\beta\mathscr{E}]^{1/2}\}/2\beta$.



71. 667 W.
73. $I_{\text{mixer}} = 6.67$ A; $I_{\text{vacuum}} = 5.00$ A; $I_{\text{chandelier}} = 5.00$ A; 7 bulbs.
75. 0, $\mathscr{E}/2R$; $\mathscr{E}/R$.
79. (a) 21.4 μs, (b) 2.4 mC.
81. (a) V_0/d, (b) $\sigma\pi r^2 V_0/d$.

CHAPTER 28

1.

3. $-z$-direction.
5. $-(7.2 \times 10^{-3}\ \text{T})\hat{k}$.
7. 34 μT.
9. (a) $\theta = (eB\,\Delta t)/m$, (b) 0.15 T.
11. −4.2 mm (horizontal).
13. (a) 2.25×10^{-3} T, (b) 2.5×10^{-2} T.
15. 5.7×10^{-14} m; 1.4×10^{-6} N.
17. Magnetic field; 0.40 T; 1.20 T.
19. $R_e = 0.57$ m; $R_p = 10.4$ m; 1.04 km.
21. (a) 5.9×10^7 m/s, 3.4° from the original direction, (b) 1.2 cm.
23. (a) 24 J (15×10^{19} eV); (b) 16×10^{-8} kg · m/s; 48 J, (c) 8×10^{-8} kg · m/s; 24 J.
25. 6.8×10^{-5} m.
27. 500 eV.
29. The circular motion is parallel to the xz-plane with radius 5.7×10^{-5} m. The motion in the y-direction has a constant acceleration of -2.6×10^{14} m/s^2.
31. (a) 1.5×10^7 Hz, (b) 4.8×10^7 m/s tangential, (c) 1.9×10^{-12} J (1.2×10^7 eV), (d) 120, (e) 8.0×10^{-6} s.
33. 9.9×10^{-16} kg · m/s $< p < 45 \times 10^{-16}$ kg · m/s; 1.9 TeV $< E <$ 8.4 TeV; 4.2×10^{-3} m/s.

35. 3.54 T.

37. $F_B = 2.4 \times 10^{-16}$ N;
$F_B/F_g = 2.6 \times 10^{13}$;
$K = 5.2 \times 10^{-43}$ J (3.2×10^{-24} eV).

39. (a) $\vec{F}_B$ is to the left and $\vec{F}_E$ is to the right, (b) $F = q|E - vB|$, (c) $E = vB$.

41. $d\omega = qB/2m$.

43. 0.03 T.

45. 8.7×10^{-10} N perpendicular to the wire and to $\vec{B}$.

47. 5.0×10^{-2} N perpendicular to the wire and to $\vec{B}$.

49. $\Delta y = ILB/2k$.

51. 0.25 T.

53. $\mu = 0.11$ A · m^2 perpendicular to the loop; $\tau = 0.024$ N · m parallel to the loop and perpendicular to $\vec{B}$.

55. $IN\pi R^2 B(1 - \cos\theta)$.

57. -10^{-22} J $\leq U \leq +10^{-22}$ J.

59. (a) 5.0 mA, (b) $6 \times 10^{-5} \cos\theta_i$ J.

61. (a) 4×10^{10} m/s, (b) 10^{-23} N · m.

63. (a) $2IRB\,\hat{j}$, (c) $-2IRB\,\hat{j}$, (c) 0, (d) 0.

65. 0.43 rad/s.

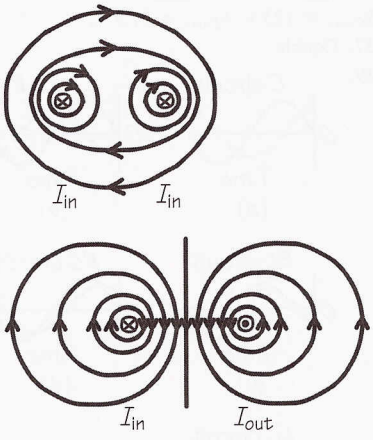
67. 1.5×10^{27} carriers/m^3.

69. 0.11 mA.

71. 5.8×10^{11} N/C; 2.6×10^5 T.

73. 0.037 T.

75. $\Delta r/r = 0.05$ (decrease).



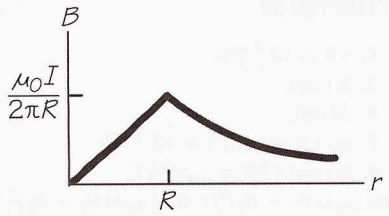
77. $e/m = 2V/B^2R^2$.

79. (a) $L = NmvR$ perpendicular to the orbit, (b) $\frac{1}{2}NevR$, (c) $L/\mu = 2m/e$.

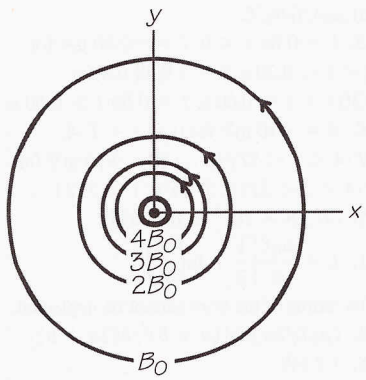
81. (b) horizontal direction,
(c) $mg\hat{k} + qB(v_y\hat{i} + v_z\hat{j}) \times \hat{i} = m(dv_y/dt)\hat{j} + m(dv_z/dt)\hat{k}$; $\vec{v} = (mg/qB)\hat{j} + (mg/qB)(\sin\omega t\,\hat{k} - \cos\omega t\,\hat{j})$.

CHAPTER 29

1.



3. 1.7×10^3 N/m.



5. 0.25 μN/m attraction.

7. $[\mu_0] = [MLC^{-2}]$; $[\varepsilon_0] = [C^2M^{-1}L^{-3}T^2]$; 3.00×10^8 m/s.

9. (a) $r = R$, (b) $B_{max} = \mu_0 I/2\pi R$ at $r = R$, (c) $B_{min} = 0$ at $r = 0$ and $r = \infty$,
(d)

11.

13. 3.0×10^{-3} T.

15. (a) $\dfrac{\mu_0 I}{2\pi(x^2 + y^2)}(-y\hat{i} + x\hat{j})$,

(b) $\dfrac{\mu_0 I}{2\pi}\left\{-\left[\dfrac{y}{(x-a)^2 + y^2} + \dfrac{y}{(x+a)^2 + y^2}\right]\hat{i} + \left[\dfrac{x-a}{(x-a)^2 + y^2} + \dfrac{x+a}{(x+a)^2 + y^2}\right]\hat{j}\right\}$,

(c) $\dfrac{\mu_0 I}{2\pi}\left\{\left[\dfrac{-y}{(x-a)^2 + y^2} + \dfrac{y}{(x+a)^2 + y^2}\right]\hat{i} + \left[\dfrac{x-a}{(x-a)^2 + y^2} - \dfrac{x+a}{(x+a)^2 + y^2}\right]\hat{j}\right\}$.

17. 6.7×10^{-4} T circular.

19. (a) away from the wire, (b) 5.9×10^{-3} m, (c) same energy.

21. $(\mu_0 Ia/2\pi)\ln[(a + d)/a]$.

25. 4.8×10^{-3} T.

27. 0.35 m.

29. 6.0×10^{-5} Wb.

31. 64 mA.

33. (a) 4.3×10^{-6} T, (b) 2.1×10^{-2} T.

35. $(\mu_0 NIL/2\pi)\ln[(R + L)/R]$.

37. $\sqrt{2}(\mu_0 I/2\pi x)$ in the yz-plane 45° below the y-axis.

39. $\sqrt{2}(\mu_0 I/4\pi H)$ in the xy-plane 45° from the $-x$-axis and the $-y$-axis.

41. (a) $-(2.2 \times 10^{-4}$ T/m$)\,dL\,\hat{j}$,
(b) $(0.56 \times 10^{-4}$ T/m$)\,dL\,\hat{k}$, (c) 0,
(d) $-(0.20 \times 10^{-4}$ T/m$)\,dL\,\hat{j}$.

43. 2.0×10^{-7} T along the axis.

45. $B = 2\mu_0 I(a^2 + b^2)^{1/2}/\pi ab$;
$B = 2\sqrt{2}\mu_0 I/\pi a$ $(a = b)$;
$B \approx 2\mu_0 I/\pi a$ $(b \gg a)$.

47. $(5.14 \times 10^{-7}$ T · m/A$)\,I/R$ out of the page.

49. 2.8×10^{-5} T into the page.

51. Circular path; $R = 2\pi mvd^3/q\mu\mu_0$.

53. 2.1×10^{-4} T into the page.

55. $\frac{1}{3}Q\omega R^2\hat{k}$.

57. $(\mathscr{E}/R)e^{-t/RC}$.

59. 5.0×10^{-8} T · m.

61. $-CV_0\omega\sin(\omega t)$.

63. $I = I_d = -4\pi R^2\sigma_0/t_0$.

65. $(\mu_0 I/D)(2/\pi + 1)$ into the paper.

67. (a) $B = (\mu_0 I/2\pi R_1^2)r$ circular CCW, $r < R_1$, (b) $B = \mu_0 I/2\pi r$ circular CCW, $R_1 < r < R_2$, (c) $B = (\mu_0 I/2\pi r)(R_3^2 - r^2)/(R_3^2 - R_2^2)$ circular CCW, $R_2 < r < R_3$, (d) $B = 0$, $R_3 < r$.

69. (a) $-6.0 \times 10^{-5}\,\hat{j}$ N (attraction).

71. (a) $F_B/F_E = 4.3 \times 10^{-26}$, (b) 2.1×10^8 electrons/cm, (c) 2.1×10^{-13}.

73. (a) $\dfrac{\mu_0 I}{2R}\left\{\dfrac{1}{[1 + (x/R)^2]^{3/2}} + \dfrac{1}{[2 - 2x/R + (x/R)^2]^{3/2}}\right\}$,
$B(0) = 0.677\mu_0 I/R$; $B(R/4) = 0.713\mu_0 I/R$; $B(R/2) = 0.716\mu_0 I/R$.

75. $NI = 336$ A · turns.

CHAPTER 30

1. Rotate the magnet around the coil; increase the speed of rotation.

3. 1.05×10^{-4} V.

5. $d\vec{B}/dt = (0.78$ T/s$)\,\hat{i}$.

7. $-BLv$ (clockwise) $(0 < t < L/v)$; $+2BLv$ (counterclockwise) $(L/v < t < 2L/v)$; $-BLv$ (clockwise) $(2L/v < t < 3L/v)$.

9. 18 V.

11. $-2B_0v_0^2t$ $(0 < t < L/v_0)$.

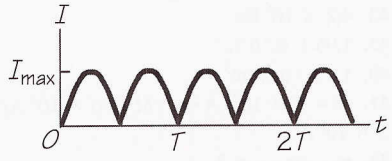
13. $-CDv^2t/2\alpha(D + vt)$ clockwise.

15. $-CD^2v/4\alpha(D + vt)$ clockwise.

17. $BA\omega\sin(\omega t)$.

19. 8×10^{-6} V.

21. 2.9×10^{-4} V.



23. 0.20 T.

25. 1.5×10^{-2} V, bottom end at the higher potential.

27. (a) 1.2×10^{-21} N, (b) 2×10^{-5} V.

29. $-2Bv(2Rvt - v^2t^2)^{1/2}$ $(0 < t < 2R/v)$.

31.
(a)

(b) $2NBA\omega/R\pi$, (c) $\pi I_{av}R/2NA\omega$.

33. 1.3×10^{-2} N; 0.46 W.

35. (a) 0.085 N, (b) 0.051 W.

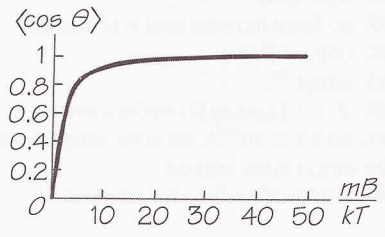
37. $mgR/(BL)^2$.

39. (a) Speed increases until v_t is reached.

41. $(d\Phi_B/dt)^2/R$.

43. aAB_0e^{-at}.

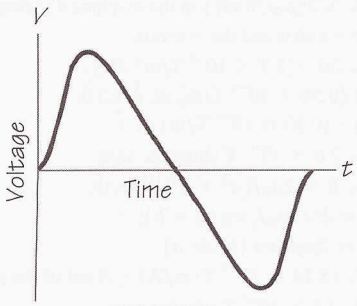
45. $E = +(\mu_0 nI_0\omega r/2)\sin(\omega t)$, circular.



47. (a) 2.7×10^{-5} A, (b) in the same sense as the current in the solenoid.

49. -0.030 V (counterclockwise).

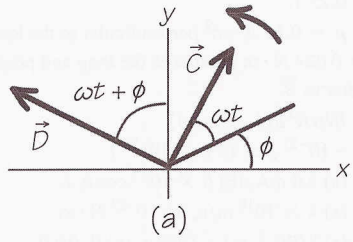
51. (a) 54 mA, (b) 4.4 mW.
53. 5.7 m/s.
55. Constant speed of E/B in the $-y$-direction; $B > 3 \times 10^{-5}$ T.
57. (a) -9.4×10^{-6} V (up), (b) 47 μA, (c) 9.7×10^{-10} J; external force.
59. (a) $(\pi r^2 \mu_0 NI\omega/2R)\sin(\omega t)$, (b) 90°.
61. Counterclockwise; away from the wire.
63. 0.50 C.
65. $Q = (4.5 \times 10^{-9}\text{ C})[1 - e^{-t/(3.0\times10^{-5}\text{ s})}]$, with lower plate positive; $I = (1.5 \times 10^{-4}\text{ A})[1 - e^{-t/(3.0\times10^{-5}\text{ s})}]$, clockwise.
67. $\mathscr{E} = (B\pi a^2\omega/2)\sin(\omega t)$; $P_{av} = B^2\pi^2 a^4\omega^2/8R$.
69. 2.4×10^{-3} V.
71. (a) 1.8×10^5 m/s, (b) 1.4×10^{-20} J, (d) -10%.



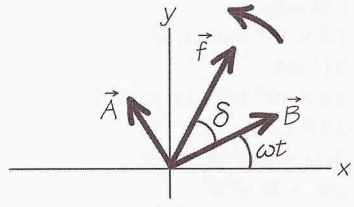
CHAPTER 31

1. 1.0×10^{-2} A · m^2 in the direction of the magnetic field.
3. 992.
5. 5 turns/m.
7. 4.6×10^2 A/m.
9. 0.014 A.
11. (a) $-(2.4 \times 10^{-5})\vec{B}_0$, (b) $+(2.6 \times 10^{-4})\vec{B}_0$.
13. 0.064 A.
15. (a) 2.2×10^{25} electrons, (b) 2.2 A/m.
17. $\lambda\pi R^3\omega$, along the axis of the ring.
19. $v = 4.1 \times 10^{10}$ m/s $> c$.
21. $M = 1.4 \times 10^6$ A/m; $\mu/\mu_0 = 3.6 \times 10^2$.
23. $(2.4 \times 10^{-3}\text{ T})\chi_m$.
25. (a) 0.16 T, (b) 2.5×10^{-4} T.
27. 1.45×10^2 A/m; 0.88 T.
29. 289 A/m.
31. 6.3×10^{-4} T.
35. -2.2×10^{-4}.
37. $H = (1.6 \times 10^{-3}\text{ A})/r$ circular; $B = (2.0 \times 10^{-9}\text{ T} \cdot \text{m})/r$ circular; $\Delta B = (1.3 \times 10^{-12}\text{ T} \cdot \text{m})/r$.
39. 0.38 A/m; 4.7×10^{-7} T.
41. (a) With $\vec{B} = B\hat{k}$, $dm_x/dt = g_S m_y B$; $dm_y/dt = -g_S m_x B$; $dm_z/dt = 0$.
43. 4.2×10^6 Hz.
45. 1.96 T; 0.16 T.
49. 1.4 A · m^2/cm^3.
51. $m = 8 \times 10^{22}$ A · m^2; $M = 6 \times 10^2$ A/m; 2×10^9 A.
53. $m_{ring}/m_{disk} = 2$.
55. (a) $C = (NmB/2\pi kT)/(e^{mB/kT} - e^{-mB/kT})$,
(b) $\langle\cos\theta\rangle = \dfrac{e^{mB/kT} + e^{-mB/kT}}{e^{mB/kT} - e^{-mB/kT}} - \dfrac{kT}{mB}$,
(c)

CHAPTER 32



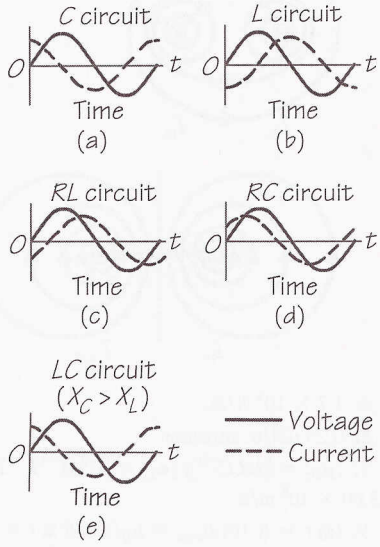
1. 6.0×10^{-5} Wb.
3. 3.1 μH.
5. 30 mH.
7. (a) 1.0 mH, (b) 3×10^{-3} Wb.
9. (a) $\mu_0 AN_1^2/\ell$ or $\mu_0 AN_2^2/\ell$, (b) $\mu_0 A(N_1 + N_2)^2/\ell$, (c) $\frac{1}{4}\mu_0 A(N_1 - N_2)^2/\ell$, (d) $\mu_0 AN_1N_2/\ell$.
13. $I = 0$ for $t < 0$; $I = -0.40$ μA for $0 < t < 0.30$ s; $I = +0.40$ μA for 0.30 s $< t <$ 0.60 s; $I = 0$ for $t >$ 0.60 s.
15. $\mathscr{E} = -10$ mV for $0 < t < T/4$, $3T/4 < t < 5T/4, \ldots$; $\mathscr{E} = +10$ mV for $T/4 < t < 3T/4$, $5T/4 < t < 7T/4, \ldots$.
19. (a) 3.9×10^{-3} H, (b) 16 H.
21. $L = \dfrac{\mu_0 \ell}{\pi}\left[\dfrac{1}{2} + \ln\left(\dfrac{a}{r}\right)\right]$.
The radius of the wire cannot be neglected.
23. $(\mu_0 L/2\pi)\ln[(a+b)^2/b(2a+b)]$.
25. 1.2 kW.
27. 24 A.
29. $0.64\,e^{-(0.04/\text{s})t}$ mW.
31. (a) Same, (b) same.
33. (a) 6.4×10^3 J, (b) 2.4 L.
35. 2.6×10^2 J.
37. 11 cm.
41. There is an upward force on the cylinder before it completely drops into the solenoid.
43. 1.6×10^{-9} J/m.
49. 25 Ω; 5.6 mH.
51. $V^2 L/2R$.
53. 1.6 mF.
55. 1.5 μF; 0.36 mH.
57. (a) $\omega_1/10$, (b) $\alpha_1/100$, (c) $\omega_2'^2 = (\omega_1^2/100) - (\alpha_1/100)^2$.
59. $\omega' = 6.6 \times 10^4$ rad/s.
61. $2Q_0^2/(LC^3)^{1/2}e^{-2\alpha t}$.
65. $T + \frac{1}{4}\pi R^2(C^3/L)^{1/2}$.
67. (a) 47 mA, (b) 2.2×10^{-8} J, (c) $U_{L\max}/U_{C\max} = 1$.
69. (a) 4.0×10^{-3} Ω, (b) 1.5×10^{-7} J at $t = 0$; 4.2×10^{-9} J at $t =$ 100 oscillations, (c) Joule heating.
73. (a) $I_2 = 0$; $I_1 = I_\mathscr{E} = I_L = 2.4$ mA, (b) 0.28 mH, (c) $I_1 = I_\mathscr{E} = 0$; $I_L = I_2 = 0.86$ mA.
75. $(\mu_0 I^2/4\pi)[(1/4) + \ln(r_2/r_1)]$.
77. (b) c.
79.



81. 3.2×10^{-2} H; the iron core increases B and M, and concentrates flux.
83. $L = 0.1$ mH; $C_1 = 3.9$ μF; $C_2 = 5.0$ μF.

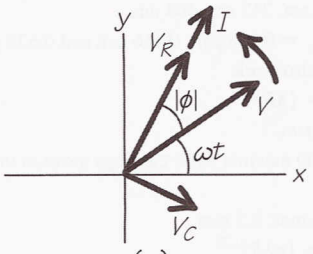
CHAPTER 33

1. 9000 V.
3. 60 turns.
5. 450 turns; 27 A.
7. 0.40 A.
9. 50 turns.
11. 13 kHz.
13. 1.1×10^4 rad/s.
15. 22.8 μF.
17. $X_{C\max} = 1.7 \times 10^3$ Ω; $X_{L\max} = 300$ Ω.
19. 15 Ω; 95 Hz.
21. (a) $\vec{D}$ is more advanced in phase, (b) 90°; $\vec{D}$ leads, (c) $\tan\delta = A/B$.

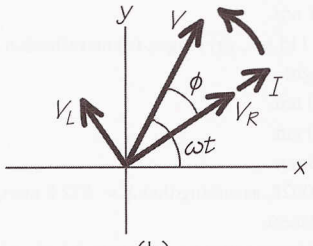


(a)

(c)



23. 35 pF.
25. $R_2 = \frac{1}{2}R_1$.
27. 2.7×10^{-4} C; 4.0 V.
29. 6.4 H.
31. $X_C = 66.3$ Ω; $X_L = 694$ Ω; $Z = 802$ Ω; $Q_{\max} = 13$ μC; $\phi = +51.5°$; $I_{\max} = 0.10$ A.
33. $V_C = -4.05$ V; $V_L = +43.1$ V.
35. $I_{\max} = 92$ mA; $V_{R\max} = 55.5$ V; $V_{C\max} = 123$ V; $V_{L\max} = 27.9$ V.
37. Double.
39.



41. $V_{C\max} = 66$ V; $V_{RL\max} = 67$ V.

43. 11 μH.

45.

(a)

(b)

47. 5.0 A.

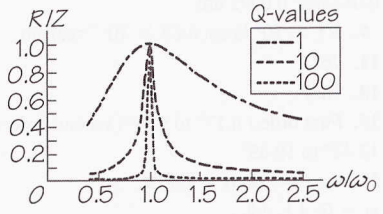
49. (a) $\langle P\rangle \to \frac{1}{2}V_0^2R/\omega L \to 0$,
(b) $\langle P\rangle \to \frac{1}{2}V_0^2R\omega C \to 0$; no current through the capacitor.

51. (a) 0, (b) 0, (c) 1.

53. (a) $R/(X_L^2 + R^2)^{1/2}$, (b) $R/(X_C^2 + R^2)^{1/2}$, (c) 0.

55. (a) 1.6 MHz; (b) 0.034 Ω.

57. 27 μF; 46 μF.



59. 345 V; 9.05 kW.

61. 9.7 kW; 16.7 kW.

63. $R = 22.2\ \Omega$; $X_L = 98\ \Omega$; $X_C = 168\ \Omega$.

65. (a) 31 W, (b) 17 W, (c) 34 W.

67.

69. (a) 0.20 V, (b) 0.19 V, (c) 5.3×10^{-6} V.

71. $R/L = 5.0 \times 10^4\ \text{s}^{-1}$.

73. $\langle I\rangle = I_0/\pi$; $I_{\text{rms}} = \frac{1}{2}I_0$,

75. At low frequency $Z \to X_C$; at high frequency $Z \to R$.

77. $I = (V_0/Z)\cos(\omega t + \phi)$;
$I_C = (V_0/X_C)[(R/Z)\sin(\omega t + \phi) - \sin(\omega t)]$;
$I_L = (V_0/X_L)$
$[-(R/Z)\sin(\omega t + \phi) + \sin(\omega t)]$; there is a resonant frequency.

79. (a) $V_{C1} = 5.14$ V; $V_{C2} = 2.20$ V, (b) 2.34 V.

83. 29 mW.

85. (a) 5.7 V, (b) 18 V.

87. 2.4 μH; 0.060 Ω.

89. 177 Ω.

91. (a) $Q_c(t) = CV_0e^{i\omega t}$; $I_c(t) = i\omega CV_0e^{i\omega t}$.

93. (a) $Q_{0C} = V_{0C}/\{\omega[i(L\omega - 1/\omega C) + R]\}$;
(b) $Q_c(t) = -i(V_0/\omega Z)e^{i(\omega t-\phi)}$;
$I_c(t) = (V_0/Z)e^{i(\omega t-\phi)}$,
(c) $Q = -(V_0/\omega Z)\cos(\omega t - \phi)$;
$I = (V_0/Z)\sin(\omega t - \phi)$.

95. $\omega = [(1/LC) - (R^2/4L^2)]^{1/2} + i(R/2L)$.

CHAPTER 34

3. $\oint \vec{E}\cdot d\vec{s} = \mu_0\dfrac{dM}{dt} - \dfrac{d}{dt}\iint_s \vec{B}\cdot d\vec{A}$.

5. $\vec{B} = (E_0/c)\cos(kz + \omega t)\hat{i}$, traveling in the $-z$-direction.

7. 94×10^6 Hz; 3.2 m.

13. $+\dfrac{\partial B_y}{\partial x} = \mu_0\varepsilon_0\dfrac{\partial E_z}{\partial t}$ and $+\dfrac{\partial B_y}{\partial t} = \dfrac{\partial E_z}{\partial x}$.

15. Plane formed by the z-axis and the line $y = -(\tan\theta)x$.

17. $(3\ \text{V/m})\cos[(1.05 \times 10^7\ \text{m}^{-1})z - (3.15 \times 10^{15}\ \text{rad/s})t]\hat{i}$.

19. $\lambda = 2L/n$, $n = 1, 2, 3, \ldots$.

21. 2.2×10^{-4} T.

23. $2.6 \times 10^{-5}\ \text{W/m}^2$.

25. $8.0 \times 10^{-11}\ \text{N/m}^2$.

27. (a) $1.3 \times 10^3\ \text{W/m}^2$, (b) $4.5 \times 10^{-6}\ \text{N/m}^2$.

29. $1.2 \times 10^{-2}\ \text{W/m}^2$; 0.070 J.

31. $E_0 = 134$ V/m; $E_{\text{rms}} = 95$ V/m;
$B_0 = 4.47 \times 10^{-7}$ T; $B_{\text{rms}} = 3.16 \times 10^{-7}$ T.

33. $2.0 \times 10^{-3}\ \text{N/m}^2$.

35. 17 kg · m/s; 3 kg · m/s (about 1/5 of the solar result).

37. 2.5×10^{-5} N · m.

39. $P = 5.9 \times 10^5$ W; vaporize.

41. $\Delta p/A = 2(S/c)\cos^2\theta\,\Delta t$.

43. $\vec{E}(x,t) = (4.8 \times 10^3\ \text{V/m})\sin\{2\pi[(20\ \text{m}^{-1})x + (6 \times 10^9\ \text{Hz})t]\}\hat{k}$;
$\vec{B}(x,t) = (1.6 \times 10^{-5}\ \text{T})\sin\{2\pi[(20\ \text{m}^{-1})x + (6 \times 10^9\ \text{Hz})t]\}\hat{j}$.

45. $\tau_{\text{average}} = 3.1 \times 10^{-16}$ N · m.

47. 4.0×10^{-7} s.

49. (a) $+y$-direction, (b) $-x$-direction, (c) $+z$-direction, (d) electric field in $-y$-direction; magnetic field in $+x$-direction; Poynting vector in $+z$-direction.

51. (a) no solution, (b) 39°, (c) 57°, (d) 72°.

53. 37°.

55. $3.5 \times 10^5\ \text{W/m}^2$.

57. 0; 1/8.

59. (a) $\frac{1}{2}I_0$, (b) 90°, (c) $(1/8)I_0\sin^2(2\theta)$.

61. The superposition is acceptable since the sum of solutions to the Maxwell's equations is itself a solution.

63. $4.7 \times 10^{-5}\ \text{W/m}^2$.

65. (a) $\vec{B} = \mu_0nI_0\cos(\omega t)\hat{k}$ (along the axis),
(b) $\vec{E} = \frac{1}{2}\mu_0nI_0\omega r\sin(\omega t)$ (circular),
(c) $0 < t < \frac{1}{4}T$: $\vec{S}$ is in $+\hat{r}$;
$\frac{1}{4}T < t < \frac{1}{2}T$: $\vec{S}$ is in $-\hat{r}$;
$\frac{1}{2}T < t < \frac{3}{4}T$: $\vec{S}$ is in $+\hat{r}$;
$\frac{3}{4}T < t < T$: $\vec{S}$ is in $-\hat{r}$.

69. $\vec{E} = (5.19 \times 10^2\ \text{V/m})\cos[(2.54 \times 10^6\ \text{m}^{-1})x + (1.47 \times 10^6\ \text{m}^{-1})y - (2\pi \times 10^{14}\ \text{s}^{-1})t]\hat{k}$.

71. 5.8×10^5 J; 0.25 kg.

73. $4.5 \times 10^{13}\ \text{photons/m}^3$.

75. $f' = [(c - v)/(c + v)]f$.

77. $a_J = 2.3 \times 10^{-7}\ \text{m/s}^2$;
$a_S = 7.1 \times 10^{-8}\ \text{m/s}^2$; 93 years.

79. $\dfrac{\partial^2E_x}{\partial z^2} = \varepsilon_0\mu_0\dfrac{\partial^2E_x}{\partial t^2} + \dfrac{\mu_0}{\rho}\dfrac{\partial E_x}{\partial t}$.

81. (a) $\vec{B} = (\mu_0r/2\pi R^2)\,dQ/dt$ circular, for $r < R$, (b) $\vec{S} = -(Qr/2\pi^2R^4\varepsilon_0)(dQ/dt)\hat{r}$.

CHAPTER 35

1. $v_{\text{ice}} = 2.29 \times 10^8$ m/s;
$v_{\text{ethyl alcohol}} = 2.21 \times 10^8$ m/s;
$v_{\text{benzene}} = 2.00 \times 10^8$ m/s;
$v_{\text{diamond}} = 1.24 \times 10^8$ m/s.

3. 492 nm; 4.62×10^{14} Hz.

5. 2.9×10^4 rev/min.

7. 6 m.

9. 1.0 ns.

11. 1.3 cm.

13. 1.62.

15. 590 m.

17. 0.031.

19. 1.4°.

21. $\theta_{\text{water}} = 45.7°$; $\theta_{\text{glass}} = 38.5°$.

23. Cannot be changed.

25. 7.4°; no total internal reflection.

27. Outside the "shadow" of the prism, there is direct illumination. For a distance of 0.57 cm from each edge, there will be no illumination. For the next distance of 0.77 cm − 0.57 cm = 0.20 cm, there will be illumination from one half. For the next distance of 0.73 cm to the center of the pattern, there will be illumination from both halves.

29. 8.3°.

31. 19 cm below the upper surface of the glass.

33. 74° from the normal.

35. 5.3 mm.

37. 0.86 m.

39. Prism will not be totally reflecting; $n_2 \le 1.283$.

41. 1.5.

43. 52%.

51. 0.48°.

53. (a) $\omega \le 12.5 \times 10^{15}$ rad/s, (b) 27.7°.

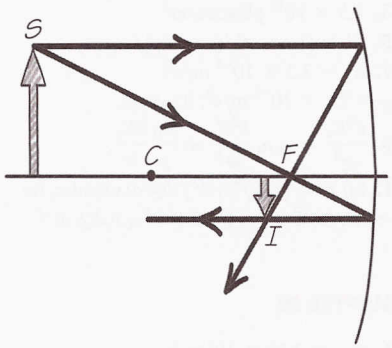
55. 0.009.

57. 1.31 cm.

59. $\Delta n = [(\cos\theta_4)(\cos\theta_2)/\sin(2\phi)]\,\Delta\theta$, where $\cos\theta_2 = \cos\{\sin^{-1}[(\sin\phi)/n]\}$ and $\cos\theta_4 = \cos\{\sin^{-1}[n\sin(2\phi - \{\sin^{-1}[(\sin\phi)/n]\})]\}$.

61. $\theta_i = \sin^{-1}(n\sin\phi)$.

63. (a) 4.6×10^6 km, (b) 3.1×10^8 m/s.



CHAPTER 36

1. 3 images.

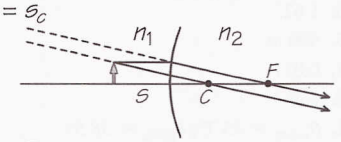
3. 82.5% of the beam has been dissipated.

5. 0.577a, a.

7. $i_2 = 26.3$ cm; $R = 30$ cm.

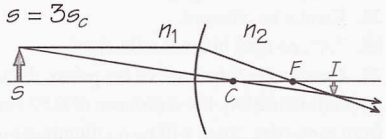
9. 0.80 cm tall, inverted, in front of the mirror.

11. $i = -400$ cm (behind the mirror); +50 cm tall.



13. $-f^2v/(s - f)^2$; $s = 2f$.

17. $i = -90$ cm (in air in front of glass).

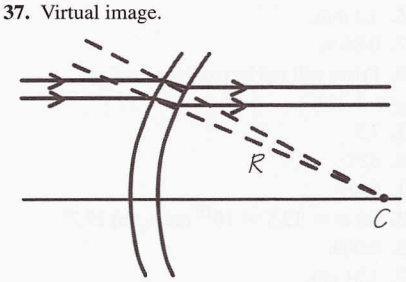


19. $i = -30$ cm (behind the glass).

21. $i = +18.4$ cm; 43 cm from the surface.

23. $s = s_c$

$s = 3s_c$



25. (b) $s = n_1R/(n_2 - n_1)$, (c) image is very far in front of the boundary, (d) image approaches the boundary.

31. (a) +16 cm, (b) converging, (c) inverted, (d) −2.1.

33. (a) 8.9 cm in front of the lens, (b) no, (c) yes, (d) +0.60.

35. (a) +38 cm, (b) +13 cm.

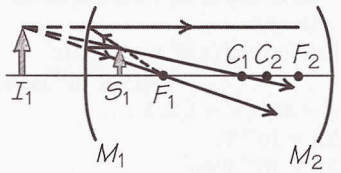
37. Virtual image.

39. Lens *a*: (a) $f_a = 32.1$ cm, 33 cm beyond the lens, (b) inverted and real, (c) $M-$; Lens *b*: (a) $f_b = +77.9$ cm, 84 cm beyond the lens, (b) inverted and real, (c) $M-$; Lens *c*: (a) $f_c = -32.1$ cm, 31 cm in front of the lens, (b) upright and virtual, (c) $M+$; Lens *d*: (a) $f_d = -77.9$ cm, 73 cm in front of the lens, (b) upright and virtual, (c) $M+$.

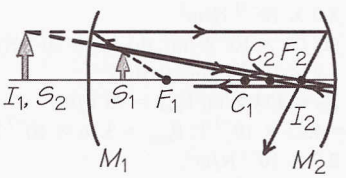
41. Lens *a*: image is 63.4 cm to the left of the lens, inverted, real, with $M = -0.98$; Lens *b*: image is 393 cm to the right of the lens, upright, virtual, with $M = +6.0$; Lens *c*: image is 21.5 cm to the right of the lens, upright, virtual, with $M = +0.33$; Lens *d*: image is 35.4 cm to the right of the lens, upright, virtual, with $M = +0.55$.

45. +53 cm.

47. +6 cm.



49. 9.6 cm.



51. f_1/f_2.

55. 1.09 cm.

57. Near *positive* lens: image is 15.8 cm in front of the negative lens, or 0.8 cm from the positive lens on the object side; near *negative* lens: image is 65.4 cm in front of the positive lens, or 50.4 cm from the negative lens on the object side; the order of the lenses is important.

59. (a) First image is 12.4 cm behind M_1, (b) second image is 7.9 cm in front of M_2.

61. $f = [f_1(d^2 - f_1d - 2f_2d + f_1f_2)]/(d^2 - 2f_1d - 2f_2d + 2f_1f_2 + f_1^2)$.

63. $d \rightarrow R/(n - 1)$.

65. The plate may be placed anywhere between the lens and the screen, with thickness 13.1 cm.

CHAPTER 37

1. 4.7×10^2 nm.

3. 0.24 m.

5. 12.2 m.

7. (a) Doubles, (b) reduces by $\frac{1}{2}$, (c) doubles, (d) no change.

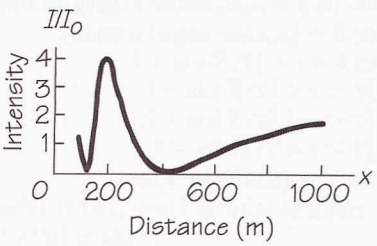
9. 6.4×10^2 nm.

11. Inward.

13. $v_{\text{fringe, ripple}} = 3 \times 10^{-6}$ m/s; $v_{\text{fringe, optical}} = 1.2 \times 10^6$ m/s.

15. (b) $\theta = \tan^{-1}\{\lambda[1/(d^2 - \lambda^2) + 1/4R^2]^{1/2}\}$.

17. 3.0×10^3 W/m^2.



19. 151°; 525 nm.

21. $I_{\text{av}} = 2I_0$.

23. $\Delta\theta = 2\sin^{-1}(\lambda/4d)$.

25. (a) along the perpendicular bisector, (b) 2.0×10^{-3} W/m^2, (c) 9.5°.

27.

29. 33.6 μm.

31. 81 nm, 242 nm, 404 nm.

33. $t_{\min} = 0.208$ μm; 0.416 μm and 0.625 μm would also work.

35. $r = (\lambda R)^{1/2}$.

37. 26 μm.

39. 1000 maxima pass; the rings move in to the center.

41. 6.4 mm; 8.5 mm.

43. $x = (n\lambda R)^{1/2}$.

45. 118 nm.

47. 790 nm.

49. 621 nm.

51. (a) 115 nm, (b) longer, (c) no reflection of green light.

53. 120 nm.

55. 120 nm.

57. 633 nm.

59. 1.00028, assuming that $\lambda = 632.8$ nm (for He-Ne laser).

61. 100 fringes must be counted to 0.1 of a fringe.

63. Uniform.

65. $u \propto \sin^2[2\pi f(x - \frac{1}{2}L)/c]$.

67. $\sin\theta' = \sin\theta - (m\lambda/d)$, $m = 0, \pm1, \pm2, \ldots$

69. 34.0.

73. Two: 0 or $4I_0$; three: I_0; four: 0.

75. $\theta = \sin^{-1}\{n^2 - [\lambda(m - \frac{1}{2})/2h]^2\}^{1/2}$, $m = 1, 2, 3, \ldots$.

CHAPTER 38

1. 450 nm.

3. 39.7 lines/cm.

5. 3.0×10^3 lines/cm.

7. 15,000, 30,000, 45,000; 0.028 nm, 0.014 nm; 0.0093 nm.

9. 3.1×10^4 lines; 8.83×10^{-4} rad/nm.

11. 76°.

13. 18.6°.

15. First order: 6.17° to 9.79°; second order: 12.42° to 19.88°.

17. $\sin\beta = \sin\alpha - m\lambda/d$, $m = 0, \pm1, \pm2, \ldots$.

19. 0.51 m.

21. (a) Maxima: −68°, 0°, 68°; minima: −38°, 38°, (b) 2.0 m.

23. $I_0/I_1 = 22.2$; 1.19°; increase θ.

27. $\Delta\theta_h/\Delta\theta_1 = 0.443$.

29. $\sin\theta = \sin\theta_i - m\lambda/a$, $m = \pm1, \pm2, \ldots$; there is a "central maximum."

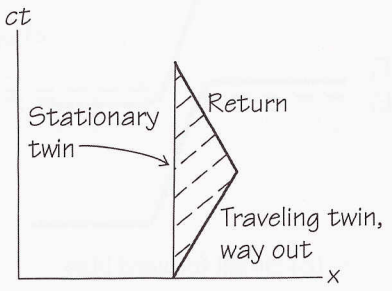
31. (b) $\alpha_{\max1} = 257.43°$, midway between 1st and 2nd minima = 270°; $\alpha_{\max2} = 442.61°$, while midway between 2nd and 3rd minima = 450°.

33. 5.0 cm; 83 m.

35. 70 m.

37. 0.73 m; shorter wavelengths.

39. 2.4 mm.



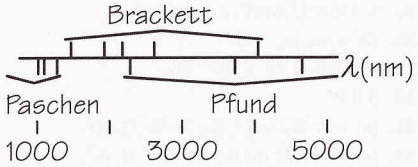
41. 21 ft.

43. Third order.

45. I/I_0: 3.97, 1.79, 2.43, 0.26.
47. $a = 0.1$ mm; $d = 0.3$ mm.
49. $n = 3m = 3, 6, 9, \ldots$; 0.084°, 0.169°, 0.253°, ...
51. 0.0274°.
53. 0.21 nm.
55. 29.0°.
57. 15×10^3 m.
59. (a) 1.0×10^{-5} rad $= (5.7 \times 10^{-4})°$, (b) 25 μm.
61. (a) $I_0\{\sin[(N\pi \cos\theta)/(N-1)]/\sin[(\pi \cos\theta)/(N-1)]\}^2$, (b) slight decrease in I for θ close to 0° and 180° and then a buildup to the maxima at 90° and 270°.
63. No.
65. 0.45 mm.
67. 22°.

CHAPTER 39

1. 4.04 h; 4.02 h.
3. 3.6×10^8 m/s; no violation.
5. 0.011 s.
7. 3.7×10^9 s (120 yr).
9. (a) 3.3×10^{12} s (10^5 yr), (b) 3.3×10^5 s ($\simeq$ 4 days).
11. 4.2×10^2 m/s.
13. 0.66 h.
15. (a) 24 m, (b) 13×10^{-8} s, (c) 10×10^{-8} s, (d) 5.0×10^{-8} s.
17. Not regularly; the rate is lower on his way out and higher as he returns.



21. 5.4×10^8 s (17 yr).
23. 2.3×10^4 m/s toward Earth.
25. 437 m.
27. (a) 1.2×10^7 m/s, (b) 4.8×10^{24} m (5.1×10^8 ly).
29. $f_2 - f_0 = -1.3 \times 10^{10}$ Hz.
31. 5 yr; (1/5) yr; 20 yr.
33. $0.69c$.
35. (a) Distance between the bags is not a measured length, (b) 140 m.
37. (a) $x = 0, t = 24$ s. (b) 9.6×10^9 m; 40 s.
39. $0.23c$.
43. $(c/n)(1 + un/c)/(1 + u/cn)$.
45. Same form.
47. 2.1×10^{-21} kg · m/s.
49. 1.1×10^{-4} kg/s (3.5×10^3 kg/yr).
51. 4.4×10^9 kg/s.
53. (a) 0.047 MeV, (b) 36 MeV, (c) 110 MeV, (d) not possible.
55. (a) $[1 - (7.9 \times 10^{-7})]c$, (b) 745 GeV.
59. 767 MeV/c^2.
61. (a) 212.19 MeV, (b) 210.42 MeV, (c) 210.50 MeV.
63. $K_M = (M^* - M)^2c^2/2M^*$.
65. $\vec{F} = m\gamma(d\vec{u}/dt) + [m(\gamma^3 u/c^2)\, du/dt]\vec{u}$.
67. $\phi = \frac{1}{2}R^2\omega^2$; slow.
69. c.
71. 2×10^{-3} nm.
73. 400 s; 365 s.
75. (a) $0.90c$, (b) 2.33 GeV.
77. (a) p; south, (b) $\frac{1}{2}c(M^2 - 4m^2)^{1/2}$.
79. $G(f) \propto e^{-mc^2(f-f_0)^2/2kT}$.
81. (a) $0.933c$, (b) 3.6×10^2 MeV/c (1.9×10^{-19} kg · m/s), (c) 12 m.
83. 6.5 GeV/c (3.47×10^{-18} kg · m/s).

CHAPTER 40

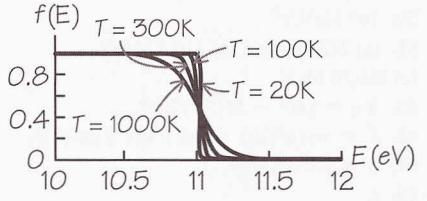
1. 0.2 MeV.
3. (a) 8.3×10^{-5} eV, (b) 1.9 eV, (c) 4.0×10^{-7} eV, (d) 7.3 keV.
5. 288 nm; only cesium is useful.
7. 1.8 eV.
9. $\lambda_{max,\,Al} = 290$ nm; $\lambda_{max,\,Cs} = 579$ nm; $\lambda_{max,\,Ni} = 241$ nm; $\lambda_{max,\,Pb} = 292$ nm.
11. (a) 2.4 eV, (b) 12 keV, (c) 1.2×10^{-4} eV, (d) 1.2×10^{-7} eV, (e) 1.2×10^{-8} eV.
13. 1.0×10^{45} photons/s.
17. $I = 6 \times 10^{-14}$ W/m^2; $I/I_0 = 4 \times 10^{-17}$.
19. 5.8×10^3 K.
21. $W = 4.60$ eV (7.37×10^{-19} J); $K_{max} = 5.75$ eV (9.21×10^{-19} J).
23. 88.4°.
25. 2.0×10^{-2} J/m^3; 2.6×10^{-2} J/m^3; 0.77.
27. 5045K.
29. (a) 0.55 nm, (b) 0.17 nm, (c) 5.5×10^{-3} nm, (d) 2.49×10^{-15} m, (e) same size as the wavelengths.
31. 4.0 nm.
33. (a) 1.8×10^{-16} J (1.1×10^3 eV), (b) 9.6×10^{-20} J (0.60 eV).
35. $h/(2mE)^{1/2}$; $hc/(E^2 + 2mc^2E)^{1/2}$.
37. 1.4×10^{-14} m; 4.6×10^{-15} m; 8.5×10^{-16} m.
39. 2.4×10^{-17} J (150 eV); 1.3×10^{-20} J (0.082 eV).
41. 0.36.
43. 0.
47. 10^{-19} J (0.6 eV).
49. 1.5×10^{-14} J (0.092 MeV).
51. 8.8×10^{-21} kg · m/s; 2.3×10^{-14} J (0.14 MeV).
53. 2.7×10^{-4} nm.
55. 3×10^8 m; 6×10^5 m.
57. $\Delta y = a + hD/\pi pa$; $a_{min} = (hD/\pi p)^{1/2}$.
59. −0.14 MeV.
61. 0.33.
63. 1.57×10^4 yr ago; 13,700 B. C.
65. Does support the assertion.
67. 1.6×10^{-7} Ci.
69. 0.20%.
71. $\lambda = 0.027$ nm; $d = 3.5$ nm; $T = 0.02$K.
73. (a) 480 nm, (b) 4500K.
75. 1.2%.
77. $\lambda = h/p = h/\{2m_e[E - U(x)]\}^{1/2}$.

CHAPTER 41

1. 91.2 nm.
3. 12.1 eV, 103 nm; 0.97 eV, 1280 nm.
5. -2.86×10^3 eV.
7. (a) $n = 2$, 3 and 4, (b) 122 nm; 103 nm; 97 nm; ultraviolet region.
9. 7.58 nm.
11. Paschen series: 1876 nm, 1287 nm, 1094 nm, 1005 nm, 955 nm, ..., 820 nm; Bracket series: 4052 nm, 2626 nm, 2165 nm, 1945 nm, ..., 1459 nm; Pfund series: 7460 nm, 4654 nm, 3740 nm, ..., 2280 nm.

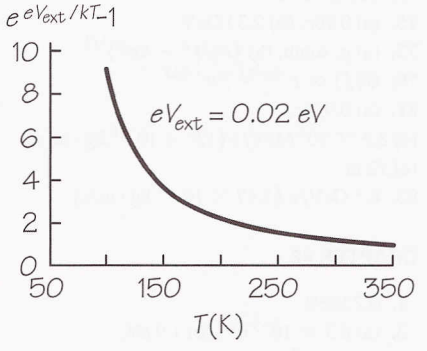
13. (a) $\alpha = 0.00731$ (a dimensionless constant); $1/\alpha = 137$, (b) $-m_ec^2\alpha^2/2n^2$, (c) αc.
15. (a) $E_{Cu} = 10.7$ keV; $E_W = 72.5$ keV.
17. $\frac{2}{3}(e^2/4\pi\varepsilon_0)^7 m_e^2/c^3L^8$.
19. $f = (m_e/4\pi\hbar^3)(e^2/4\pi\varepsilon_0)^2 [1/n^2 - 1/(n+k)^2]$; $f \simeq (m_e/2\pi L^3)(e^2/4\pi\varepsilon_0)^2 k$ for $n \gg k$; $f(n \gg k) = k(1/T)$.
21. $(3.3 \times 10^{-4})°$.
23. 0.033 nm.
25. $-(6.8\text{ eV})/n^2$; all transitions are in the UV for $n = 1$ series; all transitions in the IR for $n = 2$ series; all other transitions (up to $n \simeq 80$) in the IR.
27. $n = 1, \ell = 0$; $n = 2, \ell = 0$; $n = 2, \ell = 1$; $n = 3, \ell = 0$; $n = 3, \ell = 1$.
29. Na ($Z = 11$).
31. $Z = 54$ (Xe).
33. (a) 3 spectral lines, (b) 7 spectral lines.
35. $Z = 1$ (H); $Z = 9$ (F); $Z = 27$ (Co, should be Cl, $Z = 17$); $Z = 59$ (Pr, should be Br, $Z = 35$).
37. 7.4×10^{-3} eV.
39. 24 K.
41. 119 kg/s^2, greater than 97 kg/s^2 from Eq. (41–18).
43. $I_1 = 1.43 \times 10^{-46}$ kg · m^2; $I_0 = 1.48 \times 10^{-46}$ kg · m^2; potential has nonlinear terms.
47. 9.48×10^{33}.
49. 1.5×10^{-5} eV; 5.6×10^{-6}.
51. 2.3×10^{-33} J (1.4×10^{-14} eV).
55. $\Delta x \simeq 1 \times 10^{-10}$ m $\simeq 2a_0$.
57. (a) $3U_0(r/a)^4$, (b) $3(\hbar^2/4ma^2)^{2/3}U_0^{1/3}n^{4/3}$.

CHAPTER 42

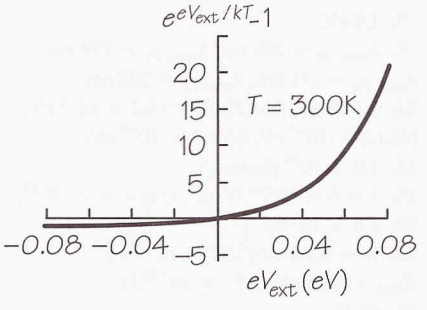


1. 6.15 eV.
3. Na: 3.25 eV; K: 2.13 eV; Al: 11.7 eV.
5. 1.31×10^{29} electrons/m^3.
7. $n_1 = n_2 = n_3 = 94$; 0.999 eV; $\Delta E = 7.1 \times 10^{-3}$ eV; 1.006 eV.
9. $p_F = \hbar(3\pi^2 n_e)^{1/3}$; $v_F = (\hbar/m_e)(3\pi^2 n_e)^{1/3}$.
11. 5.3×10^{13} N/m^2.
13. (a) $n_e \leq 5.9 \times 10^{32}$ electrons/m^3, (b) $Z \leq 14$.
15. (a) $(\pi^2\hbar^2/8m_e)(N/L)^2$, (b) $\pi^2\hbar^2N^3/24m_eL^2$, (c) $(\pi^2\hbar^2/2m_eL^2)N$.
17. 36 MeV.
19. (a) $(\hbar^2/5m)(3\pi^2)^{2/3}(N/V)^{5/3}$, (b) 5.5×10^9 N/m^2.
21. $(\hbar^2\pi^2/2m_e)n_e$.
23. (a) $12/N_{sm}^{1/3}$ km, where N_{sm} = number of solar masses, (b) $E_F = (\hbar^2/2m_n)(3\pi^2 n_n)^{2/3}$ $(\hbar^2/2m_n)(3\pi^2)^{2/3}(N/V)^{2/3} = 60N_{sm}^{4/3}$ MeV; $p_F = 335N_{sm}^{2/3}$ MeV/c, (c) $4.7M_{Sun}$.
25. $(\hbar^2\pi/m_e)n_e$; 1.57.
27. 634 nm; 4.73×10^{14} Hz.
29. 3.0 W.
31. (a) $\pi^2\hbar^2N/2mL^2$, (b) $3\pi^2\hbar^2/2mL^2$.
33. (a) 0.090 W, (b) 6.2×10^{-5} N/m^2.
37. 48.3 μV.
41. 2.5 μV.
43. 3.20 K.
45. 6.96×10^7 m.
47. $E_F = \hbar c n_e^{1/3}$.
53. (a) $0.19N_{sm}^{4/3}$ MeV, where N_{sm} = number of solar masses, (b) $R = (7.2 \times 10^3)/N_{sm}^{1/3}$ km; $R/R_{Sun} = 0.01$.
55. $M < 3 \times 10^{30}$ kg ($\simeq$1.5 solar masses).

CHAPTER 43

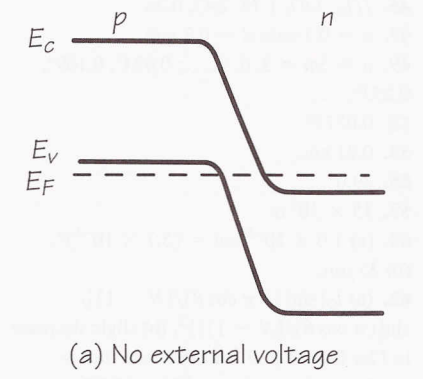


1. 5.5×10^{-11} n-carriers/cm^3 at T = 100K; 1.7×10^9 n-carriers/cm^3 ($\simeq 10^{-14}$ that of copper) at T = 300K.
3. (a) 1, (b) 0.99986, (c) 0.76, (d) 0.24, (e) 1.2×10^{-13}.
5. (a) 1.5 eV.
7. 1.03×10^{-12}.
9. (a) 6.9 μm, (b) 1.8 μm, (c) 0.867 μm.
11. 9.3×10^{11}/cm^3.
13. 0.65 eV.
15. $E_c - E_F = 0.080$ eV $\ll E_g$.
17. $n_i = n_n = n_p = 3.0 \times 10^{18}$ m^{-3} (at T = 100K); $n_i = n_n = n_p = 1.6 \times 10^{22}$ m^{-3} (at T = 300K).
19. 0.18 $(\Omega \cdot \text{m})^{-1}$.
21. (b) $n(v)\,dv =$

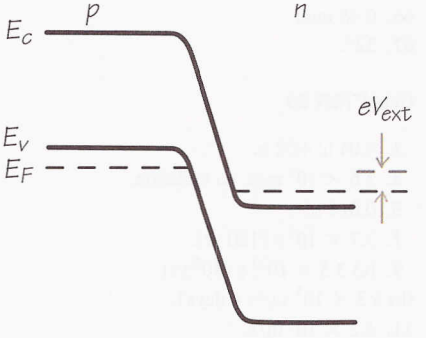


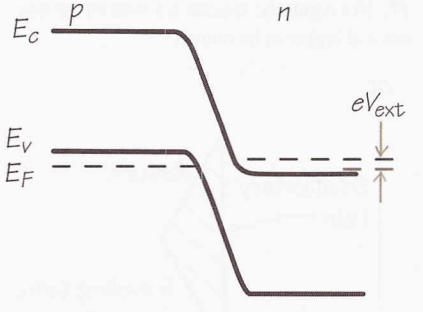
$$\left(\frac{8\pi m_e^3}{h^3}\right) e^{-[(m_e v^2/2) - E_F]/kT} v^2\,dv.$$

23.

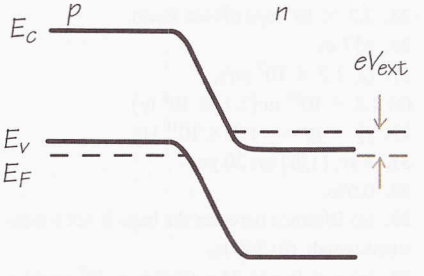


25.





29. (a) 0.64 eV, (b) 0.45 eV.
31. (a) 3.5 mW, (b) 1.6×10^{16} photons/s.
33. 0.61 m_e.
35. B is 0.19 nm closer to the tip than point A.
37. 1.2×10^{-7}.
39. 4.5×10^{10} carriers/m^3.
41. $1.2 \times 10^3 a_0$.
43. 6.8×10^{19} impurities/cm^3; 1.5×10^{-3} (0.15 atomic %).
45. 2.1×10^{13} rad/s.
47. 10^{-100} electrons/m^3 at T = 90K; 6.1×10^{-12} electrons/m^3 at T = 300K.
49. (a) 4×10^{15} photons/s, (b) 4×10^{11} photons.
51. (a) Rapid increase in the resistance, (b) 1.10×10^3 nm, (c) increases.
53. (b) The tunneling current will increase, (c) tunneling current will increase.



(a) No external voltage

(b) Reverse bias

(c) Small forward bias

(d) Larger forward bias

CHAPTER 44

1.

	^{9}Be	^{13}C	^{22}Na	^{31}P	^{57}Fe	^{72}Ge	^{107}Ag	^{131}Cs	^{208}Pb	^{241}Am
neutrons	5	7	11	16	31	40	60	76	126	146
protons	4	6	11	15	26	32	47	55	82	95

3. 8.1 barns.

5. $r_{\min} = 4Z(e^2/4\pi\varepsilon_0)/mv^2$; $v = 2[Z(e^2/4\pi\varepsilon_0)/mR]^{1/2}$.

7. (a) 18 fm, (b) 11 fm.

9. $(Z_1Z_2e^2/4\pi\varepsilon_0)^2[4m^2/(\Delta p)^4]$.

13. ^{7}Li and ^{7}Be: 3.67 fm; ^{9}B and ^{9}Be: 3.50 fm; ^{11}B and ^{11}C: 2.16 fm; ^{21}Ne and ^{21}Na: 1.86 fm; ^{23}Na and ^{23}Mg: 1.75 fm.

15. ^{15}N: $N = 8$; ^{39}K: $N = 20$; ^{40}Ca: $Z = 20$, $N = 20$; ^{56}Fe: neither; ^{140}Ce: $N = 82$; there are other important factors that contribute to the stability of a nucleus, the shell effects just give local small peaks on the curve of binding energy as a function of A.

17. (a) 14 N, (b) 560 N.

19. 1.0×10^{-3}.

21. $A/(2.0 + 0.015A^{2/3})$.

23. 3.80 MeV.

25. 18.3 MeV.

27. 4.7 MeV.

29. 10.49 MeV.

31. 6.4×10^{16} nuclei formed.

37. 0.031 cm^3/yr.

39. 0.784 MeV.

41. 13,700 B.C.

45. $dN_a/dt = -N_a/\tau_1$; $dN_b/dt = -N_b/\tau_2 + N_a/\tau_1$; $dN_c/dt = -N_c/\tau_3 + N_b/\tau_2$; $dN_d/dt = -N_d/\tau_4 + N_c/\tau_3$; ....

49. (a) 1.3 keV, (b) 0.7 MeV.

51. (a) 11.5 metric tons, (b) 4.2×10^{16} J, (c) 5.5×10^{19} fissions/s.

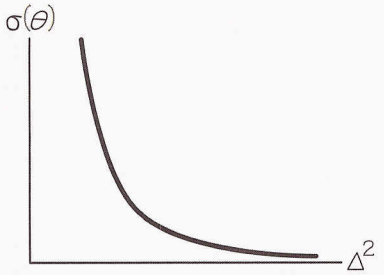
53. (a) 24.8 MeV released, (b) 7.5×10^{47} MeV (1.2×10^{34} J).

55. 2.5×10^{2} MeV.

57. 60 fm.

59. (a) Repulsive Coulomb force between the nuclei, (b) $K = 0.7$ MeV for each helium atom.

63. $E_p = (\hbar^2/10m_pr_0^2)(3^7\pi^2Z^5/16A^2)^{1/3}$; $E_n = (\hbar^2/10m_nr_0^2)[3^7\pi^2(A - Z)^5/16A^2]^{1/3}$.



CHAPTER 45

1. 2.5 fm.

3. $q = p_i + \frac{1}{2}Mc$; by a factor of $(4p_i + Mc)/(2p_i + Mc)$.

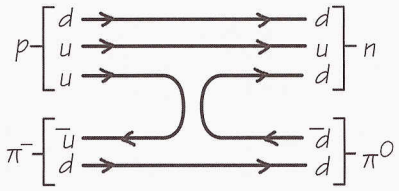
5. $\theta \simeq 0$, and $q \simeq p_i$.

7. (a) $\sigma(\theta) = Z_1^2Z_2^2(e^2/4\pi\varepsilon_0)^2[4m^2/(\Delta^2)^2]$, (b) σ would be smaller than for a point charge.

9. 3.44 TeV.

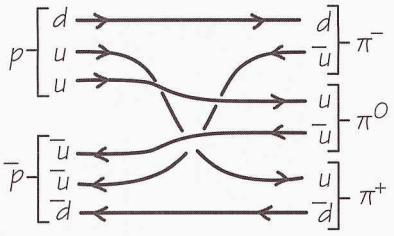
11. Charge: +1; baryon number: $B = 0$; lepton number: $L = 0$.

13. Reaction does not occur.



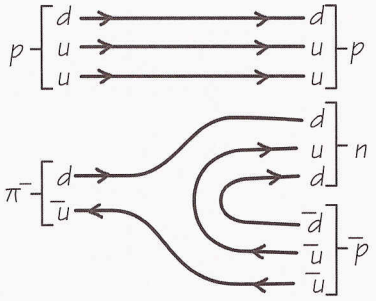
15. Unstable.

17. $(u\bar{u})$ or $(d\bar{d})$ or a combination of these two.



19. 2.5×10^{-3} fm.

21. (a) 0.26 fm, (b) 0.27 GeV.



23.

(a)

(b)

(c)

25. 460 MeV.

27. 11.9 GeV/c.

29. 8.1×10^{9} MeV.

31. 9.5×10^{4} s^{-1}.

33. 3.75 GeV.

35. 1.6 GeV; 180°.

39. $t = (\hbar G/c^5)^{1/2}$.

41. $H = n/t$.

43. 1.2×10^{9} yr.

47. 1.3×10^{5} K; 6.3×10^{5} K.

49. 1.1×10^{2} km.

51. 570 mesons (285 pairs).

57. (a) 1.25×10^{4} eV, (b) 58 fm.

Note: Italics indicate a definition or primary entry for multiple entries, where applicable.

Aberrations, 1022–23
  chromatic, *1023*
  monochromatic, *1022*
Absolute temperature, 494–97
Absolute zero, 495
AC, *See* Alternating current (AC)
AC Josephson effect, 1176
Accelerating charges, and electromagnetic waves, 957
Acceleration, *36*–48, 64–65, 78, 87
  angular, 249–50, 261
  average, *36*–37
  of center of mass, 228
  centripetal, *75*–76, 136
  constant:
    motion with, 40–41, 66–68
    special case of, 51
  dimensions of, 36
  due to gravity, 12, *44*–46
    experimental tests of, 45
  instantaneous, *37*–39, 64–65, 76
  magnitude, 76
  nonconstant, motion with, 40–41
  radial, 250
  in relative motion, 77–79
  in simple harmonic motion, 369–70
  for simple pendulum, 378–79
  tangential, 140
  in uniform circular motion, 75–77
  units of, 33, A–1
Accelerators, 174, 237, 703, 1252–56
  circular vs. linear colliders, 1256
  electron collisions, 1252
  fixed-target machines/colliders, 1252–55
  proton collisions, 1252
Accelerometer, 39
Acceptor impurities, 1191
Acceptors, 755
Accommodation, 1018
Accuracy, 9–11
Action and reaction, law of equal, 98
Activity, 1221
Adams, John, 356
Adaptive optics, 1022
Addition:
  associative, 18
  commutative, 17
  Galilean law of velocity addition, 1088, 1089
  law of addition of velocities, 1089
  of vectors, 17–18
  of velocities, relativistic, 1088–90
Adiabatic calorimetry, 520
Adiabatic transformations, 530–31, 534
  of ideal gas, 535–37
Air bag, 97
Air pump, 468
Airstream speed, 481
Airy disk, 1059–60
Airy, Sir George, 1059
Alkali metals, 1150
Allowed bands of energy levels, 753
Allowed states, 302
Alpha decay (α-decay mode), 1222, 1231
Alpha particles, 1120, 1208
Alpher, Ralph, 506
Alternating current (AC), 739, *917*–42
  AC circuits:
    power in, 929–31
    single elements in, 920–25
  applications, 931–35
  bandwidth, 930
  capacitive circuit, 921–22
  diodes, 932
  filters, 933–34
  impedance matching, 935
  inductive circuit, 922–23
  power factor, 931
  rectifiers, 932
  resistive circuit, 921
  in series *RLC* circuits, 926–29
  transformers, 917–20
Alternating-current (AC) generator, 863
Alternator, 932
Ammeters, 776–77, 783
  analog, 776
  clip-on, 824
Ampere (A), 739, A–1
Ampère, André Marie, 610, 739, 807, 820–21, 831
Ampère's law, 820–21, 823–*24*, 839, 886, 943, 944, 946, 967
  Maxwell's generalized form of, 839
  using to find the magnetic field, 825
  using to find the magnetic field in solenoids, 829–31
Amplitude, *367*, 376, 388, *404*
  in damped harmonic motion, 383–84
  in driven harmonic motion, 385–86
  in resonance, 386–87
  in simple harmonic motion, 367–68, 372, *375*
  of waves, 404
Analog ammeters, 776
Analog voltmeter, 777
Analyzer, 1129
  for polarization, 960–61
Angle, A–1
  Brewster's, 964, 966
  elevation, 69
  measured in radians, 67, 367
  in pendulum motion, 378–79
  plane polar coordinates, 74
  in rotational motion, 247
  of vector, 19
Angle of incidence, 963–64, 1023
Angstrom (A), 8
Angular acceleration, *249*–50, 261
  constant, 249
  units of, 249, A–1
Angular dispersion, 1054–55
Angular displacement, 247
Angular distribution, of power, 959
Angular frequency, *367*, 926
  of damped harmonic motion, 384–85
  fundamental, 452
  of precession, 305, 891
  in resonance, 385
  under spring force, 372–73
  of waves, 404, 406–407, 413, 416, 428
Angular impulse, *291*–93
Angular magnification, 1019–20, 1024
Angular momentum, *265*
  and central forces, 293–94, 305
  conservation of, 265–67, 293–98
    central forces, 293–95
    nonrigid objects, 296–98
  generalization of, 280–85
  independence of time, 266
  intrinsic, 114–8
  of point mass, 280–81
  quantization of, 301–302
  reference point, role of, 289
  transferring in collisions, 267
  as vector product, 284–85
Angular motion, work and energy in, 299–301
Angular speed, 74, 76
  units of, A–1
Angular variables, 251
Angular velocity, 247–49
  instantaneous, *248*
  of rolling, 267–70, 272
  units of, 248
Antenna:
  broadcasting, 957
  dipole, 957–59
  receiving, 957
Anti-electron, 1240
Anti-exclusion principle, 1162
Antimatter, 1099, 1262
  discovery of, 1240–41
Antineutrino, 1222
Antinodes, 415, 420
Antiparticles, 628, 1099
Antireflective coatings, optical devices, 1042
Aperture, 1019
Aphelion, 340, 348

kinetic energy, 1097–98
Momentum and energy of a particle, relationship between, 1100–1101
Momentum conservation, 1097
Momentum density, 956
Momentum transfer, 237
Monochromatic aberrations, *1022*
Monomolecular layer, 25
Monopoles, 826
Moon, corner reflectors on, 980
Morley, Edward W., 1074
Motion, 87
acceleration, 64–65
angular, work and energy in, 299–301
with constant acceleration, 40–41, 66–68
damped harmonic, 383–85
energy of an extended object in, 300–301
equations of, *109*
finding, 109–10
first law of, *89*–90
fluids in, 474–75
graphing, 34–36
linear, 259, 266–67
parallels between rotational motion and, 266–67
oscillary, 366–96
periodic, 192, 366
projectile, 68–73
trajectory, 69–71
relative, *77*–80
rhythmic, 366
rocket, 234–36
rotational, parallels between linear motion and, 266–67
second law of, 92–97, 103, 119–20, 151, 239, 261, 262, 351–52, 401
simple harmonic, *366*, 367–70
and energy, 374–77
kinematics of, 367–68
properties of, 368–69
relations among position, velocity, and acceleration in, 369–70
and springs, 371–74
straight-line, 28–59
third law of, 97–99, 209, 211, 342
trajectories, representing, 65–66
in two and three dimensions, 60–86
in two or three dimensions, 195–97
central forces, 197
potential energy for projectile motion, 196–97
uniform circular, 74–77, 388
velocity, 62–64
Motional emf, 855–56, 861
forces and energy in, 858–60
Mount Everest, 355
Mount Palomar telescope, 1022
Moving charged particles, deflection of, 649–50
Muller, K. Alex, 755
Multilayer ceramic capacitors, 728
Multi-electron atoms, and exclusion principle, 1148–51, 1156
Multi-loop circuits, 783
solving for the behavior of:
Multimeters, 776
Multiplets, 1147
Muons, 1081, 1159, 1243, 1266
negative, 1158, 1243
Musical instruments, 376, 385, 421, 435, 438
Mutual inductance, 894–95, *See also* Inductance

Nanoamps (nA), 739
Nanometer (nm), 8
Narrowing in interference, 446
NASA, 73

National Institute of Standards and Technology, 6
National Synchroton Light Source (Brookhaven National Laboratory), 1266

rotational motion, dynamical equation for, 260–62
on a spinning top, 304–305
units of, A–1
Torque on a current loop, 808
Torsion constant, 394
Torsion pendulum, 393–94
Torus, 831
Total energy flow per unit time, 958
Total internal reflection, 983–85
Total mechanical energy, *186*
Track, *428*
Trajectory, *60*, 69–71
flight time, 70–71
maximum height, 71
range, *69*–70
representing, 65–66
Transformations, *See* Adiabatic transformations; Constant-pressure transformation; Constant-volume transformation; Cyclic transformations; Isobaric transformation; Isothermal transformation; Thermal transformation
Transformers, 895, 917–20
ratio of currents in, 919
ratio of voltages in, 919
step-down transformers, 919
step-up transformers, 919
Transistors, 755, 931, 1196
Transition region, 1194
Transmission grating, 1052
Transmission of light, 981
Transmitted pulses, 449–52
amplitudes of, 450
uses for, 451
Transport of energy, 954–56
Transport phenomena, 548
and collisions, 562–65
Transportation, energy consumption in, A–4
Transverse momentum, 1123
Transverse motion, 399, 447
Transverse separation, 1062
Transverse waves, *399*, 405–407
Trapped electrons, 1192
Traveling waves, *405*–12
arbitrary waveforms, propagation of, 411–12
harmonic, 4427
longitudinal waves, *399*, 407–409
shear waves in solids, 410–11
speed of, 406–407
speed of sound in air, 410
transverse waves, *399*, 405–407
wave speed, 409–10
Tribology, *133*
Triggers, 1257
Triple point, *495*
True spectrum of hydrogen, 1144–47
angular momentum, 1144–46
wave function, 1144
Tunneling, *195*, 1120–22, 1231
barrier, 706
of pairs, 1174–76
as a periodic phenomenon, 1122
STM (scanning tunneling microscopy), 1200–1201
Turbulence, 482–83
Turbulent flow, *474*
Turn density, of solenoids, 830
Turning points, 192
Twin paradox, 1082
Two-source interference pattern, 1031–33
Type I superconductors, 886
Type II superconductors, 886

PROBLEM-SOLVING TECHNIQUES BOXES

Chapter	*Subject*	*Page*
2	General problem-solving techniques	32
4	How to draw a free-body diagram	107
6	The scalar product	161
6	Integration, a quick review	165
8	Collisions	225
9	Rigid-body motion	262
10	The vector product	284
11	Suggestions for statics problems	318
16	Using Bernoulli's equation	477
21	Calculating electric forces	621
23	Using Gauss' Law	668
27	Multi-loop circuits	774
29	Static magnetic fields	835
36	Ray tracing	1004

SOME MATHEMATICAL CONSTANTS†

Constant	*Value*
π	3.14159
e (the "exponential")	2.71828
$\sqrt{2}$	1.41421
$1/\sqrt{2}$	0.707107
ln(10)	2.30259
ln(2)	0.693147
1 rad	57.2958°
1°	0.0174533 rad

†To six significant figures.

THE GREEK ALPHABET

Alpha	A	α	Nu	N	ν
Beta	B	β	Xi	Ξ	ξ
Gamma	Γ	γ	Omicron	O	o
Delta	Δ	δ	Pi	Π	π
Epsilon	E	ϵ	Rho	P	ρ
Zeta	Z	ζ	Sigma	Σ	σ
Eta	H	η	Tau	T	τ
Theta	Θ	θ	Upsilon	Y	υ
Iota	I	ι	Phi	Φ	ϕ
Kappa	K	κ	Chi	X	χ
Lambda	Λ	λ	Psi	Ψ	ψ
Mu	M	μ	Omega	Ω	ω

SOME USEFUL CONSTANTS

Constant	*Value*
Acceleration of gravity	$g = 9.81\ \text{m/s}^2$
Density of air (STP)	$1.29\ \text{kg/m}^3$
Specific heat of air at constant pressure	$1.01 \times 10^3\ \text{J/kg·K}$
Specific heat of air at constant volume	$0.72 \times 10^3\ \text{J/kg·K}$
Density of water (STP)	$10^3\ \text{kg/m}^3$
Density of ice (STP)	$0.917\ \text{kg/m}^3$
Speed of sound in air (STP)	331 m/s
Average range of audible frequencies	20 Hz–16,000 Hz
Index of refraction of water	1.33
Range of wavelengths for visible light	380 nm–750 nm
Resistivities of typical conductors	10^{-8}–$10^{-6}\ \Omega\text{·m}$
Resistivities of typical insulators	10^{9}–$10^{14}\ \Omega\text{·m}$

TABLES IN THE TEXT

Table	*Name of Table*	*Page*
1–1	Orders of Magnitude for Length	5
1–2	Orders of Magnitude for Time	6
1–3	Orders of Magnitude for Mass	6
1–4	Unit Prefixes for Powers of 10	7
2–1	Times for a 100-m Dash	35
5–1	Some Coefficients of Static Friction	129
6–1	Some Orders of Magnitude for Kinetic Energies	155
10–1	Analogies between Linear and Rotational Motion	301
11–1	Young's Moduli for Various Solids	326
11–2	Tensile Strengths for Various Solids	328
13–1	Periods of Mechanical Systems in Simple Harmonic Motion	376
14–1	The Speed of Sound Waves in Various Media	409
15–1	Properties of Reflected Waves and Transmitted Waves	451
16–1	Mass Densities	465
17–1	Some Thermometers	494
17–2	Temperatures Occurring in Nature	496
17–3	Coefficients of Thermal and Volume Expansion (at 20°C)	497
18–1	Molar Heat Capacities and Specific Heats of Some Materials at Constant Volume	520
18–2	Some Latent Heats	522
18–3	Thermal Conductivities for Various Materials	524
19–1	Some a and b Coefficients That Appear in the van der Waals Equation of State	554
21–1	Mass and Charge of Atomic Constituents	614
22–1	Values of Electric Fields (N/C)	634
22–2	An Electric Dipole Rotating in a Uniform Electric Field	652
23–1	Experimental Measurements of Deviation from an Inverse-Square Force Law: Force $\propto 1/r^{2\pm\delta}$	676
24–1	Electric Fields and Potentials for Various Charge Configurations	701
25–1	Dielectric Properties of Materials	724
26–1	Values of Various Currents	740
26–2	Resistivities, Conductivities, and Temperature Coefficients	747
28–1	Some Magnetic Fields	795
31–1	Some Magnetic Susceptibilities	875
31–2	Magnetic Bulk Properties and Their Relations	876
31–3	Magnetic Forces on Materials Near a Large Electromagnet	877
32–1	Analogy Between *RC* and *RL* Circuits	901
32–2	Analogy Between *LC* Circuit and Mass on a Spring	904
32–3	Analogy Between *RLC* Circuits and Damped Harmonic Motion	906
33–1	Analogy Between Driven *RLC* Circuits and Driven Spring Motion	926
35–1	Indices of Refraction for Various Substances (λ = 600 nm)	976
35–2	Index of Refraction of Glass as a Function of Wavelength	988
36–1	Sign Conventions for Mirrors, Refracting Surfaces, and Lenses	1009
43-1	Gap Widths of Some Semiconductors	1186
44-1	Some Atomic Masses	1212
44-2	Some Nuclear Binding Energies	1213
44-3	Parameters of the Semiempirical Mass Formula	1218
45-1	Properties of Quarks	1244
45-2	Fundamental Forces	1246
45-3	Characteristics of Some Colliders	1253

SOME SI BASE UNITS

Physical Quantity	*Name of Unit*	*Symbol*
length	meter	m
mass	kilogram	kg
time	second	s
electric current	ampere	A
thermodynamic temperature	kelvin	K
amount of substance	mole	mol

SOME SI DERIVED UNITS

Physical Quantity	*Name of Unit*	*Symbol*	*SI Unit*
frequency	hertz	Hz	s^{-1}
energy	joule	J	$kg \cdot m^2/s^2$
force	newton	N	$kg \cdot m/s^2$
pressure	pascal	Pa	$kg/m \cdot s^2$
power	watt	W	$kg \cdot m^2/s^3$
electric charge	coulomb	C	$A \cdot s$
electric potential	volt	V	$kg \cdot m^2/A \cdot s^3$
electric resistance	ohm	Ω	$kg \cdot m^2/A^2 \cdot s^3$
capacitance	farad	F	$A^2 \cdot s^4/kg \cdot m^2$
inductance	henry	H	$kg \cdot m^2/A^2 \cdot s^2$
magnetic flux	weber	Wb	$kg \cdot m^2/A \cdot s^2$
magnetic flux density	tesla	T	$kg/A \cdot s^2$

SI UNITS OF SOME OTHER PHYSICAL QUANTITIES

Physical Quantity	*SI Unit*
speed	m/s
acceleration	m/s^2
angular speed	rad/s
angular acceleration	rad/s^2
torque	$kg \cdot m^2/s^2$, or $N \cdot m$
heat flow	J, or $kg \cdot m^2/s^2$, or $N \cdot m$
entropy	J/K, or $kg \cdot m^2/K \cdot s^2$, or $N \cdot m/K$
thermal conductivity	$W/m \cdot K$

SOME CONVERSIONS OF NON-SI UNITS TO SI UNITS

Energy:

1 electron-volt (eV) = 1.6022×10^{-19} J
1 erg = 10^{-7} J
1 British thermal unit (BTU) = 1055 J
1 calorie (cal) = 4.186 J
1 kilowatt-hour (kWh) = 3.6×10^6 J

Mass:

1 gram (g) = 10^{-3} kg
1 atomic mass unit (u) = 931.5 MeV/c^2
= 1.661×10^{-27} kg
1 MeV/c^2 = 1.783×10^{-30} kg

Force:

1 dyne = 10^{-5} N
1 pound (lb or #) = 4.448 N

Length:

1 centimeter (cm) = 10^{-2} m
1 kilometer (km) = 10^3 m
1 fermi = 10^{-15} m
1 Angstrom (Å) = 10^{-10} m
1 inch (in or ″) = 0.0254 m
1 foot (ft) = 0.3048 m
1 mile (mi) = 1609.3 m
1 astronomical unit (AU) = 1.496×10^{11} m
1 light-year (ly) = 9.46×10^{15} m
1 parsec (ps) = 3.09×10^{16} m

Angle:

1 degree (°) = 1.745×10^{-2} rad
1 min (′) = 2.909×10^{-4} rad
1 second (″) = 4.848×10^{-6} rad

Volume:

1 liter (L) = 10^{-3} m^3

Power:

1 kilowatt (kW) = 10^3 W
1 horsepower (hp) = 745.7 W

Pressure:

1 bar = 10^5 Pa
1 atmosphere (atm) = 1.013×10^5 Pa
1 pound per square inch (lb/in^2) = 6.895×10^3 Pa

Time:

1 year (yr) = 3.156×10^7 s
1 day (d) = 8.640×10^4 s
1 hour (h) = 3600 s
1 minute (min) = 60 s

Speed:

1 mile per hour (mi/h) = 0.447 m/s

Magnetic field:

1 gauss = 10^{-4} T

SOME FUNDAMENTAL PHYSICAL CONSTANTS

Constant	*Symbol*	*Value*
speed of light in a vacuum	c	3.00×10^{8} m/s
gravitational constant	G	6.67×10^{-11} $m^3/kg \cdot s^2$
Avogadro's number	N_A	6.02×10^{23} mol^{-1}
universal gas constant	R	8.31 J/mol·K
Boltzmann's constant	k	1.38×10^{-23} J/K
elementary charge	e	1.60×10^{-19} C
permittivity of free space	ϵ_0	8.85×10^{-12} $C^2/N \cdot m^2$
	$1/(4\pi\epsilon_0)$	8.99×10^{9} $kg \cdot m^3 \cdot s^{-2} \cdot C^{-2}$
permeability of free space	μ_0	$4\pi \times 10^{-7}$ T·m/A
electron mass	m_e	9.11×10^{-31} kg
proton mass	m_p	1.67×10^{-27} kg
neutron mass	m_n	1.67×10^{-27} kg
Planck's constant	h	6.63×10^{-34} J·s
$h/2\pi$	$\hbar$	1.05×10^{-34} J·s
		$= 6.58 \times 10^{-22}$ MeV·s
	$\hbar c$	197 MeV·fm
electron charge-to-mass ratio	$-e/m_e$	-1.76×10^{11} C/kg
proton-electron mass ratio	m_p/m_e	1840
molar volume of ideal gas at STP		22400 cm^3/mol
Bohr magneton	μ_B	9.27×10^{-24} J/T
magnetic flux quantum	$\Phi_0 = h/2e$	2.07×10^{-15} Wb
Bohr radius	a_0	0.529×10^{-10} m
Rydberg constant	R_∞	1.10×10^{7} m^{-1}

SOME ASTRONOMICAL CONSTANTS

Constant	*Symbol*	*Value*
standard gravity at Earth's surface	g	9.80665 m/s^2
equatorial radius of Earth	R_e	6.374×10^{6} m
mass of Earth	M_e	5.976×10^{24} kg
mass of Moon		7.350×10^{22} kg $= 0.0123\ M_e$
mean radius of Moon's orbit around Earth		3.844×10^{8} m
mass of Sun	$M_\odot$	1.989×10^{30} kg
mean radius of Earth's orbit around Sun	AU	1.496×10^{11} m
period of Earth's orbit around Sun	yr	3.156×10^{7} s
diameter of our galaxy		7.5×10^{20} m
mass of our galaxy		2.7×10^{41} kg $= (1.4 \times 10^{11})\ M_\odot$
Hubble parameter	H	2.1×10^{-18} s^{-1}
